ABSTRACT

The intermediate-mass star-forming core UYSO 1 has previously been found to exhibit intriguing features. While deeply embedded and previously only identified by means of its (sub-)millimeter emission, it drives two powerful, dynamically young, molecular outflows. Although the process of star formation has obviously started, the chemical composition is still pristine. We present *Herschel* PACS and SPIRE continuum data of this presumably very young region. The now complete coverage of the spectral energy peak allows us to precisely constrain the elevated temperature of 26 – 28 K for the main bulge of gas associated with UYSO1, which is located at the interface between the hot H ii region Sh 2-297 and the cold dark nebula LDN 1657A. Furthermore, the data identify cooler compact far-infrared sources of just a few solar masses, hidden in this neighbouring dark cloud.

Key words. Stars: formation – Instruments: Herschel – Infrared: ISM, stars – ISM: structure — Stars: Individual: NAME UYSO 1

1. Introduction

Star formation occurs predominantly in structured environments in the case of intermediate and high-mass star formation. In particular, one often finds different stages of evolution located within close proximity. This poses a challenge for working on the earliest phases of star formation, which can only be revealed with long-wavelength observations. To observe these deeply embedded objects at the spectral peak of their emission, airborne or satellite missions are necessary, which in the past delivered only a very modest spatial resolution (>20”). We use ESA’s new far-IR and sub-millimeter satellite *Herschel* (Pilbratt et al. 2010) — with its unprecedented spatial resolution — to scrutinize a sample of very young low- and high-mass star-forming cores within our programme “Earliest Phases of Star Formation” (EPoS, PI: O. Krause). One of these targets is a core located in the Canis Majoris OB1/R1 region (e.g., Gregorio-Hetem et al. 2009) of the outer Galaxy at a distance of ~ 1 kpc. Originally detected as a distinct submillimetre source in the vicinity of IRAS 07029-1215 (Forbrich et al. 2004), it was coylly named “UYSO 1” (unidentified young stellar object 1) since it was only detected at 450 and 850 µm and seemed to have no counterpart at other wavelengths. In the optical, the entire region is dominated by the strong H ii region Sh 2-297, excited by the early B star HD 53623. The mid-IR emission is dominated by warm dust and PAH emission from the associated southern photon-dominated region (PDR). All these sources, however, do not coincide with UYSO 1, located more than 1’ to the north-west. Further to the west, one finds the optical dark cloud LDN 1657A, about which little is known. Members of our group carried out a multiwave-length study of UYSO 1 (Forbrich et al. 2009), which revealed more puzzles. The source drives a dynamically young, but strong CO molecular outflow. The imprints of two crossed jets are visible in shocked H ii emission in the near-IR, and their vertex is very close to the position of UYSO 1. Millimeter continuum interferometry resolved the source into two peaks separated by 4′2. Spitzer/MIPS data indicated that at 24 and 70 µm, UYSO 1 is still too deeply embedded to be directly detected, a finding we revise in the present paper for 70 µm with *Herschel*. In addition to the core being chemically pristine and showing no signs of more evolved chemistry, this object is very interesting for the investigation of the early evolution of (intermediate-mass) protostars.

2. Observations and data reduction

The object UYSO 1 and its vicinity were observed in the blue (70 µm), green (100 µm), and red (160 µm) filters with the PACS instrument (Poglitsch et al. 2010) aboard *Herschel* on October 9, 2009, within the science demonstration program. Scan maps in two orthogonal directions with scan leg lengths of 7’ were obtained with a scan speed of 20″/s, for which the spatial resolution is 5″.6, 6″.8, and 11″.3, respectively. The raw data were reduced with the HIPE software (e.g., Poglitsch et al. 2010), version 3.0, build 455. Beside the standard steps leading to level-1 calibrated data, a second-level deglitching and a correction for offsets in the detector sub-matrices were performed. Finally, the data were highpass-filtered, using a median window of the size of the full scan legs, to remove the effects of bolometer sensitivity drifts during data acquisition and 1/f noise. We masked out emission

* *Herschel* is an ESA space observatory, with its science instruments PACS, SPIRE, and HIFI provided by European-led Principal Investigator consortia, and with important participation from NASA.
structures (visible in a first iteration) before computing and subtracting this running median; this step minimises oversubtraction of source emission. Finally, the data were projected onto a coordinate grid using the photProject routine inside HIPE, and flux calibration factors (Poglitsch et al. 2010) were applied.

Maps at 250, 350, and 500 µm were obtained with SPIRE (Griffin et al. 2010) on October 19, 2009. Two 9′ scan legs covered the source with the nominal speed of 30′/s. The data were processed within HIPE with the standard photometer script up to level 1. During baseline removal, we masked out the high-emission area in the center. For these observations, no cross-scan data was acquired; therefore the resulting maps still show residual striping along the scan direction. An iterative destriping algorithm (Bendo et al. 2010) was applied to mitigate this effect. We adopt FWHM beam sizes of 18′.1, 25′.2, and 36′.9 at 250, 350, and 500 µm, respectively.

### 3. Results

The Herschel data show the detailed structure of the entire star-forming complex containing UYSO1. The data are shown in Fig. 1 where we have combined the PACS and SPIRE data into two colour composites. In the southern region, there is a ridge of far-IR emission roughly oriented east-west. The extended emission there covers the formal position of IRAS 07029-1215. The IRAS positions, however, have usually been derived from the IRAS 12 µm maps. We note that the reported position coincides with neither the much stronger far-IR peak associated with UYSO 1 (see below) nor the peak position of centimetre emission arising from the H ii region (cf. Fig. 1). Parts of this emission ridge represent a PDR adjoining the H ii region. Nevertheless, the bright condensation east of the IRAS position within this PDR ridge might correspond to another embedded compact core.

While this southern ridge is the brightest source at mid-IR wavelengths (λ ≤ 25 µm), the Herschel data present a far different picture. The emission area around UYSO1 dominates the Herschel bands: UYSO1 itself is situated on top of a highly structured emission plateau (not detected in the SCUBA 450 µm data of Forbrich et al. 2004) with a similar extent and structure as the 850 µm map by Forbrich et al. (2004). The emission in the close eastern vicinity (~ 30") of UYSO1 is also a PDR excited by the B star as indicated by the [O i] line observed by Forbrich et al. (2009). We do not delve into a detailed study of the temperature distribution for the whole region (see Stutz et al. 2010 for CB 244). However, from inspection of Fig. 1 it is apparent that the extended emission around UYSO1 has its maximum shortwards of 160 µm, while the region extending to the north-west contains emission that only becomes pronounced at

* Photometry obtained with large aperture (see Sect. 3.1. The corresponding SPIRE fluxes used for Fig. 3 are: (91.1±13.7) Jy (250 µm), (32.5±4.9) Jy (350 µm), and (11.2±1.7) Jy (500 µm).
the SPIRE wavelengths, indicating that even colder material is located in the LDN 1657A dark cloud.

### 3.1. UYSO 1

At far-IR wavelengths, the UYSO 1 core dominates the continuum emission of the region. The PACS instrument offers unprecedented spatial resolution of around $5\arcsec$ for the $70 \mu$m filter providing the opportunity to relate the far-IR emission to high-resolution data at other wavelengths. Forbrich et al. (2009) reported *Spitzer*/MIPS observations of UYSO 1 at $70 \mu$m as well as 3 mm interferometric data pinpointing the two continuum peaks in UYSO 1. A large position shift of $> 9\arcsec$ was found between the mm interferometric sources and the $70 \mu$m peak. Thus, the authors concluded that the optical depth at the column density peak is still too high for a direct detection of the sources at $70 \mu$m. This large discrepancy in peak positions is not confirmed by our PACS data. Figure 2 shows the PACS view on the central region around UYSO 1. As a position reference for the two related mm sources, we use new SMA 349 GHz continuum data (H. Beuther, priv. comm.) that are in very good positional agreement with the 3 mm PdBI data from Forbrich et al. (2004). The typical 1-$\sigma$ absolute pointing accuracy of *Herschel* is $2\arcsec$; however, deviations of up to $4\arcsec$ have been reported for a few operational days. Fortunately, the PACS data reveal several point sources northeast of UYSO 1 (not covered by the MIPS $70 \mu$m data) that were also detected in the MIPS 24 $\mu$m map (see Sect. 3.3). We concatenated the PACS astrometry to the MIPS 24 $\mu$m astrometry (see Fig. 2). As a result, the $70 \mu$m peak is now close to the stronger of the two interferometric point sources. The two positions still do not perfectly coincide, but the remaining offset of $\sim 2\arcsec$ is of the order of our final pointing uncertainties. Thus, there is a clear close association between the $70 \mu$m peak and the millimetre source(s). As a test, we smoothed our PACS $70 \mu$m data to the MIPS $70 \mu$m spatial resolution of $21\arcsec$ by convolving with an appropriate beam and regridding the resultant map to the same pixel scale. The final map is similar to the MIPS data, and the new peak position is indeed offset from that in the original PACS data by over $10\arcsec$. Because of the almost 4 times coarser spatial resolution of *Spitzer* at $70 \mu$m, the true peak position had been smoothed out and merged with the surrounding PDR emission, and thus appeared shifted.

The comparison with the PACS $70 \mu$m point-spread function (PSF) in Fig. 2 illustrates that UYSO 1 is not an unresolved point source. The PACS PSF has a characteristic triangular outer shape. However, UYSO 1 is marginally resolved at $70 \mu$m; the slight elongation is along the connecting line between the two mm continuum sources. On the other hand, the stronger of the two outflows is also oriented in this north-west/south-east direction (cf. Forbrich et al. 2009, their Fig. 2). Therefore, both source multiplicity and warm material along the outflow cone can explain our findings.

The SED of UYSO 1 was estimated by fitting a Planck function, modified by wavelength-dependent opacities, to the *Herschel* data. Our approach was to use fluxes derived from uniformly sized apertures. We chose a circle with an area equivalent to the SPIRE 500 $\mu$m beam area ($1543\arcsec^2$). We used the opacities of coagulated grains with thin ice mantles (Ossenkopf & Henning 1994). One temperature component was sufficient to obtain a very good fit (see Fig. 3). The derived temperature of $\sim 28.1$ K was lower than the previous estimate of 40 K in Forbrich et al. (2009), based on MIPS SED mode observations that probably covered more of the adjacent warmer PDR material. Nevertheless, our photometry also includes a small contribution from the PDR, which is heated from the outside, thus, the intrinsic luminosity is slightly overestimated (in principal agreement with simulations performed by Steinacker et al.)
2006). Thanks to the clarified astrometry, actual Herschel fluxes for \( \lambda < 450 \mu m \) could be included that exceed the \textit{Spitzer} upper limits (which had been obtained after subtracting an extended-emission component) of Forbrich et al. (2009). Consequently, the derived luminosity (244 L\(_\odot\)) is higher than their estimate (50 L\(_\odot\)). We note that the derived total mass of 5.7 M\(_\odot\) strongly depends on the chosen dust model. We repeated the fitting with Draine & Lee (1984) opacities, deriving instead a total mass of 26.4 M\(_\odot\) (and \( T = 26.1 \) K).

### 3.2. New very cold source detections

While UYSO 1 was the prime target of the \textit{Herschel} observations, we also discovered new sources 3′ – 4′ to the north-west of UYSO 1, within the neighbouring dark cloud LDN 1657A. From the SCUBA 850 \mu m map shown in Forbrich et al. (2004), it was obvious that this region is associated with submillimetre emission. The PACS data resolve this region into a “pearl necklace” of five compact sources (Table 1). Nothing is known about these objects except the association of LDN 1657A-3 with faint 2MASS K band emission. There is no counterpart at 1.4 GHz in the NVSS VLA survey. Unfortunately, the region is at the very edge of previous ROSAT X-ray observations (Gregorio-Hetem et al. 2009) and thus not properly covered. However, inspection of the entire dataset of MIPS 24 \mu m dat\[4\] of which just the central part was published in Forbrich et al. (2009), reveals that 4 of these 5 new sources are indeed detected (cf. Fig. 4). At wavelengths \( \leq 160 \mu m \) all these sources are unresolved. Only at SPIRE wavelengths does a more pronounced extended emission component become apparent (Fig. 4). Faint far-IR filaments seem to connect UYSO 1 and these north-western sources. Hence, we assume that they are associated with the general star-formation complex. The distances to the region are at the very edge of previous ROSAT X-ray observations (Gregorio-Hetem et al. 2009) and thus not properly covered. However, inspection of the entire dataset of MIPS 24 \mu m dat\[4\] of which just the central part was published in Forbrich et al. (2009), reveals that 4 of these 5 new sources are indeed detected (cf. Fig. 4). At wavelengths \( \leq 160 \mu m \) all these sources are unresolved. Only at SPIRE wavelengths does a more pronounced extended emission component become apparent (Fig. 4). Faint far-IR filaments seem to connect UYSO 1 and these north-western sources. Hence, we assume that they are associated with the general star-formation complex.

While clearly not in the hot-core region, we investigated the possibility that the true emission peak position from emission arising from the surrounding PDR material. The PACS data show that the 70 \mu m emission is closely associated with the known location of the central millimetre peak(s) in UYSO 1. This re-voices an earlier finding of large offsets (based on \textit{Spitzer}/MIPS 70 \mu m data). Hence, the measured \textit{Herschel} photometry can be used with more confidence than for previous data to estimate the \textit{SED} of UYSO 1. Since the core was not clearly detected at 24 \mu m (which otherwise would indicate a distinct component of warmer dust), a one-temperature modified black-body component (with \( T = 28 \) K fits the data between 70 – 500 \mu m very well. While clearly not in the hot-core/hot-corino regime, this temperature is higher than the typical values of \( \leq 17–20 \) K found in other very young regions of star formation. The known outflow activity can be one explanation. However, the influence of the nearby PDR has also to be taken into account (Forbrich et al. 2009). The Herschel data reveal the serendipitous discovery of five compact very red sources, situated to the north-west of UYSO 1, within the neighbouring dark cloud LDN 1657A. These objects have lower temperatures than UYSO 1. A particularly intriguing object is LDN 1657A-4, which has a very red \textit{SED} and exhibits a 24 \mu m shadow. We note that two different methods for the column density estimation provided very consistent results. For both objects, the Ossenkopf & Henning (1994) grain opacities seem more suitable than the use of ISM grains.
