Abstract

Ca2+/calmodulin-dependent protein kinase II (CaMKII) is highly enriched in excitatory synapses in the central nervous system and is critically involved in synaptic plasticity, learning, and memory. However, the precise temporal and spatial regulation of CaMKII activity in living cells has not been well described, due to lack of a specific method. Here, based on our previous work, we attempted to generate an optical probe for fluorescence lifetime imaging (FLIM) of CaMKII activity by fusing the protein with donor and acceptor fluorescent proteins at its amino- and carboxyl-termini. We first optimized the combinations of fluorescent proteins by taking advantage of expansion of fluorescent proteins towards longer wavelength in fluorospectrometric assay. Then using digital frequency domain FLIM (DFD–FLIM), we demonstrated that the resultant protein can indeed detect CaMKII activation in living cells. These FLIM versions of Camui could be useful for elucidating the function of CaMKII both in vitro and in vivo.

Keywords: Ca2+/calmodulin-dependent protein kinase II; Fluorescence resonance energy transfer; Fluorescence lifetime imaging; Two-photon laser scanning microscopy; Fluorescent proteins

Ca2+/calmodulin-dependent protein kinase II (CaMKII) is a serine/threonine protein kinase crucial for synaptic plasticity in the central nervous system [1]. Ca2+-influx through postsynaptic NMDA receptor triggers the activation of CaMKII by a series of autophosphorylation events catalyzed by both inter- and intrasubunit reactions. This enables activated CaMKII to stay activated, even in the absence of Ca2+, until all subunits are dephosphorylated. This process has been suggested as an underlying mechanism for persistent change in synaptic efficacy, represented by long-term potentiation (LTP). The elevated CaMKII activity likely remolds the postsynaptic protein complex, which eventually leads to an insertion of new AMPA receptors on dendritic spine surfaces, and enhances the synaptic transmission [2–4]. Although this model is widely accepted, there are surprisingly few studies that confirm the constitutive activation of CaMKII specific to the potentiated synapse [5–7]. To detect this activation, we previously designed an approach to observe CaMKII activity by detecting conformational change of CaMKII associated with its activation. This was accomplished by constructing a tandem fusion of YFP, CaMKII, and CFP, the engineered sensor named Camui, and measuring its fluorescence resonance energy transfer (FRET) [8].

Camui showed FRET in its inactive state. In the presence of ATP and calmodulin, the stimulation with Ca2+ causes a rapid (<1 min) decrease of FRET. This change arises from a conformational change due to both binding with Ca2+/calmodulin and autophosphorylation. Even after the addition of EGTA, the change in FRET persists.
This persistent, Ca\(^{2+}\)-independent change in FRET is abolished by omitting ATP or by eliminating the kinase activity (K42R) with a point mutation at the catalytic core. Therefore, a process involving autophosphorylation is contributing to the persistent change, most likely the autophosphorylation at threonine 286 (T286) on the autoinhibitory domain. In fact, a phosphoblocking mutation (T286A) blocks the persistent change in FRET, whereas a phosphomimicking mutation (T286D) is sufficient to induce change in FRET without Ca\(^{2+}\) stimulation. Therefore, Camui detects the activation of CaMKII by the Ca\(^{2+}\)/calmodulin binding and the subsequent autophosphorylation.

Recent studies pointed out certain advantages of FLIM imaging over other imaging modalities to detect protein interaction or conformational change using FRET [9–12]. FLIM imaging detects FRET-induced changes in nanosecond-order fluorescence decay-time of the donor fluorescence after excitation. The decay-time-constant of donor fluorescence is independent of the concentration of the probe [10], and can circumvent some of the difficulties associated with the ratiometric imaging of FRET such as change in tissue scattering or absorption. However, the CFP–YFP pair, used for many FRET probes including our original Camui, is not suitable for FLIM because of a complex fluorescence decay-time of CFP [13]. Also, CFP is not the brightest of the GFP-family proteins, which makes the overall signal dim, and the spectral bleed-through reduces the dynamic range. In fact, a probe for FLIM-based FRET imaging requires different properties compared with the ratiometric FRET imaging. (1) The fluorescent decay-time of the donor is ideally single exponential. (2) The acceptor can be dim, or better, shows no fluorescence at all.

A recent expansion of GFP-related fluorescent protein family will allow us to explore the ideal combination of fluorescent proteins for a FLIM probe. In this study, motivated by the new additions of the family towards longer wavelength [14], we first tested various red-shifted fluorescent proteins as well as a novel quencher mDarkVenus as the acceptor proteins. This allowed us to use GFP or YFP as a donor, which both have single exponential fluorescence decay-time-constant and are significantly brighter than CFP. After determining the optimum pairs with a fluorospectroscopic assay in cell homogenate, we tested the applicability of one of such pair to the FLIM imaging in live cells. Consequently, we identified several promising versions of Camui that could be useful for elucidating the function of CaMKII both in vitro and in vivo.

Materials and methods

Construction of Camui series. YFP (Venus variant) [15] was a gift from Drs. T. Nagai (Hokkaido University) and A. Miyawaki (RIKEN); mRFP, mOrange, and mStrawberry from Dr. Roger Tsien (UCSD); pEGFP-C1, pDsRed2-C1, and pDsRed-monomer-C1 were purchased from Clontech; TagRFP from Evrogen (Moscow, Russia). All variants of Camui were constructed from rat CaMKII\(\alpha\), with donor and acceptor fluorophore proteins fused at amino- and carboxyl-termini similarly to described [8] with standard molecular biological methods. They were in a mammalian expression vector based on Clontech’s pgEGFP-C1 series downstream to the CMV promoter. We describe the constructs here by “N-terminal fluorophore/C-terminal fluorophore”. See Table 1.

**Fluorospectrometric measurement of FRET.** Camui variants were transfected in HEK293T cells by a liposome-mediated method (Lipofectamine 2000, Invitrogen, Carlsbad, CA). After 1–2 days, the cells were homogenized in CaMKII assay buffer composed of 40 mM HEPES–Na (pH 8.0), 0.1 mM EDTA, 5 mM magnesium acetate, 0.015% Tween-20, 1 mM DTT, and protease inhibitor cocktail (1 mM phenylmethylsulfonyl fluoride; 260 μM N-o-p-tosyl-L-arginine methyl ester hydrochloride; 10 mM benzamidine). After centrifugation, the supernatant was used for measurement. Fluorescence spectra were obtained with a spectrotrofluorometer (RF-5301PC, Shimadzu, Kyoto, Japan). To stimulate Camui, Ca\(^{2+}\) (1 mM) was added in the presence of 1 μM calmodulin and 50 μM ATP at room temperature. The reaction was stopped by 1.5 mM EGTA. Fluorescence intensity was adjusted according to the volume changes. Spectroscopic parameters are in Table 1.

**Expression and imaging of GFP.** The coding region for GFP (EGFP, Clontech) was PCR-amplified and subcloned into the pET-21d vector (Novagen, San Diego, CA). GFP protein was expressed in BL21 (DE3) cells and then purified to homogeneity by using the Ni–NTA agarose (Quagen, Hilden, Germany). Imaging was done using 20 μM GFP in 20 mM Tris–HCl buffer (pH 7.4).

**Expression and imaging of Camui in HEK293T cells.** HEK293T cells were transfected as above. The cells were imaged as described [8].

fluorescence emission was detected with photo-multiplier tube (PMT) (R7400U-04, Hamamatsu Photonics, Hamamatsu, Japan), amplified (ACA-4-35-N 35 dB; 1.8 GHz, Becker & Hickl, Berlin, Germany) and digitized (Model 6915, Philips Scientifics, Mahwah, NJ) prior to the heterodyning. The laser repetition signal was provided by the photodiode output on the Spectra-Physics 3930 U, amplified and digitized (Model 6930, Philips Scientifics) before arriving at the FGPA chip. Excitation wavelength was set at 910 nm. GFP emission was detected with a band-pass filter 525/50 nm. The FLIM images were processed with Globals for Images software (Laboratory for Fluorescence Dynamics, University of California, Irvine).

Results and discussion

Improvement of Camui using GFP-mRFP Pair

We first used fluorospectrometry for testing constructs as it offers a quantitative comparison of FRET among multiple samples. The criteria we used are; (1) The extent of change in FRET efficiency in response to Ca\(^{2+}\)-stimulation as measured by dequenching of donor channel. (2) The brightness of acceptor channel (darker is better).

We employed a monomeric version of DsRed, monomeric red fluorescent protein (mRFP) [17] to construct mRFP/GFP- and GFP/mRFP-Camui, which is indeed reported as a fluorophore pair for FLIM imaging (Fig. 1A and B) [9,10]. Observing transfected cells using fluorescent microscope at their optimum excitation wavelengths showed a reasonable green and red fluorescence (not shown). In the spectral analyses of the homogenate of the cells expressing these proteins upon GFP specific excitation at 475 nm, we could observe a distinct peak corresponding to GFP emission but the mRFP peak was very small, barely seen over the skew of GFP peak (Fig. 1A).

Stimulation Ca\(^{2+}\) led to a rapid (<1 min) and stable increase in GFP peak by 53.2 ± 0.7% and eliminated the mRFP peak (Fig. 1A and B). After the addition of EGTA, the GFP peak decreased but to 25.8 ± 1.1% still above the initial level. Therefore, although mRFP peak was barely visible, FRET indeed occurred in mRFP/GFP-Camui and GFP was quenched by it. This is not surprising considering the modest extinction coefficient (44,000 M\(^{-1}\) cm\(^{-1}\))

Fig. 1. mRFP/GFP-Camui showed a significant dequenching upon stimulation. (A) The emission spectra of the Venus/CFP-Camui, mRFP/GFP-Camui, mRFP/GFP-Camui with T305D/T306D mutations and GFP/mRFP-Camui made with the HEK293T cell lysate expressing each construct before, 3 min after the addition of 1 mM Ca\(^{2+}\), and 3 min after the addition of 1.5 mM EGTA, at the donor specific excitation. The expected positions of acceptor peaks are shown by downward arrows. A 10-fold magnification of the mRFP emission peak is shown in the inset for mRFP/GFP-Camui. (B) A plot of donor and acceptor peak intensity over time, normalized by the donor peak intensity before application of Ca\(^{2+}\). The response was monitored every 1 min. (C) GFP fluorescence image of HEK293T cells expressing mRFP/GFP-Camui. (D) A summary of GFP fluorescence intensity in HEK293T cells. Intensity was normalized to the average intensity prior to stimulation for each cell. The error bars are SEM.
and low fluorescence quantum yield (0.25) of mRFP [17]. This is, in fact, beneficial for application to FLIM imaging as it requires only the donor fluorescence and contamination with the acceptor fluorescence can distort the measured lifetime of the donor. Notably, the extent of donor dequenching in mRFP/GFP-Camui was larger than Venus/CFP-Camui under the same conditions, which was approximately 31.8 ± 2.0% by the addition of Ca²⁺ and 17.8 ± 1.9% after the chelation with EGTA (Fig. 1A and B). In a control construct where Ca²⁺/calmodulin binding site is mutated so that it does not bind with Ca²⁺/calmodulin complex (T305D/T306D of CaMKIIα) [8], the spectral profile was unchanged even after the addition of Ca²⁺/calmodulin (Fig. 1A and B). Therefore, this FRET change was associated with the activation of the CaMKII moiety of the construct through Ca²⁺/calmodulin binding. The reverse construct, GFP/mRFP-Camui exhibited an overall smaller response with the same manipulation, indicating that the steric arrangement of two fluorophores is important (Fig. 1A and B).

We imaged HEK293T cells expressing mRFP/GFP-Camui and stimulated them with Ca²⁺-ionophore, 4-Br-A23187. Consistent with the observation from cell homogenates, there was an increase in GFP fluorescence by the stimulation (Fig. 1C and D). The response was slower than in cell homogenate, likely due to the time lag of the perfusing system and the drug effect. In fact, when we pre-permeabilize the cells expressing YFP/CFP-Camui with 4-Br-A23187 in Ca²⁺-free extracellular solution and locally puff-applied Ca²⁺-containing extracellular solution, the FRET started changing within 10 s and reached maximum within 1 min (K. Takao and Y. Hayashi, unpublished).

Comparison among spectral variants of mRFP and GFP

Recent expansion of the mRFP family encouraged us to explore additional members of the family [14]. We selected mOrange and mStrawberry to replace mRFP because of the better absorbance compared with the original mRFP (extinction coefficient, 71,000 and 90,000 M⁻¹ cm⁻¹ for mOrange and mStrawberry, respectively [14]). Also, in order to improve the spectral overlap of donor emission with acceptor excitation, GFP was replaced with Venus version of YFP. We focused on the constructs with the acceptor and donor at the N- and C-termini, respectively, as mRFP/GFP showed better dequenching than GFP/mRFP. The junction sequence between fluorophore proteins and CaMKII were kept the same as mRFP/GFP-Camui to see the pure effects of changing the fluorophores. This yielded mOrange/GFP-, mStrawberry/GFP-, mRFP/Venus-, mOrange/Venus-, and mStrawberry/Venus-versions of Camui (Fig. 2A). The Förster distance of the pairs was calculated (Table 1).

![Figure 2](image-url)

**Fig. 2.** Comparison of various color variants of Camui. (A) The emission spectra of various color variants of Camui in response to Ca²⁺ and subsequent chelation with EGTA at donor specific excitation. Experiments were conducted similarly to Fig. 1. (B and C) A summary of change in donor fluorescence intensity (B) and donor/acceptor ratio (C). Average ± SEM of 3–8 experiments.
Among the new mRFP family constructs, mOrange/Venus-Camui showed the best change upon stimulation with Ca\(^{2+}\)/calmodulin; the donor fluorescence intensity was increased by 71.6 \pm 4.4\% and still 37.8 \pm 4.2\% above the baseline after chelation (Fig. 2A and B). However, the acceptor fluorescence observed may hamper the use in FLIM imaging though it may be suitable for ratiometric imaging as evidenced by a larger change in the ratio of donor and acceptor peaks (Fig. 2C). mOrange/GFP-Camui has a similar calculated Förster distance compared with mOrange/Venus-Camui (Table 1) but showed a smaller response (Fig. 2A–C).

Among the remaining probes, mRFP/Venus-Camui increased the donor peak by 69.3 \pm 4.7\% in response to the Ca\(^{2+}\) stimulation and 43.7 \pm 5.0\% above the baseline after the chelation of Ca\(^{2+}\) with EGTA (Fig. 2A and B). mStrawberry/GFP- and mStrawberry/Venus-variations also showed significant dequenching of donor which persisted after the chelation of Ca\(^{2+}\). Unlike mOrange, mRFP and mStrawberry peaks were negligible in these constructs. We also constructed DsRed-monomer/Venus-Camui, using DsRed-monomer (Clontech) which has been monomerized in a completely different trajectory of mutagenesis as well as TagRFP, a newly reported red fluorescent protein from sea anemone [18]. Both did not show satisfactory dequenching upon Ca\(^{2+}\) stimulation (Fig. 2A and B). TagRFP/GFP-Camui did not show persistent change after the addition of EGTA. We speculate this is due to the specific configuration of fluorophores in this construct or simply due to overall lower efficiency of FRET.

**Application of non-radiating YFP**

As an additional effort, we employed mDarkYFP, a YFP variant with non-radiating mutations, Y145W/H148V [19], along with A206K mutation that prevents weak dimer formation [20] and mDarkVenus, a Venus variant with the same mutations, as acceptors, both with monomeric GFP (mGFP) as a donor. Among them, mDarkVenus/mGFP-Camui showed a good dequenching, 54.9 \pm 4.4\% above baseline upon stimulation and 30.2 \pm 3.0\% after chelation of Ca\(^{2+}\) (Fig. 2A and B) but the extent did not exceed that of mRFP- or mStrawberry-versions.

In summary, mRFP/GFP-, mStrawberry/GFP-, mRFP/Venuse-, mStrawberry/Venuse-, mDarkVenus/mGFP-Camui, appeared comparably promising as FLIM probes for CaMKII activity with a robust dequenching upon stimulation and barely visible acceptor fluorescence. Different versions responded differently in a way not readily predicted by the calculated Förster distance, underscoring the importance of actually testing different fluorophore combinations (Table 1, Fig. 2B). One reason for this dissociation might be the tolerance of the fluorescent protein fusing with another protein [14].

**Fluorescence lifetime imaging of Camui activation in HEK293T Cells**

We chose the Camui with prototypical mRFP/GFP pair to perform FLIM imaging in living cells. We imaged mRFP/GFP-Camui in HEK293T cells (Fig. 3A–D). The averaged fluorescence lifetime was 1.82 \pm 0.02 ns (\(\tau_p\)) and 2.62 \pm 0.20 ns (\(\tau_m\)) (Fig. 3C–D), which was significantly smaller than the GFP (2.90 \pm 0.44 ns (\(\tau_p\)) and 2.75 \pm 0.23 ns (\(\tau_m\)) indicating the occurrence of FRET. Upon stimulation with Ca\(^{2+}\)-ionophore, 4-Br-A23187, the average fluorescence lifetime increased eventually to 2.13 \pm 0.03 ns (\(\tau_p\)) and 2.83 \pm 0.23 ns (\(\tau_m\)) after 10 min, consistent with a decrease in FRET seen in fluoroscopic assay (Fig. 3B–D). In order to see if this change was truly induced by Ca\(^{2+}\)/calmodulin binding, we imaged mRFP/GFP-Camui with T305D/T306D mutations that abolish the binding with Ca\(^{2+}\)/calmodulin. The mRFP/GFP-Camui mutant showed a much smaller fluorescence lifetime, 1.61 \pm 0.05 ns (\(\tau_p\)) and 2.12 \pm 0.03 ns (\(\tau_m\)) at the basal status and was unresponsive to Ca\(^{2+}\) stimulation.

![FLIM imaging of mRFP/GFP-Camui in HEK293T cells. (A) Pseudocolor images of fluorescence intensity. Warmer hue corresponds to higher intensity. Time stamp indicates the time elapsed after the bath application of 4-Br-A23187. The photon count reached a set value, application was stopped to maintain a similar standard deviation in measured fluorescence lifetime values. Therefore the brightness of image can be compared only within an image. (B) Pseudocolor image of \(\tau_p\). The warmer hue indicates longer \(\tau_p\). (C) A histogram of distribution of \(\tau_p\) before and after the application of 4-Br-A23187. (D) A plot of \(\tau_p\) in eight cells from two independent experiments. Results are average \pm SEM.](image-url)
(Fig. 4A–D), consistent with the idea that the change in time-constant seen in mRFP/GFP-Camui was indeed triggered by Ca\(^{2+}\)/calmodulin.

FLIM has several advantages over ratiometric imaging for detecting FRET. It offers the ability to determine the absolute ratio of population showing FRET. Also, it does not depend on the fluorescence intensity or the acceptor channel. The latter feature makes FLIM ideal for in vivo imaging [9,10]. In brain tissue, light is scattered significantly, depending on the depth of the tissue being imaged and the existence of local structures, such as vasculatures. Also, neuronal activity may change the scattering. If scattering affects donor and acceptor channels differently, it will give a pseudo-positive signal in the ratiometric imaging. This is no longer a concern in FLIM, however, because the scattering does not change the fluorescence lifetime. In addition, mRFP, mStrawberry, and mDarkVenus, are significantly dimmer than the donor (GFP or Venus), and therefore the emission from the acceptor is negligible (Figs. 1 and 2) [14]. This allows us to use a wider band-pass filter for donor channel, thereby improving the effectiveness of photon detection, unlike ratiometric imaging that requires narrow band-pass filters to separate the two channels. Furthermore, GFP and Venus are both significantly brighter than CFP, which has been the popular donor choice for ratiometric imaging.

In addition to elucidating the physiological regulation of CaMKII in living cells, the FLIM Camui probe will allow us to identify synapses undergoing synaptic potentiation, thereby empowering us in studying the functional anatomy of local synaptic circuits. Together with recent developments of two-photon imaging techniques such as imaging in freely-moving animals and of imaging deep brain structures such as hippocampus using relay lens [21,22], Camui will provide important information on the learning processes in unprecedented ways.
