Abstract

We show that the recently proposed multi-natural inflation can be realized within the framework of 4D $\mathcal{N} = 1$ supergravity. The inflaton potential mainly consists of two sinusoidal potentials that are comparable in size, but have different periodicity with a possible non-zero relative phase. For a sub-Planckian decay constant, the multi-natural inflation model is reduced to axion hilltop inflation. We show that, taking into account the effect of the relative phase, the spectral index can be increased to give a better fit to the Planck results, with respect to the hilltop quartic inflation. We also consider a possible UV completion based on a string-inspired model. Interestingly, the Hubble parameter during inflation is necessarily smaller than the gravitino mass, avoiding possible moduli destabilization. Reheating processes as well as non-thermal leptogenesis are also discussed.

I. INTRODUCTION

The recent observations of the cosmic microwave background (CMB) by the Planck satellite [1] showed that ΛCDM cosmology is consistent with the data and fluctuations in the cosmic microwave background (CMB) can be explained by single-field inflation [2, 3], which solves the fine-tuning problems in the early universe. The spectral index $n_s$ and the tensor-to-scalar ratio $r$ are tightly constrained by the Planck data combined with other CMB observations [1]:

$$n_s = 0.9603 \pm 0.0073,$$

$$r < 0.11 \ (95\% \ CL).$$

The index $n_s$ is determined by the shape of the inflaton potential, whereas the ratio $r$ is done by the energy scale of the potential:

$$H_{\text{inf}} \simeq 8.5 \times 10^{13} \text{ GeV} \left(\frac{r}{0.11}\right)^{1/2}.$$ (3)

Here, $H_{\text{inf}}$ is the Hubble scale during inflation.

To construct a viable inflation model, the inflaton potential should be under good control so as not to break the slow-roll condition and to suppress the inflation scale compared with the the Planck scale. There have been many attempts to accomplish this. One way is to introduce a certain symmetry which keeps the inflaton potential flat. See Refs. [5–19] for various chaotic inflation models along this line. In this sense, an axion is a good candidate for the inflaton due to the approximate shift symmetry

$$\phi \rightarrow \phi + \text{const.},$$ (4)

which controls its potential structure and suppresses the scale of inflation to be consistent with observation. Here, $\phi$ is an axion. So, it is possible to consider a natural inflation

---

1 After submission of this paper, the BICEP2 collaboration announced the detection of the primordial B-mode polarization, which can be explained by $r = 0.20^{+0.07}_{-0.05}$ [4]. See note added at the end of this paper.
model \cite{20, 21} with an axion potential $V(\phi)$ given by:

$$V(\phi) = \Lambda^4 \left[1 - \cos \left(\frac{\phi}{f}\right)\right]. \quad (5)$$

In this model, the shift symmetry is broken non-perturbatively by the dynamical scale $\Lambda$ much smaller than the Planck scale. However, the decay constant $f$ is required to be larger than the Planck scale, $f \gtrsim 5M_{\text{Pl}}$, for the predicted $n_s$ and $r$ to be consistent with the observed values, where $M_{\text{Pl}} \simeq 2.4 \times 10^{18}\text{GeV}$ is the reduced Planck mass.\textsuperscript{3} So, one might worry about the control of the correction $f/M_{\text{Pl}}$ after all.

Recently, two of the present authors (MC and FT) proposed an extension of natural inflation, called multi-natural inflation \cite{28}, in which the inflaton potential mainly consists of two (or more) sinusoidal functions. Interestingly, multi-natural inflation is versatile enough to realize both large-field and small-field inflation. In the case of large-field inflation with super-Planckian decay constants, the predicted values of the spectral index as well as the tensor-to-scalar ratio can be closer to the center values of the Planck results, with respect to the original natural inflation.

In the case of small-field inflation with sub-Planckian decay constants, we arrange those sinusoidal functions so that they conspire to make the inflaton potential sufficiently flat for slow-roll inflation. In a certain limit, this axion hilltop inflation is equivalent to hilltop quartic inflation \cite{3}. The hilltop quartic inflation has been studied extensively so far, and it is known that, for the e-folding number $N_e \simeq 50$, its predicted spectral index tends to be too low to explain the Planck results \cite{1}. There are various proposals for resolving this tension in the literature.

The purpose of this paper is twofold. First, we will show that the predicted spectral index for the axion hilltop inflation can be increased with respect to the hilltop quartic inflation case by including a relative phase between two sinusoidal functions. This gives a better fit to the Planck data. Second, we consider a UV completion of multi-natural

\textsuperscript{2} See \cite{22} for realizing a large decay constant effectively, \cite{23, 24} for other ways to relax the bound on the decay constant, and \cite{13, 14, 25, 27} for other models with axion(s).

\textsuperscript{3} Hereafter, we take the Planck unit of $M_{\text{Pl}} = 1$ for a simplicity, unless otherwise stated.
inflation within supergravity (SUGRA)/string theory. This is because a viable inflation model can be easily realized for large decay constants close to the GUT or Planck scale, and because the string theory offers many axions through compactifications [29, 31], some of which could play an important role in inflation. Also, non-perturbative dynamics which explicitly break the axionic shift symmetry can be studied rigorously in a supersymmetric (SUSY) framework.

The rest of this paper is organized as follows. In Sec. II we build an axion hilltop inflation model with one axion multiplet in the context of SUGRA, taking into account SUSY breaking effects. In Sec. III we consider a UV completion of multi-natural inflation in the string-inspired model, which is reduced to the model analyzed in Sec. II in the low energy effective theory. The last section is devoted to discussion and conclusions.

II. MULTI-NATURAL INFLATION IN SUGRA

A. Setup

Let us consider a supergravity realization of multi-natural inflation in which an axion plays the role of the inflaton [28]. To this end, we introduce the following Kähler and super-potentials with an axion chiral superfield Φ,

\[ K = K(\Phi + \Phi^\dagger), \]
\[ W = W_0 + Ae^{-a\Phi} + Be^{-b\Phi}, \]

where \( a > 0, b > 0 \) and \( a \neq b \).

In the following we assume \( |a^4A| < |b^4B| \) without loss of generality. The scalar potential is given by

\[ V = e^K[K^{ij}(D_iW)(\overline{D_jW}) - 3|W|^2], \]

with \( D_iW = (\partial_iK)W + \partial_iW \). For convenience we write the scalar component of \( \Phi \) as

\[ \Phi = \sigma + i\varphi, \]

The case of the irrational ratio of \( a/b \) was considered in Ref. [32]. The following discussion holds even in this case.
where $\sigma$ and $\varphi$ are the saxion and the axion, respectively. Note that the Kähler potential respects the axionic shift symmetry,

$$\varphi \rightarrow \varphi + \text{const},$$

which is explicitly broken by the two exponentials in the superpotential. We assume that the breaking of the shift symmetry is so weak that the axion mass is hierarchically smaller than the saxion mass. As we shall see shortly, this is the case if

$$|A|, |B| \ll |W_0| < 1.$$ (11)

The saxion is then decoupled from the inflaton dynamics. The softly broken shift symmetry is one of the essential ingredients for multi-natural inflation, and such a small breaking naturally arises from non-perturbative effects at low-energy scales\(^5\). On the other hand, if the saxion mass were comparable to the axion, one would have to follow the multi-field dynamics during inflation. Although the analysis becomes rather involved, it is possible to realize successful inflation as is the case with racetrack inflation \(^{27}\).

\section{B. Saxion stabilization}

First we study the saxion stabilization in the above setup. For simplicity and concreteness we consider the following Kähler potential to stabilize the saxion:

$$K = f^2 (\Phi + \Phi^\dagger)^2$$ (12)

with $f \lesssim 1$. We will see in the next section that the Kähler potential of this form is indeed obtained in the low energy effective theory of a more realistic string-inspired model.

The kinetic term for the saxion and the axion is given by

$$\mathcal{L}_{\text{kin}} = K_{\phi\phi} \partial \Phi^\dagger \partial \Phi = f^2 (\partial \sigma)^2 + f^2 (\partial \varphi)^2.$$ (13)

---

\(^{5}\) Such softly broken shift symmetries and the associated light axions may play an important cosmological role in a different context. For instance, the axion with mass 7 keV \(^{33}\) can explain the recently observed X-ray line at about 3.5 keV \(^{31,32}\).
For the moment let us focus on the saxion stabilization by setting $A = B = 0$. Then the saxion potential has a $Z_2$ symmetry, $\sigma \rightarrow -\sigma$, and therefore the saxion potential has an extremum at the origin $\sigma = 0$. In fact, the origin can be the potential minimum as shown below.

The saxion potential is approximately given by

$$V = e^{2f^2\sigma^2} \left( 4f^2\sigma^2 - 3 \right) |W_0|^2 + \Delta V \tag{14}$$

$$\simeq 2f^2|W_0|^2\sigma^2 + \cdots, \tag{15}$$

where we have expanded the potential around the origin in the second equality, and we have added a sequestered uplifting potential $\Delta V$ to cancel the cosmological constant$^6$,

$$\Delta V = 3e^{2K/3}|W_0|^2 \simeq \left( 3 + 4f^2\sigma^2 + \cdots \right)|W_0|^2. \tag{16}$$

Thus, the saxion is stabilized at the origin with mass $m_\sigma \simeq \sqrt{2}|W_0|$. Note that the saxion is stabilized by the SUSY-breaking effect through the equation

$$\partial_\Phi K = 0. \tag{17}$$

The saxion can be similarly stabilized for a more general Kähler potential; see Refs. [41–43] for detailed discussions on the saxion stabilization. In general, the saxion mass is considered to be of order the gravitino mass.

The axion mass is protected by a shift symmetry. For a sufficiently small breaking of the shift symmetry, therefore, the axion acquires a mass much smaller than the saxion mass, while the saxion stabilization studied above remains almost intact. See Fig. for the saxion potential in the presence of small explicit breaking of the shift symmetry, with and without the uplifting potential. We can see that the saxion is stabilized near the

---

$^6$ For instance, one can consider $K = -3\log \left[ e^{-K(\Phi+\Phi^\dagger)/3} - \{XX^\dagger - (XX^\dagger)^2/\Lambda^2 \}/3 \right]$ and $W = W_0 + \sqrt{3}W_0X + W(\Phi)$ to break the SUSY and to obtain a small cosmological constant. In this model the vacuum and the mass are given by $\langle X \rangle \sim \Lambda^2 \ll 1$ and $m_{3/2}/\Lambda \gg m_{3/2}/\Lambda^2$. Then, $\Delta V = e^K|D_XW|^2K^{XX} = 3|W_0|^2e^{2K(\Phi+\Phi^\dagger)/3}$. The SUSY breaking fields can be integrated out during inflation as long as its mass is heavier than or comparable to the gravitino mass. See [37–40] for related topics.
FIG. 1: The saxion potential for $A = 2.3 \times 10^{-12}$, $B = A/4$, $a = 2\pi/10$, $b = 2\pi/5$, $f = 0.1$ and $W_0 = 10^{-4}$. We have set $\varphi = 0$. The dashed (blue) line shows the saxion potential without the uplifting potential; the saxion is stabilized at $\sigma \sim \pm 5$, where the vacuum energy $3|W_0|^2$ is added for visualization purpose. The saxion can be stabilized near the origin if the sequestered uplifting potential $\Delta V$ is added, as shown by the solid (red) line.

origin, when the sequestered up-lifting potential is added. The saxion vacuum is located near the origin as long as the parameters satisfy the relation

$$\frac{|A|}{|W_0|f^2} \sim \frac{|B|}{|W_0|f^2} \lesssim 10^{-2},$$

i.e., the axion mass is much lighter than that of the saxion by a factor of ten.

We shall see that the Hubble parameter during inflation is necessarily smaller than the gravitino mass as long as (11) is met. Then the saxion stabilization is hardly affected by inflation, and we can integrate out the saxion during inflation. This makes the inflation dynamics extremely simple: the inflationary epoch is described by single-field inflation driven by the axion.
C. Axion hilltop inflation

Let us study the axion potential. Using $U(1)_R$ symmetry and an appropriate shift of $\phi$, we can set $W_0$ and $A$ real and positive, while $B$ is complex in general. To take account of this complex phase, we replace $B$ with $B e^{-i \theta}$, where $B$ is a real and positive constant, and $\theta$ represents the relative phase between the two exponentials. Using $\langle \sigma \rangle \simeq 0$, the axion potential can be approximately written as

$$V_{\text{axion}}(\phi) \simeq 6 A W_0 \left[ 1 - \cos \left( \frac{\phi}{f_1} \right) \right] + 6 B W_0 \left[ 1 - \cos \left( \frac{\phi}{f_2} + \theta \right) \right]$$

$$-2 A B \left( \frac{2}{f_1 f_2} - 3 \right) \left[ 1 - \cos \left( \frac{1}{f_1} - \frac{1}{f_2} \phi - \theta \right) \right] \right] + \text{const},$$

where $\phi \equiv \sqrt{2} f \varphi$ is the canonically normalized axion field, and we have defined

$$f_1 \equiv \frac{\sqrt{2} f}{a}, \quad f_2 \equiv \frac{\sqrt{2} f}{b},$$

with $f_1 \neq f_2$. We have added the vacuum energy from SUSY breaking to obtain the Minkowski spacetime in the true vacuum and the last constant term in Eq. (19) depends on $\theta$; it vanishes for $\theta = 0$.

We impose relation (11) to realize a hierarchy between the saxion mass and the axion mass. Then, the third term in Eq. (19) becomes irrelevant and the first two terms are equivalent to the inflaton potential for the multi-natural inflation discussed in Ref. [28]. A successful multi-natural inflation requires the two sinusoidal functions to have comparable magnitude and periodicity, i.e.,

$$A \sim B \ll W_0,$$

$$f_1 \sim f_2.$$

The inflation scale is roughly given by $H_{\text{inf}} \sim (A W_0)^{1/2} \ll W_0$, and so, the saxion mass is generically heavier than the Hubble parameter during inflation, which justifies our

---

Footnote:

7 In the presence of two axion fields, the third term can be responsible for natural inflation with an effective super-Planckian decay constant [22].
assumption. Also, the upper bound on the tensor mode places the following condition,\[ AW_0 \lesssim 10^{-10}, \quad (23) \]
for \( f_1 \sim f_2 \lesssim \mathcal{O}(1). \)

The inflaton potential must have a flat plateau in order to realize successful inflation with sub-Planckian decay constants. In the following we show that, in a certain limit, the axion potential is reduced to the hilltop quartic inflation model. For the moment we focus on the first two terms in Eq. (19). In the numerical calculations we will include all the terms.

Requiring that the first, second and third derivatives of \( V_{\text{axion}} \) vanish and the fourth derivative of \( V_{\text{axion}} \) is negative at \( \phi = \phi_{\text{max}} \), we obtain the following conditions among the parameters:

\[
\sin \left( \frac{\phi_{\text{max}}}{f_1} \right) = \sin \left( \frac{\phi_{\text{max}}}{f_2} + \theta \right) = 0, \quad (24) \\
- \cos \left( \frac{\phi_{\text{max}}}{f_1} \right) = \cos \left( \frac{\phi_{\text{max}}}{f_2} + \theta \right) = 1, \quad (25) \\
\frac{A}{f_1^2} = \frac{B}{f_2^2}, \quad (26)
\]
where we have used our assumption \( a^4 A < b^4 B \), i.e., \( A/f_1^4 < B/f_2^4 \), to fix the sign of the cosine functions. Note that \( A > B \) as well as \( f_1 > f_2 \) must be satisfied to meet the above conditions. We choose the following solutions without loss of generality,

\[
\phi_{\text{max}} = \pi f_1, \quad (27) \\
\theta = -\pi \frac{f_1}{f_2} \quad \text{(mod } 2\pi) \quad (28)
\]

The inflaton potential becomes simple for a particular choice of \( f_1 = 2f_2 \) (i.e. \( A = 4B \)), as the relative phase \( \theta \) vanishes.

Expanding the inflaton potential around \( \phi_{\text{max}} \), we obtain

\[
V_{\text{axion}}(\dot{\phi}) \simeq V_0 - \lambda \dot{\phi}^4 + \cdots \quad (29)
\]
FIG. 2: The scalar potential for the saxion and the axion (left) and the axion potential at the section of $\langle \sigma \rangle = 0$ (right). In the left panel, we show the logarithm of the scalar potential for the visualization purpose. We use the same model parameters as in Fig. 1. For comparison, the case with $B = 0$ is also shown by the dashed (blue) line in the right panel.

with

\[ V_0 = \mathcal{O}(A W_0), \]
\[ \lambda = \frac{W_0}{4} \left( \frac{B}{f_2^4} - \frac{A}{f_1^4} \right), \]

where we have defined $\hat{\phi} \equiv \phi - \pi f_1$, the constant term $V_0$ is fixed so that the potential vanishes at the minimum, and the dots represent the higher order terms. Therefore, for the parameters satisfying (26), (27), and (28), the axion potential is equivalent to the hilltop quartic inflation. In Fig. 2 we show the scalar potential for the saxion and the axion and its section along $\langle \sigma \rangle = 0$. We can see that the saxion is stabilized during inflation and that the axion potential is given by a flat-top potential.

For sub-Planckian decay constants, the quartic coupling $\lambda$ is fixed by the Planck normalization on the curvature perturbation as

\[ \lambda_{\text{Planck}} \simeq 6.5 \times 10^{-14} \left( \frac{N_e}{50} \right)^{-3}, \]
where $N_e$ is the e-folding number. For instance, the Planck normalization is satisfied if

$$AW_0 \approx 8.7 \times 10^{-14} f_1^4 \left( \frac{N_e}{50} \right)^{-3},$$  \hspace{1cm} (33)

for $f_1 = 2 f_2$ (i.e. $\theta = 0$ and $A = 4B$). For this choice of the parameters, the axion mass at the potential minimum is given by

$$m_\phi \simeq \frac{2\sqrt{3}AW_0}{f_1} \simeq 2.5 \times 10^{11} \text{GeV} \left( \frac{N_e}{50} \right)^{-\frac{3}{2}} \left( \frac{f_1}{0.1} \right).$$  \hspace{1cm} (34)

Assuming the axion coupling with the standard model (SM) gauge bosons $L \supset c(\phi/f_1)F_{\mu\nu}\tilde{F}^{\mu\nu}$, the decay rate is given by

$$\Gamma(\phi \to A_\mu A_\mu) = N_g \frac{c^2 m_\phi^3}{4\pi f_1^2},$$  \hspace{1cm} (35)

where $N_g = 8 + 3 + 1$ counts the number of SM gauge bosons. The reheating temperature after the inflation is then estimated as

$$T_R \equiv \left( \frac{\pi^2 g_\ast}{90} \right)^{-\frac{1}{4}} \sqrt{\Gamma} \simeq 4 \times 10^8 c \left( \frac{N_e}{50} \right)^{-\frac{4}{3}} \left( \frac{f_1}{0.1} \right)^{\frac{1}{2}} \text{GeV},$$  \hspace{1cm} (36)

where $g_\ast$ counts the relativistic degrees of freedom in plasma and we have substituted $g_\ast = 106.75$ in the second equality.

So far we have adopted the special case of $f_1 = 2 f_2$. The typical scales of the inflaton mass and the reheating temperature are similar for other choices. Here let us take another case. If the two decay constants are very close to each other, i.e., $(f_1 - f_2)/f_2 \ll 1$, we can approximate the inflaton potential by keeping the leading order term in $(f_1 - f_2)/f_2$:

$$V_{\text{axion}}(\phi) \approx 6AW_0 \left( \frac{f_1 - f_2}{f_2} \right) \left( v_0 - 2 \cos \frac{\phi}{f_1} + \left( \pi - \frac{\phi}{f_1} \right) \sin \frac{\phi}{f_1} \right) + \cdots ,$$  \hspace{1cm} (37)

where the dots represent higher order terms of $O((f_1 - f_2)^2/f_2^2)$, $v_0 \approx 4.8206$, and the potential maximum and minimum are located at $\phi_{\text{max}}/f_1 = \pi$ and $\phi_{\text{min}}/f_1 \approx -1.3518$, respectively. This approximation is valid only for $|\phi/f_1| \ll \frac{f_2}{f_1 - f_2}$. The potential height $V_0$, the quartic coupling $\lambda$, and the inflaton mass at the minimum are approximately given
We can see that the inflaton mass is of similar order to Eq. (34). As the Planck normalization fixes $\lambda$, $AW_0$ scales as $f_2/(f_1 - f_2)$, while the inflaton potential shape itself is not significantly changed even when $f_1 \approx f_2$. Indeed, using the Planck-normalized quartic coupling, we can rewrite the inflaton potential as

$$V_{\text{axion}}(\phi) \simeq 12\lambda_{\text{Planck}} f_1^4 \left( v_0 - 2\cos\frac{\phi}{f_1} + \left(\pi - \frac{\phi}{f_1}\right) \sin\frac{\phi}{f_1}\right),$$

in the limit of $f_1 \approx f_2$. The inflaton potential is shown in Fig. 3. Note that there are many other potential minima and maxima; the inflation takes place near the hilltop around $\phi/f_1 \lesssim \pi$.

The spectral index for hilltop quartic inflation is predicted to be

$$n_s \simeq 1 - \frac{3}{N_e} = 0.94 - 0.95,$$

for $N_e = 50 - 60$. As is well known, the predicted spectral index tends to be too low to fit the Planck result (1). In the context of new inflation in supergravity 44, 45, the resolution of the tension was discussed in detail in the literature, and it is known that the prediction of $n_s$ can be increased to be consistent with the Planck data either by adding a logarithmic correction 46, 47, or a linear term 48, or by considering higher powers of the inflaton coupling 49. As we shall see below, in the axion hilltop inflation, we can easily increase the spectral index by varying the relative phase $\theta$ around (28).

Let us study the axion potential by varying the parameters around the solutions (26), (27), and (28). Expanding the potential in terms of $\hat{\phi} = \phi - \pi f_1$, we obtain

$$V_{\text{axion}}(\hat{\phi}) = V_0 + \frac{6BW_0 \sin \Theta}{f_2} \hat{\phi} - 3W_0 \left(\frac{A}{f_1^2} - \frac{B}{f_2^2} \cos \Theta\right) \hat{\phi}^2 - \frac{BW_0 \sin \Theta}{f_2^3} \hat{\phi}^3$$

$$- \frac{1}{4} W_0 \left(\frac{B}{f_2^2} \cos \Theta - \frac{A}{f_1^4}\right) \hat{\phi}^4 + \ldots,$$

(43)
FIG. 3: The scalar potential for the saxion and the axion (left) and the axion potential at the section of $\langle \sigma \rangle = 0$ (right) similarly to Fig.2. We use $A = 4.0 \times 10^{-11}, B = (6/7)^2 A, a = \pi/7, b = \pi/6, f = 0.1, W_0 = 10^{-4}$ and $\theta = -7\pi/6$. The case with $B = 0$ is also shown by the dashed (blue) line in the right panel, where the minima are chosen to coincide for visualization purposes.

where we have defined $\Theta \equiv \theta + \pi f_1/f_2$. It is the linear term in $\hat{\phi}$ that affects the inflaton dynamics significantly. As pointed out in Ref. [48], if there is a small linear term in the hilltop quartic inflation model, the inflaton field value at the horizon exit of cosmological scales can be closer to the hilltop, making the curvature of the potential smaller and therefore increasing the spectral index.

We have numerically solved the inflaton dynamics based on the potential given by Eq. (19) to evaluate the predicted values of $n_s$ and $r$. To be concrete, we have varied the model parameters $B/A$ and $\theta$ around the solutions (26), (27), and (28) with $f_1 = 0.5$ and $f_2 = 0.45$. The results are shown in Fig. 4. Note that the Planck normalization can be satisfied by varying $W_0$ for fixed $A/W_0$ and $B/W_0$ without affecting the predicted values of $n_s$ and $r$. From Fig. 4 we can see that the spectral index can be increased to fit the $2\sigma$ limit of the Planck data shown by the shaded (green) region. We have also confirmed that the spectral index can be similarly increased to give a good fit to the Planck data.
FIG. 4: Plots of $n_s$ (left) and $r$ (right) for varying values of $B$ and $\theta$ for fixed decay constants $f_1 = 0.5$ and $f_2 = 0.45$, which corresponds to the case of $f_1 \approx f_2$ studied in the text. The green shaded region corresponds to the $2\sigma$ allowed region for $n_s$ from the Planck data.

for different values of $f_1$ and $f_2$, e.g. $f_1 = 2f_2$. In general, for smaller values of the decay constants, the deviation from the solution (28) must be smaller. On the other hand, as expected, the tensor-to-scalar ratio $r$ is well below the upper bound from the Planck data ($r < 0.11$). For a larger value of the decay constant, e.g. $f = 1$ ($f_1 \approx 2.25$) $r$ can be as large as $\sim 10^{-3}$ in the allowed region of $n_s$.

Fig. 5 also shows the behavior of $n_s$ and $r$ as a function of $f_1$ with the same parameters as in Fig. 2. The behavior is similar to a hilltop quartic model as discussed in Ref. [28] for $\theta = 0$, but the spectral index can be increased by allowing a non-zero relative phase.

III. UV COMPLETION BASED ON STRING-INSPIRED MODEL

A. Set-up

We now provide a further UV completion of the effective SUGRA model given in the previous section, based on the string-inspired model. Let us consider a model with three
Kähler moduli on a Calabi-Yau space with the following Kähler and super-potentials\(^8\)

\[ K = -2 \log(t_0^{3/2} - t_1^{3/2} - t_2^{3/2}); \quad t_i = (T_i + T_i^\dagger) \quad \text{for} \ i = 0, 1, 2, \quad (44) \]

\[ W = W_0 - C e^{-2\pi T_0} - D e^{-2\pi (T_1 + T_2)} + A e^{-\frac{2\pi}{n_1} T_2} + B e^{-\frac{2\pi}{n_2} T_2}, \quad (45) \]

where \( T_i \) are complex Kähler moduli, and \( W_0, \ A, \ B, \ C \) and \( D \) are determined by the vacuum expectation values (VEVs) of heavy dilaton/complex structure stabilized via three-form flux compactification [29, 52]. (See [53] for realization of a small \( W_0 \).) The exponential terms in the superpotential are assumed to be generated by gaugino condensations in a pure \( SU(N) \times SU(M) \times SU(n_1) \times SU(n_2) \) gauge theory. Those gauge fields are living on the D-branes wrapping on the divisors whose volume is determined by the real part of the moduli, \( T_0, T_1 + T_2, T_2 \) and \( T_2 \) respectively. In other words, (at least some

\( ^8 \) A similar UV completion may be possible in a LARGE volume scenario with string-loop corrections and non-perturbative superpotentials, if a (moderately) big cycle allows a gauge coupling which generates the axion mass through non-perturbative effects. A large mass hierarchy between the saxion and the axion can then be realized: the saxion mass is suppressed by the power of the Calabi-Yau volume while the axion mass is exponentially suppressed by the volume [51].
part of) the gauge coupling of each gauge group is given by the corresponding moduli. We define \( T \equiv T_1 + T_2 \) and \( \Phi \equiv -T_1 + T_2 \), and express the lowest component of \( \Phi \) as \( \Phi = \sigma + i\phi \) for later use.

Using the \( U(1)_R \) symmetry and an appropriate shift of the imaginary components of the moduli fields, we can take \( W_0, A, C, \) and \( D \) real and positive without loss of generality. We will include a relative phase in \( B \) by replacing it with \( Be^{-i\theta} \) where \( B \) is a real and positive constant. We assume that those parameters satisfy

\[
A, B, C, D = \mathcal{O}(1), \quad W_0 \ll 1. \tag{46}
\]

We also assume that \( N, M, n_1 \) and \( n_2 \) are integers satisfying \(^9\)

\[
n_1 \sim n_2 \quad \text{and} \quad n_1 \neq n_2 \tag{47}
\]

\[
2n_1 < M \lesssim N. \tag{48}
\]

The mild hierarchy between \((M, N)\) and \((n_1, n_2)\) implies that \( T_0 \) and \( T = T_1 + T_2 \) are stabilized in a supersymmetric manner by the first two exponentials. On the other hand \( \Phi = -T_1 + T_2 \) remains relatively light, and this combination becomes the axion supermultiplet in the previous section. We shall see that, while \( \sigma = \text{Re}[\Phi] \) can be stabilized by the SUSY breaking effect through the Kähler potential, the axion, \( \phi = \text{Im}[\Phi] \), acquires an even lighter mass by the last two exponentials. In order to have successful inflation with sub-Planckian decay constants, the resultant two exponentials expressed in terms of \( \Phi \) must be comparable in size. This is possible for \( A \sim B \), if \( n_1 \) is close to \( n_2 \) within 10\(\%\) or so.\(^{10}\)

---

\(^9\) We shall see that the axion hilltop inflation with \( f_1 \approx f_2 \) is realized for this choice of the parameters.

The other cases such as \( f_1 = 2f_2 \) can also be realized if there is a hierarchy between \( A \) and \( B \). See Appendix A.

\(^{10}\) Precisely speaking, this is the case if \( |n_2 - n_1| \lesssim n_1 n_2 / \pi \langle T \rangle \). If \( n_1 \) is not close to \( n_2 \), some hierarchy between \( A \) and \( B \) is necessary.
B. Heavy moduli stabilization

We first study the stabilization of the heavy moduli, $T_0$, $T$ and $\sigma$. For $A = B = 0$, the model is reduced to the string-theoretic QCD axion model considered in Ref. [42]; there exists a Minkowski vacuum where, while the other moduli are stabilized, $\text{Im}[\Phi]$ remains (almost) massless and eventually becomes the QCD axion. Because of the assumed mild hierarchy between $(M, N)$ and $(n_1, n_2)$, our model is similar to this model as long as the heavy moduli stabilization is concerned.

The scalar potential of the moduli and the sequestered SUSY-breaking up-lifting potential $V_{\text{up}}$ are given by

$$V = V_{\text{moduli}} + V_{\text{up}}, \quad \text{where } V_{\text{up}} = \hat{\epsilon} e^{2K/3}, \quad \hat{\epsilon} = \mathcal{O}(W_0^2),$$

where $V_{\text{moduli}}$ is given by Eq. (8) with the above Kähler and super-potentials, and $\hat{\epsilon}$ is fixed so that a (nearly) Minkowski vacuum is realized in the low energy. The moduli stabilization is determined by the conditions for extremizing the potential $V$, $D_{T_0} W \simeq D_T W \simeq \partial_\Phi K \simeq 0$:

$$\frac{2\pi}{N} T_0 \simeq \frac{2\pi}{M} T \simeq \log \left( \frac{\log(1/W_0)/W_0}{W_0} \right) \gg 1, \quad \text{Re}[\Phi] = 0.$$  \hfill (50)

The VEVs of these moduli fields fix the volume of the Calabi-Yau space $\mathcal{V}$ as well as the gravitino mass as

$$\mathcal{V} = t_0^{3/2} - \frac{t^{3/2}}{\sqrt{2}},$$

$$m_{3/2} = W_0/\mathcal{V},$$

where $t = T + T^\dagger$. The moduli masses are given by

$$m_{T_0} \simeq m_T \simeq \log(M_{\text{Pl}}/m_{3/2}) m_{3/2},$$

$$m_\sigma \simeq \sqrt{2} m_{3/2},$$

where we used a fact that the up-lifting potential after integrating out $T_0$ and $T$ is approximately given by

$$V_{\text{up}} \simeq 3 m_{3/2}^2 + f^2 m_{3/2}^2 (\Phi + \Phi^\dagger)^2 + \cdots.$$  \hfill (55)

17
See Appendix B for the higher order terms in $V_{upL}$. Note that the axion $\phi$ remains massless in this case, which should be contrasted to the original KKLT \cite{37}. The SUSY-breaking $F$-terms of the moduli fields are given by

$$\frac{F_{T_i}}{T_i + T_i} \sim \frac{m_{3/2}}{\log(M_{Pl}/m_{3/2})} \sim m_{\text{soft}} \lesssim m_{3/2},$$

and, therefore, all the SUSY particles generically acquire a soft SUSY breaking slightly lighter than the gravitino mass through the modulus mediation. The anomaly mediation also gives a comparable contribution to the soft mass. Although the mass of the SUSY SM particles are relevant for the observed SM-like Higgs boson mass, they are irrelevant for the inflaton dynamics during inflation.

For $A$, $B \neq 0$, the axion can have a non-zero mass much smaller than the gravitino mass\textsuperscript{11}, while the stabilization of the heavy moduli is not changed drastically. This is because, as long as (48) is satisfied, the last two exponential terms in the superpotential (45) are much smaller than the others: $A e^{-\frac{\pi}{n_1} \langle T_2 \rangle} \sim W_0^{\frac{M}{\pi_1}} \ll W_0(\ll 1)$.

### C. Axion inflation in low energy effective theory

In this subsection, we focus on the lightest axion multiplet $\Phi$ at scales below the heavy moduli masses. We discuss multi-natural inflation within the low energy effective theory of this string-inspired model, using the results obtained in the previous section.

After integrating out the heavy moduli $T_0$ and $T$, we obtain the low energy effective theory for $\Phi$,

$$K_L \approx \frac{f^2}{2} (\Phi + \Phi^\dagger)^2 + \cdots,$$

$$W_L \approx W_0 + \hat{A} e^{-\frac{\pi}{n_1} \Phi} + \hat{B} e^{-\frac{\pi}{n_2} \Phi - i\theta}.$$  

The higher order terms in $K_L$ are given in Appendix B. Here, we have defined

$$f^2 \equiv \frac{3}{2 \sqrt{2} \sqrt{\lambda}} \lesssim 1, \quad \hat{A} \equiv A e^{-\frac{\pi}{n_1} (T)}, \quad \hat{B} \equiv B e^{-\frac{\pi}{n_2} (T)}.$$  

\textsuperscript{11} In order to implement the QCD axion, one would need to introduce another moduli field. Alternatively, the QCD axion may originate from an open string mode.
A natural value of $f$ is considered to be of order 0.1 since it is on the order of the string scale.

The above Kähler and super potentials are equivalent to (7) and (12) studied in the previous section, and successful axion inflation is possible for a certain choice of the parameters. The parameters are related as

$$a = \frac{\pi}{n_1}, \quad b = \frac{\pi}{n_2}$$

$$f_1 = n_1 f_a, \quad f_2 = n_2 f_a,$$

where we have defined $f_a \equiv \sqrt{2} f/\pi$.

Note that the prefactors of the exponentials, $\hat{A}$ and $\hat{B}$, are comparable to each other, and much smaller than $W_0$,

$$\hat{A} \sim \hat{B} \sim W_0^{M/2n_1} \ll W_0 \ll 1.$$  \hspace{1cm} (62)

As we have seen before, this hierarchy is one of the essential ingredients for multi-natural inflation. Indeed, the ratio of the axion mass to the saxion mass is much smaller than unity;

$$\frac{m_\phi^2}{m_\sigma^2} \sim \frac{\hat{A} W_0}{W_0^2} \sim W_0^{M/2n_1 - 1} \ll 10^{-2} \quad \text{for } M > 2n_1,$$

and therefore the saxion remains stabilized near the origin, $\langle \sigma \rangle \approx 0$.

In order to have axion hilltop inflation, the model parameters must satisfy the relations (26), (27), and (28) to a high accuracy. In particular, the condition (26) reads

$$\hat{A} \approx \left( \frac{n_1}{n_2} \right)^2 \hat{B},$$

which implies that the gaugino condensation from $SU(n_1)$ should be comparable to that from $SU(n_2)$ in size. In terms of the gauge couplings at the cut-off scale, this condition can be expressed as

$$\frac{g_2^2}{g_1^2} \sim \frac{n_1}{n_2} \left[ 1 + \frac{n_2 g_2^2}{8 \pi^2} \log \left( \frac{n_2}{n_1} \right) \right],$$

where $g_i$ ($i = 1, 2$) is the gauge coupling in $SU(n_i)$ gauge group at the cut-off scale and we have used the fact that $\hat{A}$ and $\hat{B}$ are proportional to $n_1$ and $n_2$, respectively:
\( W_{SU(n_i)} = n_i \Lambda_{SU(n_i)}^3 = n_i e^{-8\pi^2/m_i g_i^2} \), where the \( \theta \)-term is omitted. Thus, successful axion hilltop inflation requires a certain relation between the rank of the gauge groups and the value of the gauge couplings of a gauge theory where gaugino condensations form in the low energy. This is equivalent to the relation between the world volume of the relevant D-branes and the number of such branes in string theory. For further discussions on the magnitude of \( A \) and \( B \), see Appendix A.

Lastly let us express the inflaton mass and the Hubble parameter during inflation in terms of the gravitino mass. To this end we consider the case where \( n_1 \) is not degenerate with \( n_2 \). The axion mass at the potential minimum, the potential height and the inflation scale are estimated as

\[
\begin{align*}
    m_{\phi}^2 &\sim \frac{\hat{A} W_0}{n_1^2 f_a^2} \sim m_{3/2}^2 \left( \frac{m_{3/2}}{n_1 f_a} \right)^2 \left( \frac{m_{3/2}}{M_{Pl}} \right)^{\frac{M}{2n_1}} \left[ \frac{1}{\log(M_{Pl}/m_{3/2})} \right]^{\frac{M}{2n_1}}, \\
    V_0 &\sim \frac{\hat{A} W_0}{\hat{M}_{Pl}} \sim m_{3/2}^4 \left( \frac{m_{3/2}}{M_{Pl}} \right)^{\frac{M}{2n_1}} \left[ \frac{1}{\log(M_{Pl}/m_{3/2})} \right]^{\frac{M}{2n_1}}, \\
    H_{\text{inf}} &\sim \sqrt{\frac{V_0}{\hat{M}_{Pl}}} \sim m_{3/2}^2 \left( \frac{m_{3/2}}{M_{Pl}} \right)^{\frac{M-2n_1}{M}} \left[ \frac{1}{\log(M_{Pl}/m_{3/2})} \right]^{\frac{M}{2n_1}}
\end{align*}
\]

for \( M > 2n_1 \). For instance, \( m_{\phi} \simeq 10^{11}\text{GeV} \) is obtained for \( m_{3/2} \simeq 10^{14}\text{GeV} \), \( f_a \simeq 10^{17}\text{GeV} \), \( n_1 = 6 \) and \( M = 24 \). The last equation implies that the Hubble parameter during inflation is necessarily smaller than the gravitino mass,

\[
    H_{\text{inf}} < m_{3/2},
\]

which enables us to avoid the moduli destabilization [54]. This is because the flatness of the inflaton potential is not due to SUSY, but (mostly) due to both the axionic shift symmetry and the dynamical origin of the potential.

\[12\] When \( n_1 \) is close to \( n_2 \), the factor proportional to \( (n_1 - n_2)/n_2 \) should be included as discussed in the previous section.
D. Reheating and leptogenesis

In order to have successful inflation, the inflaton must transfer its energy to the SM particles. Also, as any pre-existing baryon asymmetry is diluted by the inflationary expansion, the right amount of baryon asymmetry must be created after inflation. Here we study reheating and the baryon number generation through leptogenesis [55].

As for reheating, the axion will decay into the SM gauge bosons through its couplings to the SM gauge fields,

\[ \mathcal{L}_{\text{SM}} = \frac{1}{16\pi} \int d^2 \theta T^\alpha_2 \mathcal{W}^\alpha_{\text{SM}} \mathcal{W}_{\alpha \text{SM}} + \text{h.c.} \geq \frac{1}{32\pi} \int d^2 \theta \Phi \mathcal{W}^\alpha_{\text{SM}} \mathcal{W}_{\alpha \text{SM}} + \text{h.c.} \]  

(70)

\[ \Gamma_g^\phi \equiv \Gamma(\phi \rightarrow 2A_\mu) \simeq \frac{N_g m^3_{\phi}}{32\pi t^2 f^2} \simeq \frac{N_g g^2_{\text{SM}} m^3_{\phi}}{4096\pi^3 f^2_a}, \]  

(71)

where \( t \simeq 16\pi/g^2_{\text{SM}} \). We have assumed that the SM is living on the D-brane wrapping on \( T_2 \)-cycle. Thus, the reheating temperature is given by

\[ T^g_R \simeq \left( \frac{\pi^2 g_*(T_R)}{90} \right)^{-1/4} \sqrt{\Gamma_g^\phi M_{\text{Pl}}} \simeq 4 \times 10^5 \text{ GeV} \left( \frac{m_{\phi}}{10^{11} \text{ GeV}} \right)^{3/2} \left( \frac{f_a}{10^{17} \text{ GeV}} \right)^{-1}, \]  

(72)

if this is the main decay mode.\(^{13}\) Here we have used \( N_g = 12 \) and \( g^2_{\text{SM}}/4\pi = 1/25 \) and \( g_*(T_R) = 106.75 \).

Next, let us consider the origin of the baryon asymmetry. Among various baryogenesis scenarios, leptogenesis is a plausible and interesting possibility in the light of the observed neutrino masses and mixings. We focus on non-thermal leptogenesis [58, 59], because it can generate a sufficient amount of baryon asymmetry with a relatively low reheating temperature.

The right-handed neutrino \( \nu^c \) can be produced by the axion decays via the coupling below

\[ W = C_{\nu^c} e^{-\frac{2\pi}{\alpha_1} T^g_R} \nu^c \bar{\nu}^c, \]  

(73)

\(^{13}\) The axion cannot decay into the SM gauginos since their mass is heavier than the axion mass. Even if it is possible, the estimation will not be changed drastically as studied in [56]; the R-parity may have to be violated to avoid the overabundance of dark matter. The moduli-induced baryogenesis may work in this case.
in which $C_{\nu e}$ is a constant. Note that the mass of the neutrinos is given by

$$m_{\nu e} \simeq 2C_{\nu e}M_{\text{Pl}}\left[\frac{m_3/2}{M_{\text{Pl}}}\right]^{\frac{M}{2n_1}},$$

(74)

while $m_\phi \sim W_0^{(M+2n_1)/4n_1}/f$; $m_{\nu e}/m_\phi \sim W_0^{(M-2n_1)}f < 1$. For instance, one obtains $m_{\nu e} \simeq 10^{10} \text{ GeV}$ when taking $W_0 = 10^{-4}$, $M = 24$, $n_1 = 6$ and $C_{\nu e} = 30$. Such a term is generated when the right-handed neutrino is coupled to the gauge field of $SU(n_1)$:

$$\int d^2\theta \nu^e [W^\alpha W^\alpha]_{SU(n_1)}.$$ (A similar origin is also discussed in the literatures [60–62].) The decay fraction is given by

$$\Gamma_{\nu e} \equiv \Gamma(\phi \to 2\nu^e) \simeq \frac{1}{16\pi} \left(\frac{m_{\nu e}}{n_1 f_\alpha}\right)^2 m_\phi.$$ (75)

The reheating will proceed mainly via the decay into the neutrinos if

$$\frac{m_{\nu e}}{m_\phi} \gtrsim 10^{-2}.$$ (76)

The reheating temperature is then estimated as

$$T_R^{\nu e} \simeq 1 \times 10^7 \text{ GeV}\left(\frac{m_\phi}{10^{11} \text{ GeV}}\right)^{1/2}\left(\frac{m_{\nu e}}{10^{10} \text{ GeV}}\right)^{1/2}\left(\frac{n_1 f_\alpha}{10^{17} \text{ GeV}}\right)^{-1}.$$ (77)

Using the reheating temperature $T_R \simeq \sqrt{(\Gamma_{\nu e} + \Gamma_\phi)M_{\text{Pl}}}$, the net baryon asymmetry is written as

$$\frac{n_B}{s} \simeq \frac{28}{78} \cdot \frac{3}{2} \frac{T_R}{m_\phi} B_{\nu e}^\phi,$$ (78)

with

$$\epsilon \simeq \frac{3}{16\pi} \frac{m_{\nu_3} m_{\nu e}}{v^2} \delta_{\text{eff}}.$$ (79)

where $B_{\nu e}^\phi$ is the decay fraction into the right-handed neutrino, $m_{\nu_3}$ is the heaviest neutrino mass, $v \simeq 174 \text{ GeV}$ is the Higgs VEV, and $\delta_{\text{eff}}$ is an effective CP-phase in the neutrino Yukawa couplings. Here we have assumed the SM contribution for the sphaleron process and assumed that the axion decays mainly into lightest right-handed neutrino. Then, we can generate a right amount of the baryon asymmetry,

$$\frac{n_B}{s} \simeq 5.4 \times 10^{-11} \delta_{\text{eff}} \left(\frac{T_R/m_\phi}{10^{-4}}\right) \left(\frac{m_{\nu_3}}{0.05 \text{eV}}\right) \left(\frac{m_{\nu e}}{10^{10} \text{ GeV}}\right) \left(\frac{B_{\nu e}^\phi}{1}\right).$$ (80)
FIG. 6: Plots for the baryon asymmetry and the Planck normalization in the \((M, m_{3/2})\)-plane. The green shaded region shows \(0.5 \times 10^{-10} \leq n_B/s \leq 1.5 \times 10^{-10}\). The blue line shows the Planck normalization corresponding to \(\lambda_{\text{Planck}} = 3.7 \times 10^{-14}\) for \(N_e \simeq 60\). In the red shaded region, the saxion vacuum deviates from the origin. We used \(n_1 = 7, n_2 = 6, f_\alpha = 2.3 \times 10^{17}\) GeV and \(C_{\nu\phi} = 8; f_1 = 7f_\alpha\) and \(f_2 = 6f_\alpha\). Then \(m_\phi \simeq 9.6 \times 10^{11}\) GeV is obtained, using Eq. (40). We find also \(m_{3/2} \sim 10^{13}\) GeV, \(m_{\nu\phi} \sim 10^{11}\) GeV and \(T_R \sim 10^7\) GeV in the viable region, where we can obtain the correct curvature perturbation and baryon asymmetry.

Thus, if the axion decays mainly into the lightest right-handed neutrinos, non-thermal leptogenesis works successfully. In Fig. 6, the plots for the baryon asymmetry are shown with \(\delta_{\text{eff}} = 1\), using the relation between the mass scales and the gravitino mass of Eq. (66) and (74). In the successful case, we can obtain \(m_{3/2} \sim 10^{13}\) GeV, \(m_{\nu\phi} \sim 10^{11}\) GeV and \(T_R \sim 10^7\) GeV.

No dark matter candidate has been considered in the setup so far. As the inflation
scale is lower than the typical scale of the soft SUSY breaking mass, no SUSY particles are produced during and after reheating. Therefore, the QCD axion or light axion-like particles, light sterile neutrinos, hidden photons, etc., or their combination, are candidates for dark matter.

Finally, we give a comment on the SM-like Higgs boson mass. In this model, the soft SUSY-breaking terms will be on the order of the gravitino mass or slightly smaller [38]. For $m_{\text{soft}} \sim m_{3/2}/\log(M_{\text{Pl}}/m_{3/2}) \sim 10^{12}$ GeV in the viable region for inflation, the Higgs mass becomes $\sim 126$ GeV for $\tan \beta \sim 1$ [63]. The small value of $\tan \beta$ can be realized in the presence of a shift symmetry or an exchange symmetry in the Higgs sector [64–66].

IV. DISCUSSION AND CONCLUSIONS

We have studied multi-natural inflation [28] in SUGRA for a UV completion. In this model the inflaton potential mainly consists of two sinusoidal functions that are comparable in size, but have different periodicity. For sub-Planckian values of the decay constants, this model is reduced to the hilltop quartic inflation in a certain limit. It is known however that the predicted spectral index, $n_s \simeq 0.94$, for the e-folding number $N_e \simeq 50$ tends to be too low to explain the Planck results. We have shown that, allowing a relative phase between the two sinusoidal functions, the spectral index can be increased to give a better fit to the Planck data based on the axion hilltop inflation in SUGRA. We have also considered a further UV completion based on a string-inspired framework, and have shown that the axion hilltop inflation model can be indeed obtained in the low energy limit.

The axion hilltop inflation requires a rather flat potential near the (local) potential maximum. For realizing the flat-top potential, there should exist a relation between the ratio of the decay constants and the dynamical scale: $(f_1/f_2)^2 \approx A/B$. This in turn implies that in string theory there should be a relation between the world volume of D-branes where the non-perturbative effects occur and the number of such branes.

It is also noted that because we have used supergravity, the gravitino mass is related
to physical quantities. For successful inflation, the typical scale of the gravitino mass is \( m_{3/2} \sim 10^{13} \text{GeV} \), whereas the soft mass is about one order of magnitude smaller, \( m_{\text{soft}} = 10^{12} \text{GeV} \), while the inflaton mass is \( m_\phi \sim 10^{11} \text{GeV} \). Thus, the SUSY particles are not produced in the Universe after reheating. The dark matter candidates can be considered such as the QCD axion, axion-like particles, or sterile neutrinos, if they exist. In particular, a light dark matter is interesting in light of its longevity. The recently discovered X-ray line at 3.5 keV \[34, 35\] may be due to the decay of one of such light dark matter\(^{14}\). It may be possible to explain the baryon asymmetry from the inflaton decay into right-handed neutrinos.

**Note added:** After the submission of our paper, the BICEP2 experiment found the primordial B-mode polarization \[4\], which suggests \( r = 0.20^{+0.07}_{-0.05} \). Although we have focused on the hilltop inflation limit of the multi-natural inflation when we evaluate the spectral index and the tensor-to-scalar ratio, most of the discussion including the realization of the multi-natural inflation in supergravity and string-inspired set-up, the reheating, and leptogenesis is applicable to a more general multi-natural inflation. In particular, for such a large value of \( r \), the inflaton mass will be of order \( 10^{13} \text{GeV} \), leading to the reheating temperature close to \( 10^9 \text{GeV} \) (cf. Eq. (72)). Therefore, thermal leptogenesis will be possible. See also the related papers on the multi-natural inflation \[69, 70\] that appeared after BICEP2.

Appendix A: The tuning for the inflation in the string-inspired model

In this section of the Appendix, we will discuss the tuning of

\[ \hat{B} \approx \left( \frac{n_2}{n_1} \right)^2 \hat{A} \]  

found in Sec. III C. Here, we define the phase of \( B \):

\[ \theta \equiv \arg[1/B]. \]  

It should be noted that the phase \( \theta \) will be given by the VEVs of the dilaton and the complex structure moduli stabilized by closed string fluxes. In terms of \( A \) and \( B \) this relation becomes

\[ B \approx A \left( \frac{n_2}{n_1} \right)^2 \left( \frac{W_0}{\log[1/W_0]} \right)^{\frac{1}{16} \left( \frac{1}{n_2} - \frac{1}{n_1} \right)}. \]  

Here we substituted the solutions of moduli VEVs in Eq.(50). For instance, one finds \( B \sim 15A \) for \( W_0 = 10^{-4} \), \( n_1 = 7 \), \( n_2 = 6 \) and \( M = 22 \). In this case, complex structure moduli can play a role in 1-loop threshold corrections from the heavy modes, which depend on the gauge group. On the other hand, for \( W_0 = 10^{-4} \), \( n_1 = 6 \), \( n_2 = 3 \) and \( M = 22 \), one finds \( B \sim 3.2 \times 10^8A \). In the latter case, the heavy moduli such as the dilaton and complex structure may play an important role in the relevant gauge couplings, e.g.,

\[ \frac{4\pi}{g^2_1} \sim T_2, \quad \frac{4\pi}{g^2_2} \sim T_2 - \Delta f, \]  

where \( \Delta f \) contains heavy moduli and \( 1 - \Delta f/T_2 \sim 1/2 \). Then one finds that \( B \sim e^{2\pi \Delta f} \sim e^{2\pi T_2} \gg 1 \) \[68\], using the fact that the size of one gaugino condensation is similar to the other. \( A e^{-2\pi T_2/6} \sim B' e^{-2\pi (T_2 - \Delta f)/3} \), where \( B' = Be^{-2\pi \Delta f/3} = \mathcal{O}(1) \). Note that even if \( B \) is much larger than unity, the heavy moduli/saxion stabilization does not change as long as

\[ \left( \frac{m_\phi}{m_\sigma} \right)^2 \leq \frac{\hat{B}}{|W_0|f^2} \lesssim 10^{-2}. \]  

A relation \( M > 2n_2 \) is important to satisfy the above condition.
Appendix B: Higher order terms in Choi-Jeong models

We write down higher order terms in $\Phi$:

$$K_L \approx \frac{f^2}{2} (\Phi + \Phi^\dagger)^2 + f^2 k_4^4 (\Phi + \Phi^\dagger)^4 + f^2 k_6^6 (\Phi + \Phi^\dagger)^6 + \cdots , \quad (B1)$$

$$W_L \approx W_0 + Ce^{-\frac{\pi}{2n} (\Phi + \langle T \rangle)} - De^{-\frac{\pi}{2n} (\Phi + \langle T \rangle)} , \quad (B2)$$

$$V_{upL} \approx 3m_{3/2}^2 + f^2 m_{3/2}^2 (\Phi + \Phi^\dagger)^2 + f^2 m_{3/2}^2 \zeta (\Phi + \Phi^\dagger)^4 + \cdots . \quad (B3)$$

Here, we defined

$$f^2 \equiv \frac{3}{2\sqrt{2} t V} , \quad k_4 \equiv \frac{9 \sqrt{2} t^{3/2} + 6 \mathcal{V}}{8 t^2 \mathcal{V}} \sim f^2 < 1 , \quad k_6 \equiv \frac{15 (18 t^3 + 9 \sqrt{2} t^{3/2} \mathcal{V} + 14 \mathcal{V}^2)}{32 t^4 \mathcal{V}^2} \sim f^4 < 1 ,$$

$$m_{3/2} = e^{K/2} W = \frac{W_0}{\mathcal{V}} , \quad \zeta = \frac{(7 t^{3/2} + \sqrt{2} \mathcal{V})}{16 \sqrt{2} t^2 \mathcal{V}} \sim f^2 < 1 , \quad (B4)$$

where $t = T + T^\dagger , \quad \mathcal{V} \equiv t_0^{3/2} - t^{3/2}/\sqrt{2}$ and $\hat{e} \approx 3 W_0^2 / \mathcal{V}^{2/3}$ are used, and it is noted that $t$ and $\mathcal{V}$ are given by the VEVs. The higher order term of $\Phi$ in the Kähler potential will become irrelevant for $f \lesssim 1$, when the uplifting potential is added.
