Abstract: Sichuan Province, the most industrialized and populated region in southwestern China, has been experiencing severe ozone pollution in the boreal warm season (April–September). With a surface ozone monitoring network and reanalysis dataset, we find that nearly all cities in Sichuan Province showed positive increasing trends in the warm-season ozone levels. The warm-season daily maximum 8-h average (MDA8) ozone levels increased by 2.0 ppb (4.8%) year$^{-1}$ as a whole, with slightly larger trends in some sites such as a site in Zigong (5.2 ppb year$^{-1}$). Seasonally, the monthly ozone level in Sichuan peaks from May to August (varies with year). The predominant warm-season synoptic patterns were objectively identified based on concurrent hourly meteorological fields from ERA5. High-pressure systems promote ozone production and result in high ozone concentrations, due to strong solar radiation as well as hot and dry atmospheric conditions. The increased occurrence of high-pressure patterns probably drives the ozone increase in Sichuan. When ozone pollution is relatively weak (with MDA8 ozone around 170 µg m$^{-3}$), the air quality standard could be achieved in the short term by a 25% reduction of NO$_x$ and VOCs emissions. Strengthened emission control is needed when ozone pollution is more severe. Our study provides implications for effective emission control of ozone pollution in Sichuan.

Keywords: ozone; Sichuan; synoptic pattern; pollution control

1. Introduction

Ozone in the troposphere is mainly produced from the complex oxidation of volatile organic compounds (VOCs) with nitrogen oxides (NO$_x$ = NO + NO$_2$) in the presence of sunlight. Surface ozone is harmful to human health as it can damage the respiratory and circulatory systems [1–3]. In addition, surface ozone can also deteriorate the vegetations, ecosystems, and building materials [4–6]. Due to effective reductions in anthropogenic emissions of ozone precursors, surface ozone concentrations began to reduce since the 1990s in the United States and Europe [7,8]. However, observations from the nationwide...
measurement networks showed that the ozone concentrations in China have been increasing rapidly since 2013. The increasing rate during the time period 2013–2019 is especially high in the North China Plain of 3.3 ppb year$^{-1}$ in terms of the warm-season mean MDA8 (daily maximum 8-h average) values [9,10]. Regional ozone pollution events occurred frequently in China in recent years [11–14]. As one of the most industrialized and densely populated regions in southwestern China, Sichuan Province has strong anthropogenic emissions of ozone precursors [9]. Due to the intense emissions, complex terrain, and special meteorological conditions, Sichuan suffered from severe ozone pollution in recent years [15–18]. According to the results from air quality prediction, the government of Chengdu (the capital of Sichuan) issued a yellow warning of heavy ozone pollution on 27 July 2021. The yellow warning predicted a severe ozone pollution event on 29 July that it will last for at least three days [19]. The first yellow warning of ozone pollution in China [19] indicated that ozone pollution should draw more attention.

Surface ozone concentrations are influenced by both the emissions of precursors and meteorological conditions. High temperature, low humidity, high solar radiation, and weak diffusion environment are typical weather conditions that are favorable for high ozone concentrations [15,16,20]. Categorizing the weather patterns and accordingly pinpointing the relationship between weather and ozone concentrations can help us better understand the formation of ozone pollution and predict air quality in the future. Many studies explored the influences of weather patterns on air pollution. Studies focus on meteorology conditions with ozone pollutions [16,18,21,22] are relatively less than that with fine particle pollutions [23–27], which started much earlier in China. Zhao and Wang [28] found that winter-time air quality in Hangzhou is not only affected by local anthropogenic emissions, but also the meteorology conditions, which influence transportation of pollutants. Shen et al. [29] used Empirical Orthogonal Functions (EOFs) to reveal the leading weather patterns in the eastern United States over 1980–2012 and defined that the polar jet frequency could be a metric to predict ozone variability in future climate regimes. Kim et al. [22] concluded that synoptic weather and its long-term trends play essential roles in the increased surface ozone concentrations observed in South Korea in recent years. With the Lamb-Jenkinson circulation classification method and linear regression model Liang et al. [21] quantified the relationship between surface ozone concentrations and circulation types in Hangzhou.

Sichuan is characterized by both mountain and basin areas. Located in the east part of Sichuan Province, the Sichuan basin (SCB) is one of the biggest basin areas in China (Figure S1). The west of Sichuan covers part of the eastern Tibetan Plateau. Influenced by the special topography, the meteorological conditions in Sichuan are complex and variable. Untangling the impacts of synoptic patterns on ozone pollution in Sichuan is challengeable but important for revealing the formation mechanisms of ozone pollution. Lu et al. [16] found that the spring ozone concentrations in Chengdu were sensitive to the synoptic patterns in 2015–2019. Ning et al. [30] classified 7 dominant synoptic patterns in the SCB in summer and pointed out that the synoptic patterns with high pressure which tend to increase ozone concentrations in the SCB have occurred more frequently over the past 40 years.

Chemically, the sensitivity of ozone formation to its precursors is nonlinear. When ozone concentrations are limited by NO$_x$ concentrations, the ozone formation regime is NO$_x$-limited. The ozone formation regime is identified as VOC-limited (NO$_x$-saturated) when ozone concentration is positively related to VOCs concentrations but negatively related to NO$_x$ concentrations. Ozone concentrations in the transition regime are sensitive to both NO$_x$ and VOCs concentrations. Previous studies showed that the ozone chemical regime in most industrial cities in China is more likely to be VOC-limited while the rural area is in a NO$_x$-limited or transition regime [13]. Studies also suggested that the formation regime in most areas in Sichuan Province except for Chengdu is NO$_x$-limited [31]. In Chengdu, the ozone formation regime is categorized as VOC-limited for most of the
Effective mitigation of local ozone pollution requires a better understanding of ozone formation to anthropogenic NOx and VOCs emissions.

In this study, we will first characterize the spatial distributions, seasonal variations, and trends of ozone pollution in Sichuan Province during the period 2013–2020. Then, using the principal component analysis in T-mode (PCT) method implemented in a classification software named Cost733class, we classify the predominant synoptic weather patterns in the warm season (April–September, including spring and summer ozone pollution period) over Sichuan during the same period. Accordingly, we investigate the sensitivity of the daily variability of ozone pollution to synoptic patterns. We further use the Community Multiscale Air Quality model with the decoupled direct 3D method (CMAQ-DDM-3D) to derive the typical Empirical Kinetic Modeling Approach (EKMA) ozone isopleths under different emissions control levels and accordingly provide some suggestions on emission control for ozone pollution in Sichuan Province.

2. Materials and Methods

2.1. Surface Ozone Observations and Reanalysis Dataset

Hourly surface ozone concentrations in Sichuan Province from 2014 to 2020 are obtained from the China National Environmental Monitoring Center (CNEMC) network (http://106.37.208.233:20035/, accessed on 10 August 2021). The observation sites in Sichuan increased from 38 in 2014 to 92 in 2020 (Figure S2). We follow Lu et al. [9,34] to apply data quality controls to remove unreliable data outliers and select sites with continuous observations from 2014 to 2020 for trend analysis. Thirty sites in 8 cities including Chengdu, Mianyang, Yibin, Panzhihua, Luzhou, Zigong, Deyang, and Nanchong as shown in Figure S1b are used. We use 12 metrics as introduced in Lu et al. [9] to characterize ozone pollution and its impacts on human health and ecosystems. The 5th percentile, 50th percentile (median), 95th percentile, daytime average (0800–2000 LST, Local Standard Time), nighttime average (2000–0800 LST), daily maximum 1-h average (MDA1), and MDA8 ozone are used to evaluate ozone pollution levels. The total number of days with MDA8 ozone greater than 70 ppb (NDGT70) and the sum of daily MDA8 ozone over 35 ppb (SOMO35) are used to estimate the acute and cumulative health effects of ozone pollution [1]. Ozone damages to vegetations are quantified by the sum of the difference between the hourly mean ozone concentration and 40 ppb for all daylight (AOT40) and the sum of all hourly ozone values during a specified time window weighted by a sigmoidal function (W126) [1].

The near-real-time air pollutant dataset, Tracking Air Pollution in China (TAP, http://tapdata.org.cn/, accessed on 24 June 2021) version2 ozone data, is used in this study. It provides a full-coverage and high-resolution mapping of daily MDA8 ozone in Sichuan at 10 km spatial resolution. TAP combines the information from ground observations, satellite retrieval, model results from the Community Multiscale Air Quality (CMAQ) model, and other ancillary data as introduced by Geng et al. [35] and Xue et al. [36]. The TAP PM2.5 dataset released earlier than the ozone dataset was widely used in PM2.5 research [37–39]. The near real-time MDA8 ozone estimates in China since 2013 were released in March 2021.

2.2. Meteorological Data and Weather Classification

ERA5 is the fifth generation reanalysis from the European Center for Medium-Range Weather Forecasts (ECMWF), which provides hourly estimates of variables describing atmospheric, land, and oceanic climate (detailed at: https://www.ecmwf.int/en/forecasts/datasets/reanalysis-datasets/era5, accessed on 19 October 2021). ERA5 has been widely used in studies on synoptic weather classification [28,40–43]. In this study, we use mean sea level pressure at 0.25° × 0.25° on 1400 LST (usually with the highest ozone pollution during the day [9], Figure S3a) from 1 April to 30 September (warm-season period) of 2013–2020 to classify the predominant synoptic weather patterns in Sichuan. The study area covers Sichuan Province and surrounding areas (95–133° E, 24–37° N). Total cloud cover, surface net solar radiation, 2-m temperature, 2-m relative humidity, 10-m wind field
(U and V component), geopotential height at 700 hPa and 500 hPa, and relative vorticity at 700 hPa on 1400 LST are used to characterize the synoptic patterns.

Weather classification methods are usually divided into objective and subjective classifications [16,28,43–45]. The subjective classification method requires expert knowledge of meteorology, physics, and geometry, thus the classification results for a region often differ from each other in different studies [46]. The objective method classifies the weather patterns automatically and can be easily replicated. It has been developed gradually with the development of computers [47]. The Principal Component Analysis (PCA) in T-mode (PCT method) implemented in the software Cost733class is used in this study. It is recommended by previous studies as it can well capture the predominant weather patterns over a study domain [48]. The PCT method makes the input meteorological data into a matrix with the grid point values in rows and cases (time dimension) in columns [46]. The matrix is in the form of principal components (PCs), scores, and loadings. Only those PCs with large eigenvalues are used for further analysis because they are expected to contain an interpretable signal. These PCs then must be obliquely rotated to obtain a meaningful classification. Finally, a circulation pattern is classified when the type has the highest loading [49]. Cost733class is a weather classification software that covers various methods and is widely used in researches on weather classification [49,50] (http://cost733class.geo.uni-augsburg.de/cost733class-1.2, accessed on 30 September 2021).

2.3. Numerical Model Description and Simulations

We use the numerical method described in Du et al. [51] to efficiently produce ozone isopleths. This method firstly uses the decoupled direct method in three-dimension (DDM-3D) [52,53] in the CMAQ model [54] to derive the first- and second-order sensitivity coefficients of ozone concentration to NO\textsubscript{x} and VOCs emissions [55,56]. It then constructs a Reduced Form Model (RFM) [57,58] to calculate the ozone concentrations under a series of NO\textsubscript{x} and VOCs control scenarios to draw an Empirical Kinetic Modeling Approach (EKMA) curve efficiently. We analyze the EKMA curves for Chengdu, Deyang, Mianyang, Leshan, Neijiang, Suining, Yaan, Ziyang, Meishan, and Guangyuan during 8.11–8.31 in 2019 (when Sichuan suffers a typical ozone pollution event). Accordingly, we give preliminary suggestions for ozone pollution control in Sichuan Province.

3. Results and Discussion

3.1. Seasonal Variations and Trends of Ozone

We analyze the linear trend of the surface ozone in the warm season (April—September) from 2014 to 2020 among the selected 30 sites with continuous observations in Sichuan Province. The locations of these sites are shown in Figure S1b. The warm-season mean MDA8 and MDA1 ozone levels respectively increased by 2.0 (4.8%) and 2.1 (4.2%) ppb year\textsuperscript{−1} across Sichuan, with more than 96% of sites showing positive trends for warm-season MDA8 ozone. The observation site in Zigong has the largest increasing trend of 5.2 ppb year\textsuperscript{−1}.

There are also several sites with an increasing trend over 3 ppb year\textsuperscript{−1} in Nanchong (4.6 ppb year\textsuperscript{−1}), Chengdu (3.8 ppb year\textsuperscript{−1}), Yibin (3.5 ppb year\textsuperscript{−1}), and Panzhuhua (3.0 ppb year\textsuperscript{−1}). Figure 1c presents the trend of 8 ozone metrics averaged over 30 sites, which indicates that ozone levels are increased at all selected percentiles. Ozone levels in Sichuan Province increased at 0.3 (7.3%), 1.4 (6.2%), and 2.9 (5.0%) ppb year\textsuperscript{−1} for the 5th, 50th, and 95th percentiles, respectively (all with \(p < 0.01\)), based on a linear trend estimate (Figure 1c). The 95th percentile’s ozone concentration shows the largest positive trend, which indicates severe ozone pollution occurred more frequently in Sichuan Province than before. The peak of the probability of functions (PDF) shifted to the high ozone concentrations from 2014 to 2020 (Figure S3b) also reflected the increased frequency of severe ozone pollution in Sichuan. Figure 1c also shows a significant positive trend in both daytime (1.8 ppb year\textsuperscript{−1}, \(p < 0.01\)) and nighttime (1.1 ppb year\textsuperscript{−1}, \(p < 0.01\)) mean ozone levels, which enhance the ozone diurnal contrast in Sichuan Province from 2014 to 2020 (Figure S3a).
Figure 1. Time series of the average (black dots) and anomaly (red circles) for (a) MDA8 and (b) MDA1 ozone in the warm season over 30 sites in Sichuan from 2014 to 2020. Gray shading indicates the range of mean values ± 50% of the standard deviation over 30 sites for each month. The red dash line represents the linear fitted curve. The inset numbers in the upper part of the plot show the linear trend in absolute values (ppb year\(^{-1}\)) and percentages (% year\(^{-1}\), calculated as the linear trend divided by the mean values in the year 2014). The inset numbers in the lower part above the x-axis denote the warm-season average values. (c) The annual trend for 8 ozone metrics in Sichuan from 2014 to 2020.

Distinct exacerbation of ozone air quality in Sichuan Province imposed adverse impacts on both human health and vegetation. MDA8 and MDA1 metrics have been used for calculating premature death related to ozone exposures [59,60]. Warm-season averaged MDA8 and MDA1 ozone increased at 2.0 (4.8%, \(p < 0.01\)) and 2.1 (4.2%, \(p < 0.01\)) ppb year\(^{-1}\). NDGT70 and SOMO35 increased at 31.9% year\(^{-1}\) and 12.0% year\(^{-1}\) across Sichuan. These increased ozone metrics indicate the increased premature mortality associated with ozone pollution from 2014 to 2020. We estimated that the warm-season averaged AOT40 and W126 in Sichuan Province respectively increased at 9.4% year\(^{-1}\) and 11.4% year\(^{-1}\), indicating increased damage of vegetations due to ozone pollution (Figure S4).

To glean a comprehensive understanding of ozone concentration changes over Sichuan, we further analyze the MDA8 ozone concentration reanalysis data from TAP. The comparison with observations from CNEMC in Figure S2 shows that the TAP can well capture the spatial and temporal characteristics of warm-season MDA8 ozone in Sichuan (NMB < 8%, NMB = \(\sum_{i=1}^{N} (R_i - O_i) / \sum_{i=1}^{N} O_i\), i: site i, R: TAP data, O: observation, N: number of observation sites). Figure 2 and Figure S2 show the spatial distribution of monthly and warm-season mean MDA8 ozone from 2013 to 2020, respectively. The highest ozone concentrations in Sichuan Province occur around Chengdu, Deyang, Miyiang, Meishan, Zigong, Neijiang, and Nanchong, reflecting the high density of population (Figure S5) and high intensity of anthropogenic emissions.
Figure 2. Monthly mean MDA8 ozone (black lines) from 2013 to 2020 and warm-season averaged MDA8 ozone (blue lines) from TAP during 2014–2020 for 21 cities in Sichuan Province. The monthly mean values for April, May, June, July, and August are shown in orange, grey, yellow, red, and green dots, respectively. The dashed blue lines represent the linear fitted curve for the warm-season mean over 2014–2020. The slopes and p-values for the fitted curves (right bottom corner), the warm-season mean MDA8 and mean altitude [61] (left upper corner) for each city over 2013–2020 are also shown inset.
The TAP reanalysis data consistently show a positive ozone trend with surface observations during 2014–2020. The warm-season MDA8 ozone concentrations over 15 cities (71.4%, Table S1) were the lowest in 2014 during the period and began to increase from 2014 to 2020 (Figure 2). To estimate the increasing trend and be consistent with CNEMC observation data, we calculate the trend from 2014 (instead of 2013) to 2020. Ozone concentrations show a positive trend in almost every city in Sichuan Province since 2014, except for Suining, where the MDA8 ozone increased rapidly from 2014 to 2016 and kept almost unchanged from 2016 to 2020. The increasing trends of MDA8 ozone in the city mean are remarkable in Zigong (2.0 ppb year$^{-1}$), Neijiang (1.8 ppb year$^{-1}$), Nanchong (1.7 ppb year$^{-1}$), and Meishan (1.6 ppb year$^{-1}$). We also notice that the occurrence time of the seasonal peak of ozone varies from year to year, but mostly in May (32.1%) and August (20.8%). Ozone concentrations in cities located at high altitudes (over 1800 m) tend to peak in May while those cities in the basin tend to peak in August. The conclusions are consistent with Zhao et al. [62], which found the ozone concentrations in Aba, Liangshan, and Panzhihua peak in spring.

3.2. Synoptic Impacts on Daily Variations of Ozone

We identify six predominant synoptic patterns (Type I–VI) in Sichuan Province in the warm season during the period 2013–2020 based on the mean sea-level pressure (Figure 3). The six synoptic patterns exhibit distinct characteristics in mean sea-level pressure and 10 m wind field. Type I has higher pressure in the southern than the northern direction of SCB, leading to the southerly wind prevailing over SCB. Type II shows a low sea-level pressure located in SCB with the strong southerly wind in southern Sichuan and southeasterly wind in northern Sichuan. Type III is characterized by a weak easterly wind. Type IV has higher sea-level pressure located at northern toward to SCB compared to pressure at southern SCB and is characterized by northerly wind at SCB. Though the sea-level pressure is higher in Type V than other synoptic types, the pressure at SCB is lower than the surroundings. Type V is characterized by northerly wind at southern SCB and easterly wind at northern SCB. There is a low-pressure system in Inner Mongolia and a high-pressure system at the Yellow sea for Type VI (Figure S6). Type VI is characterized by the southeasterly wind. Types I and II occur more frequently than the other synoptic types (Figure 3). Type VI has the lowest occurrence among the six patterns. Type I and type VI occurs mostly in April and May (Figure 4), probably associated with spring ozone pollution in SCB. Type II occurs mostly in June-August, likely leading to ozone pollution in summer.

We calculated daily anomaly with respect to monthly mean to remove the impacts of seasonally varied meteorological conditions and ozone concentrations (Figure 5, mean values of each type are shown in Figure S7). Here, TAP ozone data is used to capture the full spatial and temporal characters of ozone concentrations in Sichuan. According to the spatial distribution of the ozone concentration anomalies in each synoptic type (the rightmost column in Figure 5), we find that Type I, II, and VI are accompanied by ozone pollution with positive anomalies of 3.2, 0.5, and 1.1 ppb, respectively, in MDA8 ozone over the SCB. Type IV and V show negative anomalies of MDA8 ozone in SCB by 3.7 and 4.4 ppb, respectively. In addition, Type III is an intermediate type with few anomalies in meteorology conditions and ozone concentrations compared to the averaged conditions. Therefore, we further divide six synoptic types into ozone pollution type (Type I, Type II, and Type VI), ozone clean type (Type IV, and Type V), and intermediate type (Type III).

Synoptic patterns with high ozone concentrations are often associated with high-pressure systems. There are positive anomalies in geopotential height in SCB for Type I, Type II, and Type VI (Figure 3). There is a ridge system located to the west of SCB in Type I and Type II (Figure S8). Besides, the strong western pacific subtropical high system in Type I and Type II (Figure S8) results in a cloudless environment in SCB [63], where received mean solar radiation exceeds 2.1 MJ m$^{-2}$ at the surface along with a high surface temperature and low relative humidity. Strong solar radiation, high air temperature, and dry air are favorable conditions for ozone chemical production and emissions of natural...
ozone precursors including biogenic VOCs and soil NO\textsubscript{x} [10]. All these conditions lead to positive anomalies of MDA8 ozone in SCB for Type I and Type II by 3.2 and 0.5 ppb, respectively. The relative humidity of Type I is lower than Type II, potentially leading to higher ozone concentration in Type I. In eastern SCB, Type VI shows positive anomalies for geopotential height at 500 hPa level (Figure 3) and negative anomalies in relative vorticity at 700 hPa level (Figure S10), which enhance downward airflow in SCB. Then Type VI shows positive anomalies in surface temperature (0.6 K) and negative anomalies in mean relative humidity (0.6%), which lead to positive anomalies in MDA8 ozone of 1.1 ppb in SCB. On average, the MDA8 ozone increases by over 3 ppb in Yibin, Zigong, Luzhou, and Neijiang in Type VI.

Figure 3. Circulation of the six predominant synoptic patterns in the warm season over Sichuan from 2013 to 2020 classified by the mean sea-level pressures. The top two rows show the mean sea level pressure (contour) and 10-m wind fields (vector) in the warm season over Sichuan Province and its surroundings. The occurrence frequency of each synoptic type is shown inset. The bottom two rows show the anomalies of geopotential height (contour) and wind fields (vector) at 500 hPa.
Figure 4. The occurrence frequency of the six predominant synoptic patterns in each month of the warm season during the time period 2013–2020 in Sichuan.

Figure 5. The anomaly of classified six types of synoptic patterns of total cloud cover, surface downward solar radiation, 2-m temperature, 2-m relative humidity, and MDA8 ozone from TAP (contour) and CNEMC (dots) in warm-season over 2013–2020. The mean values over 17 basin cities are shown inset. The number of days that MDA8 ozone over 160 µg m$^{-3}$ among 21 cities in Sichuan are inset at the right corner.
Type IV and V are synoptic types controlled by low-pressure systems. From distributions of the 500 hPa geopotential height, we can observe a trough for both Type IV and Type V in SCB (Figures S8 and S9). Positive anomalies for relative vorticity (Figure S10) and negative anomalies for 500 hPa geopotential height (Figure 3) in SCB can also be observed for Type IV and Type V. Therefore, Type IV and Type V have high cloud cover (over 85%), which suppress surface solar radiation. Compared with Type IV, the positive anomalies of total cloud cover are larger in Type V, resulting in less radiation arriving on the surface in Type V than in Type IV. Cloudy sky in Type IV (Type V) decreases the surface temperature by 1.5 K (2.8 K) and increases relative humidity by 6.3% (5.2%) on the surface. Thus, the meteorology characteristics of synoptic patterns controlled by low-pressure systems are cloudy, cool, and wet, which result in negative anomalies in the MDA8 ozone by 3.7 and 4.4 ppb for Type IV and Type V, respectively. Type III tends to lead to weak changes in meteorological conditions and ozone concentrations.

The occurrence for the six predominant synoptic types in the warm season varies with year (Figures 6 and S11). The occurrence of Type I, which tends to increase spring ozone concentrations, increased by 30 days in the warm season from 2014 to 2017. Meanwhile, the April–May MDA8 ozone in Sichuan increased by 6 ppb during this period. After 2017, decreased occurrence of Type I and increased frequency of Type II kept MDA8 ozone around 52 ppb. The occurrence of ozone pollution type (Type I + Type II + Type VI) increased at 3.1 days year\(^{-1}\) while the occurrence of ozone clean type (Type IV + Type V) decreased at 1.5 days year\(^{-1}\) from 2014 to 2020. The occurrence of Type III decreased at 1.6 days year\(^{-1}\), which increased ozone concentrations in northeastern SCB and decreased ozone concentrations in the rest part of SCB. The warm-season ozone concentrations are positively related to the occurrence of ozone pollution type \((r = 0.81)\) and negatively related to the occurrence of ozone clean type \((r = -0.74)\). Therefore, the warm-season ozone concentrations changes in SCB can be partly explained by the changing of meteorology conditions. Other changes in ozone concentrations are mainly from anthropogenic emissions changes.

**Figure 6.** The annual occurrence of six synoptic types in Sichuan Province over 2013 to 2020.

### 3.3. Formation Regimes of Ozone at Different Pollution Levels

There is a severe ozone pollution event during 11–31 August 2019 in Sichuan Province. Chengdu, Neijiang, and Suining had the most days with ozone pollutions in Sichuan Province during this period. The highest MDA8 ozone occurred in Deyang on 11 August, reached 276 \(\mu g \, m^{-3}\). Most ozone pollution days (93.3%) in Chengdu are controlled by Type II and Type III, which occurred in 90.4% of the days during this period. When controlled by Type II (Type III), the city-mean MDA8 ozone over 200 \(\mu g \, m^{-3}\) occurred in 85.7% (28.6%)
of the days. The Type I weather pattern occurred only one day over this period and caused MDA8 ozone over 180 \( \mu g \text{ m}^{-3} \) in Chengdu, Mianyang, and Deyang.

According to EKMA curves, we categorize the ozone formation regime in Sichuan. The MDA8 ozone formation in Chengdu is VOC-limited in less polluted days and transition regime in heavily polluted days. Similar results are presented by Wang et al. [64] in the Beijing-Tianjin-Hebei region. The MDA8 ozone in Neijiang and Suining is \( \text{NO}_x \)-limited. We plot EKMA curves and categorize the MDA8 ozone (as city average) formation regime for 9 cities every day during 11–31 August 2019 as summarized in Table 1. Chengdu fell in VOC-limited (40.9%) and transition regime (31.8%) for the most time, while other cities in Sichuan Province mostly fell in \( \text{NO}_x \)-limited conditions.

We generally derive emissions reduction suggestions of \( \text{NO}_x \) and VOCs to achieve the air quality standard for ozone (160 \( \mu g \text{ m}^{-3} \) for MDA8 ozone) by analyzing EKMA curves in Chengdu, Neijiang, and Suining. The ozone levels are divided into heavy ozone pollution (over 200 \( \mu g \text{ m}^{-3} \)), light ozone pollution (around 170 \( \mu g \text{ m}^{-3} \)), and clean days (less than 160 \( \mu g \text{ m}^{-3} \)) (Figure 7). When heavy ozone pollution occurs, a 45–60% reduction of \( \text{NO}_x \) and VOCs emissions is needed to achieve the ozone standard. This large reduction of emissions is not achievable within a few days. To mitigate the ozone pollution in heavy ozone pollution days, we need a more effective way to reduce emissions before ozone pollution occurs. For MDA8 ozone of 160–170 \( \mu g \text{ m}^{-3} \) in Chengdu, approximately 25% reductions of \( \text{NO}_x \) and VOCs emissions are needed to achieve the ozone standard. Future work is needed to assess the impact of changes in emissions and meteorological conditions on the effectiveness of emission control.

4. Conclusions

Ozone pollution in Sichuan Province increased substantially during the time period 2013–2020. From surface observations and reanalysis data from TAP, we find high ozone concentration in cities with a high density of population and high anthropogenic emissions including Chengdu, Deyang, Mianyang, Meishan, Ziyang, Zigong, Neijiang, and Nanchong. Ozone concentration in Ganzi, Aba, Liangshan, Panzhihua, and Yaan peak in May, and other 16 cities in Sichuan peak around May to August (varies with year). From 2014 to 2020, warm-season MDA8 ozone increased at 2.0 (4.8%) ppb year\(^{-1}\) on average in Sichuan, with a more apparent increasing trend in Zigong, Nanchong, Chengdu, Yibin, and Panzhihua. Ozone levels for the 5th, 50th, and 95th percentiles increased by 0.3, 1.4, 2.9 ppb year\(^{-1}\), respectively, suggesting a higher frequency of high ozone pollution events. The ozone diurnal contrast becomes larger in Sichuan Province from 2014 to 2020. Increased MDA8, MDA1, NDGT70, SOMO35, AOT40, and W126 indicate the increased negative effects on human health and natural vegetation in Sichuan Province.

Six predominant types of synoptic patterns are divided by the objective PCT method. Type I, II, and VI are controlled by high-pressure systems and favorable to cause ozone pollution in clear-sky conditions with strong solar radiation, high surface temperature, and dry air. By contrast, Type IV and V are controlled by low-pressure systems with opposite meteorology conditions, which suppress the accumulation of ozone. Changes in mean MDA8 ozone in SCB in the warm season from 2014 to 2020 are associated with the occurrence of the ozone pollution type and ozone clean type, which indicates the crucial role of the meteorology conditions in ozone pollution over Sichuan Province.

We further categorize the MDA8 ozone formation regime and assess the emission control strategy to reduce ozone pollution over Sichuan Province by estimating the EKMA curves in different ozone pollution levels. Chengdu is mostly in transition and VOC-limited regimes while other cities in Sichuan Province are mostly in NO\(_x\)-limited regimes. By dividing the EKMA curves into heavy ozone pollution (with MDA8 ozone over 200 µg m\(^{-3}\)), light ozone pollution (with MDA8 ozone around 170 µg m\(^{-3}\)), and clean (with MDA8 ozone less than 160 µg m\(^{-3}\)) type we estimate that around 45–60% and 25% NO\(_x\) and VOCs emissions reduction should be enforced to avoid heavy and light ozone pollution events, respectively.
