ABSTRACT
The Shapley value is a conventional and well-studied function for determining the contribution of a player to the coalition in a cooperative game. Among its applications in a plethora of domains, it has recently been proposed to use the Shapley value for quantifying the contribution of a tuple to the result of a database query. In particular, we have a thorough understanding of the tractability frontier for the class of Conjunctive Queries (CQs) and aggregate functions over CQs. It has also been established that a tractable (randomized) multiplicative approximation exists for every union of CQs. Nevertheless, all of these results are based on the monotonicity of CQs. In this work, we investigate the implication of negation on the complexity of Shapley computation, in both the exact and approximate senses. We generalize a known dichotomy to account for negated atoms. We also show that negation fundamentally changes the complexity of approximation. We do so by drawing a connection to the problem of deciding whether a tuple is "relevant" to a query, and by analyzing its complexity.

1 INTRODUCTION
Various formal measures have been proposed for quantifying the contribution of a fact \( f \) to a query answer. Meliou et al. [23] adopted the quantity of responsibility that is inversely proportional to the minimal number of endogenous facts that should be removed to make \( f \) counterfactual (i.e., removing \( f \) transitions the answer from true to false). Following earlier notions of formal causality by Halpern and Pearl [15], Salimi et al. [27] proposed the causal effect: assuming endogenous facts are randomly removed independently and uniformly, what is the difference in the expected query answer between assuming the presence and the absence of \( f \)? A recent framework has proposed to adopt the Shapley value to the task [20].

Different Farmer facts may have different Shapley values, depending on how crucial they are to the query—which products they export, whether they grow in the destination countries, and whether alternative Farmer facts export the same products. Similarly, each Grows\((c, p)\) fact has its Shapley value. However, while the Shapley value of Farmer facts can be either positive or zero (since they can only help in satisfying the query), the Shapley value of Grows facts can be either negative or zero (since they can only help in violating the query). As explained by Livshits et al. [20], understanding the complexity of the Shapley value for Boolean queries such as (1) is also necessary and sufficient for underestimating the complexity of the Shapley value for aggregate queries such as

\[
\text{Count}\{c \mid \text{Farmer}(m), \text{Export}(m, p, c), \neg\text{Grows}(c, p)\}
\]

that counts the countries that import one or more products that they do not grow.

As in previous work on quantification of contribution of facts [20, 23, 27], we view the database as consisting of two types of facts: endogenous facts and exogenous facts. Exogenous facts are taken as given (e.g., inherited from external sources) without questioning,
and are beyond experimentation with hypothetical or counterfactual scenarios. On the other hand, we may have control over the endogenous facts, and these are the facts for which we reason about existence and marginal contribution. The exogenous and endogenous facts are analogous to the observations and hypotheses in the study of abductive diagnosis [10, 11] that we refer to later on. In our context, the Shapley value considers only the endogenous facts as players in the cooperative game.

Livshits et al. [20] have studied the complexity of computing the Shapley value, and their work is restricted to positive CQs and UCQs (and aggregates thereof). In this paper, we study the impact of negation on this complexity. Negation transforms the query into a non-monotonic query and, as the reader might expect, the impact is fundamental. As a first step, we generalize their dichotomy in the complexity for CQs without self-joins into the class of CQs with negation and without self-joins (Theorem 3.1).

The dichotomy of Livshits et al. [20] classifies the CQs precisely as in CQ inference in probabilistic tuple-independent databases [8]: if the CQ is hierarchical, then the problem is solvable in polynomial time, and otherwise, it is #P-hard, complete (i.e., complete for the intractable class of polynomial-time algorithms with an oracle to, e.g., a counter of the satisfying assignments of a propositional formula). For illustration, the CQ of (1) falls on the hardness side. However, that classification does not take into account the assumption that some relations may contain only exogenous data. For example, in (1) we might consider the Grow relation as consisting of only exogenous information. This assumption is very significant, as it makes our example CQ a tractable one for the Shapley value, in contrast to the dichotomy. In this paper, we establish a dichotomy that accounts for both negation and exogenous relations (Theorem 3.3).

An approximation of the Shapley value of a database fact $f$ to a Boolean query can be computed via a straightforward Monte-Carlo (average-over-samples) estimation of the expectation that Shapley defines. This estimation guarantees an additive (or absolute) approximation. However, our interest is in a multiplicative (or relative) approximation, for two main reasons. First, we seek to understand the contribution of $f$ relative to other facts, even if it is the case that the Shapley value is small. Second, in order to get an approximation of the contribution of a fact to an aggregate query, a multiplicative approximation is required [20].

In the case of a UCQ, a multiplicative approximation of the Shapley value is tractable, that is, there is a multiplicative Fully Polynomial-Time Approximation Scheme (FPRAS). This holds true for a simple reason: an additive FPRAS is also a multiplicative FPRAS, due to the following gap property: if the Shapley value is nonzero, then it must be “large”—at least the reciprocal of a polynomial. Nevertheless, once the CQ includes negated atoms, the gap property is no longer true. In fact, we show in Theorem 5.1 that every natural CQ with negation violates the gap property, since the Shapley value can be exponentially small. This phenomenon explains why negated atoms make the Shapley value fundamentally more challenging to approximate.

In itself, the violation of the gap property shows that the approach of an additive FPRAS fails to provide a multiplicative FPRAS. Yet, it does not show that multiplicative FPRAS is computationally hard, since there might be an alternative way of obtaining a multiplicative FPRAS in polynomial time. In order to prove hardness of approximation, we investigate the problem of determining whether a fact $f$ is relevant to a query in the following sense: in the presence of all exogenous facts and some subset of the endogenous facts, adding $f$ can change the query answer (from false to true or from true to false). In the case of a positive CQ, being relevant to the query coincides with being an “actual cause” in the framework of causal responsibility [23]. It is also similar to being a relevant hypothesis in the context of abductive diagnosis [6, 10, 11]. We refer the reader to Bertossi and Salimi [4] who have established the connection between causal responsibility and abductive diagnosis.

The connection between the relevance to the query and the Shapley value is direct: if a fact $f$ is polarity consistent in the sense that it occurs in a relation of only positive or only negative atoms, then $f$ is relevant if and only if its Shapley value is nonzero (i.e., strictly positive or strictly negative). Therefore, a multiplicative FPRAS can decide on the relevance with high probability. In the contrapositive, if we prove that the relevance to the query is an intractable decision problem, then we also establish the intractability of an FPRAS approximation. Yet, the relevance is tractable for positive CQs, and hardness results are known only for Datalog programs with recursion [4, 11]. We prove here the existence of a CQ and a polarity-consistent fact $f$ such that the decision of relevance to the query (and, hence, the multiplicative approximation of the Shapley value) is intractable.

Nevertheless, the above approach for proving hardness of the multiplicative FPRAS of the Shapley value fails if we assume that the CQ itself is polarity consistent, that is, every relation symbol (and not just the one of $f$) occurs either only positively or only negatively. We prove that the relevance problem is solvable in polynomial time for polarity-consistent CQs. The question of whether the Shapley value has a multiplicative FPRAS for polarity-consistent CQs (and in particular CQs without self-joins) remains an open problem for future investigation.

We also consider the relevance problem for UCQs with negation. We prove that the tractability of the relevance problem generalizes to polarity-consistent UCQs. Nevertheless, the tractability does not generalize to unions of polarity-consistent CQs—we show the existence of such a UCQ where the relevance problem is intractable, and so is the Shapley zeroness (and multiplicative approximation). In other words, if every relation symbol occurs either only positively or only negatively in a UCQ, then the relevance problem is solvable in polynomial time. Yet, the assumption that this consistency holds just in every individual disjunct is (provably) not enough.

The rest of the paper is organized as follows. In the next section we introduce some basic terminology that will be used throughout the paper. In Section 3, we study the complexity of computing the Shapley value for self-join-free CQs with negation, and in Section 4 we explore the impact of exogenous relations on this complexity. We consider the approximate computation of the value in Section 5. We summarize our results and discuss directions for future work in Section 6. For lack of space, some proofs appear in the Appendix.
2 PRELIMINARIES

We first define the main concepts that we use throughout the paper.

Databases and Queries

A relational schema $S$ is a finite collection of relation symbols $R(A_1, \ldots, A_k)$, where each $A_i$ is an attribute of $R$, and $k$ is the arity of $R$, denoted by $\text{arity}(R)$. We assume a countably infinite set \( \text{Const} \) of constants that are used as database values. A database $D$ over a schema $S$ associates with each relation symbol $R$ in $S$ a finite relation $R^D \subseteq \text{Const}^{\text{arity}(R)}$. If $(c_1, \ldots, c_k)$ is a tuple in $R^D$, then we refer to $R(c_1, \ldots, c_k)$ as a fact of $D$. We then identify a database $D$ by the set of its facts. We assume that a database $D$ consists of two disjoint subsets of facts: the set $D_\text{x}$ of exogenous facts and the set $D_n$ of endogenous facts. Hence, we have $D = D_\text{x} \cup D_n$.

Example 2.1. The database of our running example is depicted in Figure 1. The relations STUD and TA store the names of graduate students and teaching assistants in the university, respectively. The relation COURSE contains information about courses given in different semesters. The relation REG associates graduate students with the courses they take, and the relation ADV associates students with their academic advisor. For example, Adam is a student and a teaching assistant in the university. He is registered to two courses—OS is given in the Electrical Engineering faculty and AI in the Computer Science faculty. Michael is the academic advisor of Adam. □

A Boolean conjunctive query over a schema $S$ is an expression of the form:

$q() \models R_1(\vec{t}_1), \ldots, R_n(\vec{t}_n)$

where each $R_i$ is a relation symbol of $S$ and each $\vec{t}_i$ is a tuple of variables and constants (where the arity of $\vec{t}_i$ matches that of $R_i$). We refer to a Boolean conjunctive query simply as a CQ. We refer to each $R_i(\vec{t}_i)$ as an atom of $q$. We denote by $R_a$ the relation corresponding to the atom $a$ of $q$. A self-join in a CQ $q$ is a pair of distinct atoms of $q$ over the same relation symbol. If $q$ does not contain any self-joins, then we say that $q$ is self-join-free. A homomorphism from $q$ to $D$ is a mapping of the variables in $q$ to the constants of $D$ such that every atom in $q$ is mapped to a fact of $D$. We denote by $D \models q$ the fact that $D$ satisfies $q$ (i.e., there is a homomorphism from $q$ to $D$) and by $D \not\models q$ the fact that $D$ violates $q$ (i.e., there is no such homomorphism).

Let $q$ be a CQ. For every variable $x$ of $q$, we denote by $A_x$ the set of all atoms $R_i(\vec{t}_i)$ of $q$ such that $x$ occurs in $\vec{t}_i$. We say that $q$ is hierarchical [7] if at least one of the following holds for all variables $x$ and $y$ of $q$: (1) $A_x \subseteq A_y$, (2) $A_y \subseteq A_x$, or (3) $A_x \cap A_y = \emptyset$. It is known [8] that if $q$ is not hierarchical, then there exist three atoms $\alpha_x$, $\alpha_y$, and $\alpha_{x,y}$ in $q$ such that the variable $x$ occurs in $\alpha_x$ but not in $\alpha_y$, the variable $y$ occurs in $\alpha_y$ but not in $\alpha_x$ and both variables occur in $\alpha_{x,y}$. We refer to each such triplet of atoms as a non-hierarchical triple of $q$.

A CQ with safe negation, or CQ$^\neg$ for short, has the form

$q() \models R_1(\vec{t}_1), \ldots, R_n(\vec{t}_n), \neg R'_1(\vec{t}'_1), \ldots, \neg R'_m(\vec{t}'_m)$

where every variable that occurs in a negated atom also occurs in an atom without negation. We refer to the atoms of $q$ appearing without negation as the positive atoms of $q$ and to the atoms that appear with negation as the negative atoms of $q$. We denote by $\text{Pos}(q)$ and $\text{Neg}(q)$ the sets of positive and negative atoms of $q$, respectively. For a CQ$^\neg$, we denote by $D \models q$ the fact that there is a homomorphism mapping variables of $q$ to constants of $D$ such that every positive atom and none of the negative atoms of $q$ is mapped to a fact of $D$. The extension to the definition of hierarchical CQs to CQ$^\neg$’s is straightforward.

Example 2.2. We use the following queries in our examples:

$q_1() \models \text{STUD}(x), \neg \text{TA}(x), \text{Reg}(x, y)$
$q_2() \models \text{STUD}(x), \neg \text{TA}(x), \text{Reg}(x, y), \neg \text{Course}(y, \text{CS})$
$q_3() \models \text{ADV}(x, y), \text{ADV}(x, z), \neg \text{TA}(y), \neg \text{TA}(z), \text{Reg}(y, \text{IC}), \text{Reg}(z, \text{DB})$
$q_4() \models \text{ADV}(x, y), \text{ADV}(x, z), \text{TA}(y), \neg \text{TA}(z), \text{Reg}(z, w), \neg \text{Reg}(y, w)$

Each of these queries is a CQ$^\neg$. The queries $q_1$ and $q_2$ are self-join-free, while the queries $q_3$ and $q_4$ have self-joins (e.g., the relation ADV occurs twice). The query $q_1$ is hierarchical since $A_y \subseteq A_x$, but the others are not, since each of them contains a non-hierarchical triplet (e.g., $\text{ADV}(x, y), \text{ADV}(x, z), \neg \text{TA}(z)$).

A Union of Conjunctive Queries (UCQ) is an expression of the form $q() \models q_1() \lor \cdots \lor q_t()$ where each $q_i$ is a CQ, and it is satisfied by a database $D$ if $D \models q_i$ for at least one $i \in \{1, \ldots, n\}$. A union of CQ$^\neg$’s is called a UCQ$^\neg$ for short.

The Shapley Value

Given a set $A$ of players, a cooperative game is a function $v: \mathcal{P}(A) \to \mathbb{R}$ that maps every subset $B$ of $A$ to a rational number $v(B)$, such that $v(\emptyset) = 0$. The value $v(B)$ represents a value jointly obtained by the players of $B$ when they cooperate. The Shapley value [29] measures the share of each player $a \in A$ in the value $v(A)$ jointly obtained by all players. Intuitively, the Shapley value is the expected contribution of $a$ in a random permutation of the players, where the contribution of $a$ is the change of $v$ due to the addition of $a$. More formally, the Shapley value is defined as

$$
\text{Shapley}(A, v, a) := \frac{1}{|A|!} \sum_{\pi \in \Pi_A} (v(\pi(A \cup \{a\})) - v(\pi(A)))
$$

where $\Pi_A$ is the set of all possible permutations of the players in $A$, and for each permutation $\pi$, we denote by $\sigma(a)$ the set of players that appear before $a$ in the permutation.

Let $S$ be a schema, $D$ a database over $S$, $q$ a CQ or CQ$^\neg$, and $f$ an endogenous fact of $D$. Following Livshits et al. [20], the Shapley value of $f$ w.r.t. $q$, denoted Shapley($D, q, f$), is the value of Shapley($A, v, a$) where:

- $A = D_n$,
- $v(E) = q(E \cup D_x) - q(D_x)$ for all $E \subseteq D_n$,
- $a = f$.

That is, we consider a cooperative game where the endogenous facts are the players and the wealth function $v(E)$ measures the change to the result of the query due to the addition of the facts of $E$ to the exogenous facts. Here, we view a Boolean CQ $q$ as a numerical query such that $q(D) = 1$ if $D \models q$ and $q(D) = 0$ otherwise.

Example 2.3. Consider again the database of our running example. We assume that all the facts in STUD, COURSE and ADV are
We elaborate on these calculations in the Appendix. Note that the sum over the Shapley values of all the endogenous facts is 1.

3 EXACT EVALUATION

In this section, we investigate the complexity of computing the Shapley value for CQ*’s without self-joins, and establish the following dichotomy in the data complexity of the problem.

**Theorem 3.1.** Let $q$ be a CQ* without self-joins. If $q$ is hierarchical, then Shapley($D, q, f$) can be computed in polynomial time, given $D$ and $f$. Otherwise, its computation is FP$^P$-complete.³

For illustration, the theorem states that the Shapley value can be computed in polynomial time for the query $q_1$ of Example 2.2, but computing it for the query $q_2$ is FP$^P$-complete. Interestingly, the classification criteria is the same as the one for self-join-free CQs without negation [20]. Hence, the added negation does not change the complexity picture for the exact computation of the Shapley value. (However, as we will show later, the addition of negation has a significant impact on the approximate computation of the value.) Next, we discuss the proof of Theorem 3.1.

Livshits et al. [20] introduced an algorithm for computing the Shapley value for hierarchical self-join-free CQs. This algorithm relies on a reduction from the problem of computing the Shapley value to that of computing the number of subsets of size $k$ of $D_\alpha$ that, along with $D_\alpha$, satisfy $q$. We denote this problem as $\text{Sat}(D, q, k)$. As the reduction does not assume anything about $q$ other than the fact that it is a Boolean query, the same reduction applies to CQ*’s. Hence, it is only left to show that $\text{Sat}(D, q, k)$ can be computed in polynomial time for a hierarchical CQ*.

**Lemma 3.2.** Let $q$ be a hierarchical CQ* without self-joins. There is a polynomial-time algorithm for computing the number $\text{Sat}(D, q, k)$ of $k$-subsets $E$ of $D_\alpha$, such that $(D_\alpha \cup E) \models q$, given $D$ and $k$.

The algorithm CntSat [20] for computing $\text{Sat}(D, q, k)$ for self-join-free CQs without negation is a recursive algorithm that reduces the number of variables in the query with each recursive call, based on the hierarchical structure of the query. The treatment of the base case, when no variables occur in $q$, is the only part of the algorithm that does not apply to queries with negation, and we explain how it should be modified in the Appendix.

In the remainder of this section, we focus on the proof of the negative side of the theorem. We start by proving hardness for the four simplest non-hierarchical CQ*’s:

\[
\begin{align*}
\text{qrs}^*() &::= R(x), S(x, y), T(y) \\
\text{qrs}^*() &::= \neg R(x), S(x, y), \neg T(y) \\
\text{qrs}^*() &::= R(x), \neg \neg S(x, y), T(y) \\
\text{qrs}^*() &::= R(x), S(x, y), \neg T(y)
\end{align*}
\]

³Recall that FP$^P$ is the class of problems that can be solved in polynomial time with an oracle to a #P-complete problem.
The proof for $q_{\text{RST}}$ is given in [20]; hence, we show the following.

**Lemma 3.3.** If $q$ is one of $q_{\text{RS-T}}, q_{\text{R-ST}},$ or $q_{\text{RS-T}},$ then computing Shapley($D, q, f$) is $\text{FP}^{\text{#P}}$-complete.

**Proof. (Sketch)** The proof of the lemma for $q_{\text{RS-T}}$ and $q_{\text{R-ST}}$ is by a reduction from the problem of computing Shapley($D, q_{\text{RST}}, f$). We show that for every database $D$ and a fact $f \in D$ we have that Shapley($D, q_{\text{RST}}, f$) = $\lnot$Shapley($D, q_{\text{RS-T}}, f$), as $f$ changes the result of $q_{\text{RST}}$ in a permutation $\sigma$ from false to true if and only if $f$ changes the result of $q_{\text{RS-T}}$ in $\sigma^R$ (which is the reverse permutation of $\sigma$) from true to false. As for the query $q_{\text{R-ST}},$ the idea is the following. Given an input database $D$ to the first problem, we construct a database $D'$ to our problem by taking the "complement" of the relation $S^D$. That is, we add a fact $f$ over the relation $S^D$ if and only if this fact is not in $S^D$. This transformation does not affect the Shapley value since we can assume that every fact of $S$ is exogenous (as the database constructed in the proof of hardness for $q_{\text{RST}}$ satisfies this property [20]). We will use this idea of the "complement" of a relation in our proofs in the next sections.

Most intricate is the proof of hardness for the query $q_{\text{RS-T}}$. This is due to its non-symmetrical structure that prevents us from constructing a direct reduction from the problem of computing Shapley($D, q_{\text{RST}}, f$). Similarly to the proof of hardness for $q_{\text{RST}}$ [20], we construct a reduction from the problem of computing the number of independent sets $|S(g)|$ in a bipartite graph $g$, which is known to be $\text{#P}$-complete. Given an input bipartite graph $g = (A \cup B, E)$, we construct $n + 1$ input instances $(D_i, f)$ for our problem (where $n = |A| + |B|$), that provide us with an independent system of $n + 1$ linear equations over the numbers $|S(g, k)|$, defined as follows.

For each $k = 0, \ldots, n$, the set $S(g, k)$ contains every subset $E \subseteq (A \cup B)$ of size $k$, such that for every $a \in (E \cap A)$, and for every $(a, b) \in E$, we have that $b \in E$; that is, for every vertex $a$ on the left-hand side of $g$ added to $E$, we also add to $E$ every neighbor of $a$ in the graph. More formally,

$$S(g) := \{A' \cup B'| A' \subseteq A, B' \subseteq B, \forall (a, b) \in E[a \in A' \Rightarrow b \in B']\}$$

Note that a subset $A' \cup B'$ in $S(g)$ may contain vertices in $B'$ that are not connected to any vertex in $A'$. Then, we denote by $S(g, k)$ the collection of subsets of size $k$ in $S(g)$. We claim that $|S(g)| = |S(g)|$. This holds since a subset $A' \cup B'$ of vertices of $g$ is an independent set if and only if the subset $A' \cup (B \setminus B')$ belongs to $S(g)$.

Each input instance $(D_i, f)$ to our problem is obtained from the bipartite graph $g$ by adding one vertex to the right-hand side of $g$ and $i$ vertices to its left-hand side. We connect every new vertex on the right-hand side to the new vertex on the left-hand side. Then, we add to $D_i$ an endogenous fact $R(a)$ for every vertex $a$ on the left-hand side of $g$, an endogenous fact $T(b)$ for every vertex $b$ on the right-hand side of $g$, and an exogenous fact $S(a, b)$ for every edge $(a, b) \in g$. We then compute, for each one of the instances, the Shapley value of the fact corresponding to the new vertex on the right-hand side of $g$, and obtain an equation over the numbers $|S(g, k)|$. We show that the equations are independent; hence, we can compute $|S(g)| = \sum_{k=0}^n |S(g, k)|$.

Using Lemma 3.3, we can prove the whole hardness side of Theorem 3.1. We adapt the reduction to the one used for the case of non-hierarchical self-join-free CQs without negation [20]. Recall that every non-hierarchical self-join-free CQ $\alpha$ contains three atoms $\alpha_x, \alpha_y, \alpha_{x,y}$ such that $x$ and $y$ are two variables of $q$, the variable $x$ occurs in $\alpha_x$ while $y$ does not, the variable $y$ occurs in $\alpha_y$ while $x$ does not, and both variables occur in $\alpha_{x,y}$. Furthermore, since $q$ is safe, we can always choose $\alpha_x, \alpha_y, \alpha_{x,y}$ such that if two of the atoms are negative, the negative ones are $\alpha_x$ and $\alpha_y$. Hence, for every such $q$, we can construct a reduction from computing the Shapley value for one of the queries $q_{\text{RST}}, q_{\text{RS-T}}, q_{\text{R-ST}}$ or $q_{\text{RS-T}}$ (depending on the polarity of $\alpha_x, \alpha_y$, and $\alpha_{x,y}$) to computing Shapley($D, q, f$), where the atoms over the relations $R$, $S$, and $T$ are represented by the atoms $\alpha_x, \alpha_y, \alpha_{x,y}$, respectively.

**Remarks.** We conclude the section with two comments. First, Livshits et al. [20] have shown how their dichotomy for CQs can be extended to arbitrary summations over CQs, using the linearity of expectation. Our dichotomy here can be extended to aggregate functions over CQs in a similar way. For example, Theorem 3.1 implies that the Shapley value of a fact can be efficiently computed for the following aggregate query that sums up all the profits $r$ of exports of products $p$ to countries $c$ where $p$ does not grow:

$$\text{Sum}([r \mid \text{Export}(p, c), \neg \text{Grows}(c, p), \text{Profit}(p, c, r)])$$

Second, the proof of Theorem 3.1 heavily relies on the assumption that the query is self-join-free. However, our hardness results for the basic non-hierarchical queries $q_{\text{RST}}, q_{\text{RS-T}}, q_{\text{R-ST}}$ and $q_{\text{RS-T}}$ can be generalized to certain CQs with self-joins, by replacing the atom over the relation $T$ with another atom over the relation $R$ (e.g., we can prove hardness for the query $\neg R(x), S(x, y), \neg R(y)$). This can be proved using a reduction from the corresponding self-join-free query (e.g., the query $\neg R(x), S(x, y), \neg T(y)$) by assuming, without loss of generality, that the values in the domain of $R$ and the values in the domain of $T$ are disjoint. In fact, this result can be generalized to a larger class of CQs with self-joins, and we give this result in the Appendix (Theorem B.5).

### 4 ACCOUNTING FOR EXOGENOUS RELATIONS

In the previous section, we showed that computing the Shapley value is FP$^{\text{#P}}$-complete for every non-hierarchical self-join-free CQ $\alpha$. Yet, this hardness result does not take into account the reasonable assumption that some of the relations in the database contain only exogenous facts. For example, Meliou et al. [23] discussed the case where all the relations in the database are exogenous, except for one (e.g., “Director” or “Movie”); this one relation may be a suspect of containing erroneous data, or the one that holds the single type of entities of whom contribution we wish to quantify. In this section, we show that accounting for such relations significantly changes the complexity picture and, in particular, it makes some of the tractable queries according to Theorem 3.1 tractable. In fact, we generalize Theorem 3.1 to account for exogenous relations and therefore establish the precise class of CQs that become tractable. Throughout this section, we underline the relations containing only exogenous facts and their associated query atoms.

**Example 4.1.** Livshits et al. [20] demonstrated their work on a database from the domain of academic publications. They reasoned about the contribution of researchers to the total number of
citations and assumed that the information about the publications is exogenous. In particular, they considered the query:

\[ q() : \text{Author}(x, y), \text{Pub}(x, z), \text{Citations}(z, w) \]

Since \( q \) is not hierarchical, their result classifies it as intractable. However, in this section, we show that there is a polynomial-time algorithm for computing the Shapley value for \( q_2 \) under the assumption that \( \text{Pub} \) and \( \text{Citations} \) contain only exogenous facts. Furthermore, we show that even if we had that prior knowledge about the relation \( \text{Citations} \) alone, we would still able to compute the Shapley value efficiently. This is due to the fact that we can reduce the problem of computing Shapley(\( D, q, f \)) to that of computing Shapley(\( D, q', f \)) for the hierarchical query \( q'(x) : \text{Author}(x, y), \text{Pub}(x, z) \), by removing the relation \( \text{Pub} \) in \( D \) every fact \( \text{Pub}(a, b) \) such that there is no fact \( \text{Citations}(b, c) \) in \( D \) and then removing the relation \( \text{Citations} \) from the query.

Next, consider the database of our running example (Figure 1). We have assumed that the information about the students and courses in the faculty is exogenous, and our goal was to understand how much the fact that a student takes or teaches a course affects the result of different queries. For example, consider again the query \( q_2 \) from Example 2.2.

\[ q_2() : \text{Stud}(x), \neg \text{TAt}(x), \text{Reg}(x, y), \neg \text{Course}(y, CS) \]

Theorem 3.1 classifies this query as intractable for computing the Shapley value, as it is not hierarchical. Yet, again, the Shapley value can be computed in polynomial time, using an algorithm that takes into consideration the assumption that every fact in \( \text{Stud} \) and \( \text{Course} \) is exogenous. Note that when negation is added to the picture, we cannot simply remove exogenous atoms, as removing an exogenous atom may turn a query with safe negation into a query with negation that is not safe (e.g., \( q'(x) = R(x), \neg S(x, y), T(y) \)).

4.1 Generalized Dichotomy

We start by formally defining the problem that we study in this section. We define an exogenous relation \( R \) to be a relation that consists only of exogenous facts. We fix a schema \( S \), a set \( X \) of exogenous relations in \( S \), and a self-join-free CQ \( q \). We denote by \( S_X \) a schema with the set \( X \) of exogenous relations. Note that we do not assume anything about the facts in the relations outside \( X \) and they may contain both endogenous and exogenous facts. Then, our goal is to compute Shapley(\( D, q, f \)), given a database \( D \) over \( S_X \) and a fact \( f \in D \).

Clearly, the assumption that some of the relations of \( S \) are exogenous does not change the fact that we can compute the Shapley value in polynomial time for any hierarchical CQ. To understand the impact of this assumption on the complexity of non-hierarchical CQs, consider the query \( q_{R-ST} \) defined in Section 3. If we assume that only \( S \) is exogenous, then the query remains hard, as \( S \) already contains only exogenous facts in the proof of hardness for \( q_{R-ST} \) (Lemma 3.3). We can generalize this example and show that having a non-hierarchical triplet \( (\alpha_x, \alpha_y, \alpha_y) \) where \( R_{\alpha_x} \notin X \) and \( R_{\alpha_y} \notin X \) is a sufficient condition for \( \text{FP}^{\text{NP}} \)-hardness, as the hardness proofs of the previous section can be easily generalized to this case. Is having such a triplet a necessary condition for hardness? Next, we answer this question negatively. Consider Figure 2: The Gaifman graphs of the queries \( q \) (left) and \( q' \) (right) of Example 4.2.

\[
q() : \neg R(x, w), S(z, x), \neg P(z, w), T(y, w)
\]
\[
q'(x) : \neg R(x, w), S(z, x), \neg P(z, y), T(y, w)
\]

In both queries, the exogenous relation are \( S \) and \( P \), and they differ only in one variable that occurs in the atom of \( P \). While the two queries are very similar and are both classified as intractable by Theorem 3.1, we will show that in the model considered in this section, Shapley(\( D, q, f \)) can be computed in polynomial time for every endogenous fact \( f \), while computing Shapley(\( D, q', f \)) is \( \text{FP}^{\text{NP}} \)-complete. This holds true as while in both cases the non-exogenous atoms are connected via the exogenous atoms, they are connected in different ways. While the connection in \( q \) between the variable \( x \) in \( \neg R(x, w) \) and the variable \( y \) in \( T(y, w) \) goes through the variable \( w \) in \( q' \) the connection between \( x \) and \( y \) is possible through the variable \( z \) as well, and we need to be able to distinguish between these two cases. In the terminology we set next, we say that \( x \) and \( y \) are connected via a non-hierarchical path in \( q' \) (but not in \( q \)).

Let \( S_X \) be a schema. The Gaifman graph \( G(q) \) of a CQ \( q \) is the graph that contains a vertex for every variable in \( q \) and an edge between two vertices if the corresponding variables occur together in an atom of \( q \). We say that a CQ \( q \) has a non-hierarchical path if there are two atoms \( \alpha_x, \alpha_y \) and two variables \( x, y \) in \( q \) such that: (1) \( R_{\alpha_x} \notin X \) and \( R_{\alpha_y} \notin X \), (2) the variable \( x \) occurs in \( \alpha_x \) but not in \( \alpha_y \), while the variable \( y \) occurs in \( \alpha_y \) and not in \( \alpha_x \), and (3) the graph obtained from \( G(q) \) by removing every vertex corresponding to a variable occurring in \( \alpha_x \) or in \( \alpha_y \) contains a path between \( x \) and \( y \). In this case, we say that the non-hierarchical path of \( q \) is induced by the atoms \( \alpha_x \) and \( \alpha_y \).

Example 4.2. Consider the query:

\[
q() : \neg R(x, v), Q(x, v), S(x, z), U(z, w), \neg P(w, y), T(y, v)
\]

The Gaifman graph \( G(q) \) is illustrated in Figure 2a. We claim that \( q \) has a non-hierarchical path induced by the atoms \( \neg R(x) \) and \( T(y, v) \). Note that there is a path \( x \rightarrow v \rightarrow y \) in \( G(q) \) between \( x \) and \( y \); however, this is not enough to determine that \( q \) has a non-hierarchical path, as we need to find a path that does not pass through the variables of \( \neg R(x) \) and \( T(y, v) \). And indeed, if we remove from \( G(q) \) the variable \( v \) occurring in the atom \( T(y, v) \) and every edge connected to it (i.e., every dotted line in the graph of Figure 2a), there is a path \( x \rightarrow z \rightarrow w \rightarrow y \) between the variables \( x \) and \( y \) in the resulting graph, and we conclude that \( q \) has a non-hierarchical path.
Next, consider the query:

\[ q'(t) := U(t, r), \neg T(y), Q(y, w), -V(t), R(x, y), -S(x, z), O(z), P(u, y, w) \]

The reader can easily verify, using the graph of Figure 2b, that \( q' \) does not have a non-hierarchical path. This is because the variables of \( U(t, r) \) and the variables of \( \neg T(y) \) or \( Q(y, w) \) are not connected in \( \mathcal{G}(q') \). Moreover, every variable in \( \neg T(y) \) also appears in \( Q(y, w) \); hence, no non-hierarchical path can be induced by these two atoms.

We prove the following generalization of Theorem 3.1 that accounts for exogenous relations.

**Theorem 4.3.** Let \( S_X \) be a schema and let \( q \) be a CQ* without self-joins. If \( q \) has a non-hierarchical path, then computing Shapley\((D, q, f)\) is \( \mathcal{P}^{\text{NP}} \)-complete. Otherwise, Shapley\((D, q, f)\) can be computed in polynomial time, given \( D \) and \( f \).

The proof of the hardness side of Theorem 4.3 is very similar to the proof of hardness for Theorem 3.1. Given a self-join-free CQ* that has a non-hierarchical path, we construct a reduction from the problem of computing Shapley\((D, q', f)\) where \( q' \) is one of \( q_{\text{ST}}, q_{\text{SST}}, q_{\text{STT}}, \) or \( q_{\text{SSTT}} \) to that of computing Shapley\((D, q, f)\). The main difference between the proofs is that in the proof of Theorem 3.1 we used the atom \( \alpha \) to represent the atom \( S(x, y) \) in \( q' \), whereas we use the whole non-hierarchical path (or, more precisely, the atoms along the edges of the non-hierarchical path) to represent this atom. The atoms inducing the non-hierarchical path are used to represent the atoms over the relations \( R \) and \( T \) in \( q' \), and their polarity determines the specific \( q' \) we reduce from. (The full proof is in the Appendix.) In the remainder of this section, we discuss the proof of the positive side of Theorem 4.3.

### 4.2 Algorithm for the Tractable Cases

We will show that computing the Shapley value for a self-join-free CQ* that does not have a non-hierarchical path can be reduced to computing the Shapley value for a hierarchical query \( q' \) without self-joins. Our reduction consists of three steps that will form the basis to our algorithm. Since the Shapley value can be computed in polynomial time for hierarchical CQ*s (Theorem 3.1), and the same algorithm works for the model that we consider in this section, we will conclude that the Shapley value can be computed in polynomial time for such queries.

For the remainder of this section, we fix a schema \( S_X \) and a self-join-free CQ* \( q \) that does not have a non-hierarchical path. We first introduce some definitions and notations that we will use throughout the proof. We denote by \( \text{Atoms}(q) \) and \( \text{Vars}(q) \) the sets of atoms and variables of \( q \), respectively. We say that an atom \( a \) of \( q \) is an exogenous atom if \( R_a \in X \). We say that a variable \( x \) of \( q \) is an exogenous variable if it occurs only in exogenous atoms of \( q \). We denote the set of all exogenous variables and variables of \( q \) by \( \text{Atoms}_{\text{ex}}(q) \) and \( \text{Vars}_{\text{ex}}(q) \), respectively. We denote by \( \text{Atoms}_{\text{ex}}(q) \) the set \( \text{Atoms}(q) \setminus \text{Atoms}_{\text{ex}}(q) \) of non-exogenous atoms in \( q \) and by \( \text{Vars}_{\text{ex}}(q) \) the set \( \text{Vars}(q) \setminus \text{Vars}_{\text{ex}}(q) \) of non-exogenous variables.

Next, we define the exogenous atom graph \( g_{e}(q) \) of \( q \) to be the graph that contains a vertex for every exogenous atom in \( q \) and an edge between two vertices if the corresponding two atoms share an exogenous variable. The following lemma draws a connection between the properties of \( g_{e}(q) \) and the existence of a non-hierarchical path in \( \mathcal{G}(q) \). In particular, we prove that if a query \( q \) does not have a non-hierarchical path, then for every connected component \( C \) of \( g_{e}(q) \) there is a non-exogenous atom \( \alpha \) of \( q \) such that \( \text{Vars}_{\text{ex}}(C) \subseteq \text{Vars}(\alpha) \). This property is of high significance, as our reduction strongly relies on it.

**Lemma 4.4.** For every connected component \( C \) of \( g_{e}(q) \) there is an atom \( \alpha \in \text{Atoms}_{\text{ex}}(q) \) such that \( \text{Vars}_{\text{ex}}(C) \subseteq \text{Vars}(\alpha) \).

**Proof.** Let \( C \) be a connected component of \( g_{e}(q) \). Assume, by way of contradiction, that there is no \( \alpha \in \text{Atoms}_{\text{ex}}(q) \) such that \( \text{Vars}_{\text{ex}}(C) \subseteq \text{Vars}(\alpha) \), and let \( \alpha \in \text{Atoms}_{\text{ex}}(q) \) be an atom of \( q \) such that \( \text{Vars}_{\text{ex}}(C) \cap \text{Vars}(\alpha) \) is maximal among all atoms in \( \text{Atoms}_{\text{ex}}(q) \).

Since \( \text{Vars}_{\text{ex}}(C) \neq \emptyset \) and every non-exogenous variable occurs in a non-exogenous atom, there exists \( x \in (\text{Vars}_{\text{ex}}(C) \cap \text{Vars}(\alpha)) \). Moreover, since \( \text{Vars}_{\text{ex}}(C) \not\subseteq \text{Vars}(\alpha) \), there exists \( y \in \text{Vars}_{\text{ex}}(C) \) that does not occur in \( \alpha \). Since \( y \) is not an exogenous variable, there is another \( \alpha' \in \text{Atoms}_{\text{ex}}(q) \) such that \( y \in \text{Vars}(\alpha') \). It cannot be the case that \( x \in \text{Vars}(\alpha') \) (as otherwise, we get a contradiction to the maximality of \( \text{Vars}_{\text{ex}}(C) \cap \text{Vars}(\alpha) \)); hence, we conclude that \( x \in (\text{Vars}(\alpha) \setminus \text{Vars}(\alpha')) \), \( y \in (\text{Vars}(\alpha') \setminus \text{Vars}(\alpha)) \), and \( x, y \in \text{Vars}(C) \).

We claim that \( \alpha \) and \( \alpha' \) induce a non-hierarchical path in \( \mathcal{G}(q) \).

Since \( x, y \in \text{Vars}(C) \), there exist two atoms \( \beta_1, \beta_2 \in C \) such that \( x \in \beta_1 \) and \( y \in \beta_1 \). Since \( \beta_1 \) and \( \beta_2 \) belong to the same connected component, there exists a path in \( g_{e}(q) \) between \( \beta_1 \) and \( \beta_2 \), such that the edges along the path correspond to exogenous variables of \( q \). Therefore, there is a path \( x - v_1 - \cdots - v_n - y \) in \( \mathcal{G}(q) \), such that each \( v_i \) is an exogenous variable (hence, \( v_i \notin \text{Vars}(\alpha) \) and \( v_i \notin \text{Vars}(\alpha') \)). This path is a non-hierarchical path by definition.

**Example 4.5.** Consider the query \( q' \) of Example 4.2. We have already established that \( q' \) does not have a non-hierarchical path. Figure 3a illustrates both the exogenous atom graph of \( q' \) and the result of Lemma 4.4. The atoms in the white rectangles are the exogenous atoms of \( q' \), and the atoms in the gray circles are the non-exogenous atoms. Every gray rectangle containing a set of exogenous atoms represents a connected component in \( g_{e}(q') \). For example, the atoms \( R(x, y) \) and \( \neg S(x, z) \) share the exogenous variable \( x \) and the atoms \( \neg S(x, z) \) and \( O(z) \) share the exogenous variable \( z \). Hence, all three atoms form a connected component \( C \) in the graph.

The only non-exogenous variable in \( C \) is \( y \) and, indeed, there is a non-exogenous atom \( \neg T(y) \) that uses \( y \). In fact, there are two such atoms, and in the next step we can arbitrary select one of them. The exogenous atom \( P(u, y, w) \) is a connected component on its own, as its only exogenous variable \( u \) does not occur in any other atom. And, again, there is a non-exogenous atom \( Q(y, w) \) that uses both non-exogenous variables \( y \) and \( u \) of \( P(u, y, w) \).

Next, we discuss the first step of our reduction. We prove that we can replace every connected component \( C \) of \( g_{e}(q) \) with a single exogenous atom in \( q \), obtained by “joining” all the atoms of \( C \) (and the corresponding relations of \( D \)), without affecting the Shapley value. Since some of the atoms in a connected component \( C \) may be negated, and it is not clear how to combine positive and negative atoms into a single atom, we first replace them with positive atoms.
and compute the complement of the corresponding relations. Formally, given a negated atom \( \alpha \), we denote by \( \overline{\alpha} \) the atom obtained from \( \alpha \) by removing the negation. Then, we denote by \( R_{\overline{\alpha}} \) the relation obtained from \( R_{\alpha} \) by adding every fact over the domain of \( D \) if and only if it does not appear in \( R_{\overline{\alpha}} \). That is, if the arity of \( R_{\alpha} \) is \( k \), then we add to \( R_{\overline{\alpha}} \) a fact \( R_{\alpha}(c_1, \ldots, c_k) \), where each \( c_i \) is a constant from the domain of \( D \), if and only if \( R_{\alpha}(c_1, \ldots, c_k) \notin R_{\overline{\alpha}} \). Hence, we obtain a query \( q' \) by replacing every negated exogenous atom \( \alpha \) of \( q \) with the atom \( \overline{\alpha} \), and we construct a database \( D' \) by replacing every exogenous relation \( R' \) corresponding to a negated atom of \( q \) with the complement relation \( R_{\overline{\alpha}} \). The same idea has been used in the proof of hardness for the query \( q_8 \) in the previous section (Lemma 3.3), and we prove that this transformation of the database and the query does not affect the Shapley value (i.e., \( \text{Shapley}(D, q, f) = \text{Shapley}(D', q', f) \) for every \( f \) ) in the Appendix. From now on, we assume that every exogenous atom of \( q \) is positive. We use that assumption to prove the following.

**Lemma 4.6.** Computing \( \text{Shapley}(D, q, f) \), given \( D \) and \( f \), can be efficiently reduced to computing \( \text{Shapley}(D', q', f) \) for a \( CQ^+ \) \( q' \) without self-joins such that: (1) every exogenous variable of \( q' \) occurs is a single atom, and (2) \( q' \) does not have any non-hierarchical path.

In the proof ofLemma 4.6, given in the Appendix, we show that we can combine all the atoms \( a_1, \ldots, a_n \) of a connected component \( C \) in \( q_8(q) \) into a single atom \( \alpha_C \) such that \( \text{Vars}(\alpha_C) = \bigcup_{\alpha_i \in \{a_1, \ldots, a_n\}} \text{Vars}(\alpha_i) \), while simultaneously replacing all the relations \( R_{a_1}, \ldots, R_{a_n} \) in \( D \) with a single relation \( R_{\alpha_C} \) obtained by joining the \( k \) relations according to the variables of the corresponding atoms, without affecting the Shapley value. We repeat this process with every connected component of \( q_8(q) \) and obtain a query \( q' \) satisfying the first property of Lemma 4.6. As for the second property, we show that the existence of a non-hierarchical path \( x - v_1 - \cdots - v_n - y \) in \( q' \) induced by the atoms \( \alpha_x \) and \( \alpha_y \) implies the existence of a non-hierarchical path in \( q \) induced by the same atoms, since every two consecutive variables \( v_i, v_{i+1} \) in the path either occur together in a non-exogenous atom of \( q \) or in a connected component of \( q_8(q) \).

One may suggest that it is possible to avoid replacing the negated exogenous atoms of \( q \) with positive atoms before combining exogenous atoms, by simply constructing the relation \( R_{\overline{\alpha}} \) in \( D \) using the query \( q_C(\overline{x}) : a_1, \ldots, a_k \), where \( a_1, \ldots, a_k \) are the original (possibly negated) atoms in the connected component \( C \), and \( \overline{x} \) contains every variable of \( C \). The problem with this approach is that the resulting \( q_C \) may have non-safe negation, as a non-exogenous variable of \( C \) may appear only in negated atoms of \( C \) (and in a positive atom outside \( C \)). Thus, it is essential to replace the relations corresponding to negated exogenous atoms of \( q \) with their complement relations, before combining the atoms of \( C \) into a single one.

**Example 4.7.** Consider again the query \( q' \) illustrated in Figure 3. Since the atom \( \neg S(x, z) \) in the topmost connected component \( \{R(x, y), \neg S(x, z), O(z)\} \) is negated, we first replace it with a positive atom \( S(x, z) \). Then, we combine all three atoms into a single atom \( R(x, y, z) \), as illustrated in Figure 3b, and replace these atoms in the query with the new atom. The new relation in the database will contain every answer to the query \( q_C(x, y, z) : R(x, y), S(x, z), O(z) \) on \( D \). Note that \( \neg V(t) \) is a connected component on its own, but we still replace it with a positive atom \( V(t) \).

Next, we use the results of Lemmas 4.4 and 4.6 to reduce the computation of \( \text{Shapley}(D, q, f) \) to the computation of \( \text{Shapley}(D', q', f) \) for a query \( q' \) where every exogenous atom corresponds to a non-exogenous atom such that the two have the exact same variables.

**Lemma 4.8.** Computing \( \text{Shapley}(D, q, f) \) can be efficiently reduced to computing \( \text{Shapley}(D', q', f) \) for a \( CQ^+ \) \( q' \) without self-joins such that: (1) for every \( \alpha \in \text{Atoms}_q(q') \) there exists \( \alpha' \in \text{Atoms}_{q}(q') \) for which \( \text{Vars}(\alpha) = \text{Vars}(\alpha') \), and (2) \( q' \) does not have any non-hierarchical path.

Recall that \( \text{Atoms}_q(q) \) and \( \text{Atoms}_k(q) \) are the sets of exogenous and non-exogenous atom in \( q \), respectively. To establish Lemma 4.4, we first observe that we can remove every exogenous variable from \( q \) without affecting the Shapley value, as Lemma 4.6 implies that we can assume that every exogenous variable occurs in a single exogenous atom. Then, Lemma 4.4 implies that for every exogenous atom \( \alpha \) there exists a non-exogenous atom \( \beta \) such that \( \text{Vars}(\alpha) \subseteq \text{Vars}(\beta) \). Hence, for each such \( \alpha \), we select such an atom \( \beta \) and replace the atom \( \alpha \) in \( q \) with the atom \( R_{\alpha'}(x_1, \ldots, x_n) \), where \( \{x_1, \ldots, x_n\} \) is the set of variables in \( \beta \). In the database, we replace the relation corresponding to the atom \( \alpha \) with a new relation \( R_{\alpha'} \) that
contains every fact obtained from the Cartesian product of: (1) the projection of \( R_D \) to the attributes corresponding to non-exogenous variables in \( \alpha \), and (2) every possible combination of \(|\text{Vars}(\beta)| - |\text{Vars}_0(\alpha)| \) values from the domain of \( D \). The fact that \( q' \) does not have a non-hierarchical path is rather straightforward based on the fact that every pair \( \{u_1, u_2\} \) of variables of \( q' \) occurring together in an atom of \( q' \) necessarily occur together in a non-exogenous atom of \( q \) that is also an atom of \( \alpha \).

Example 4.9. Figure 3c illustrates the implications of Lemma 4.8 on the query \( q' \) of Example 4.2. We replace the relation \( R(x, v, z) \) with the relation \( T'(v) \) obtained from it by removing the exogenous variables \( x \) and \( z \). As for the atom \( V(t) \), it does not contain any exogenous variables, but the non-exogenous atom \( U(t, r) \) containing all the variables of \( V(t) \) also uses the variable \( r \); hence, we add this variable and obtain a new atom \( U'(t, r) \).

Our final observation is that a query \( q' \) satisfying the properties of Lemma 4.8 is hierarchical. This holds true since \( \text{Atoms}_{\alpha}(q') \) does not contain a non-hierarchical triplet (otherwise, the original \( q \) would contain a non-hierarchical path). Adding an atom \( \alpha \) to a hierarchical query \( q \) such that \( \text{Vars}(\alpha) = \text{Vars}(\alpha') \) for some atom \( \alpha' \) in \( q \) cannot change the non-hierarchical structure of the query.

We summarize the section with the algorithm ExoShap\((D,q,f)\) (Algorithm 1) for computing the Shapley value for a self-join-free CQ\(^{\neg} \) that does not contain a non-hierarchical path. The algorithm starts by modifying \( q \) and \( D \) according to the steps described throughout this section. First, it replaces the negated exogenous atoms of \( q \) with positive atoms, and the corresponding relations in \( D \) with their complement relations. Then, it combines the exogenous atoms in every connected component of \( q \) into a single atom while joining the corresponding relations of \( D \). Finally, it removes the exogenous variables of \( q \), and adds to every exogenous atom the missing variables from the non-exogenous atom containing it. The final database is constructed from the Cartesian product of the projection of every exogenous relation \( R_D^{\neg} \) to the attributes corresponding to the non-exogenous variables of \( \alpha \), and the set \( \{c_1, \ldots, c_r \mid c_i \in \text{Dom}(D)\} \), where \( r \) is the number of non-exogenous variables we have added to \( \alpha \). Then, the algorithm invokes an algorithm for computing the Shapley value for hierarchical queries.

4.3 Application to Probabilistic Databases

We conclude by observing that our results in this section also apply to the problem of query evaluation over tuple-independent probabilistic databases [8]. Fink and Olteanu [12] have studied this problem for queries with negation. They considered the class RA\(^{-}\) of queries that includes the CQ\(^{-}\)s. When restricting to CQ\(^{-}\)s, they established that query evaluation is possible in polynomial time for hierarchical CQ\(^{-}\)s, and it is FP\(^{\text{PT}}\)-complete otherwise. The proofs of this section immediately provide a generalization of their result to account for deterministic relations, where the probability of every fact is 1. The only difference is that instead of using the algorithm for computing the Shapley value for hierarchical CQ\(^{-}\)s, we will use the algorithm for query evaluation over tuple-independent probabilistic databases for hierarchical CQ\(^{-}\)s. Hence, we obtain the following result (where \( X \) is the set of deterministic relations).

**Theorem 4.10.** Let \( S_X \) be a schema and let \( q \) be a CQ\(^{-}\) without self-joins. If \( q \) has a non-hierarchical path, then its evaluation over tuple-independent probabilistic databases is FP\(^{\text{PT}}\)-complete. Otherwise, the query can be evaluated in polynomial time.

5 APPROXIMATION

As seen in the previous sections, computing the exact Shapley value is often hard. Hence, in this section, we consider its approximate computation. There exists a Multiplicatively Fully-Polynomial Randomized Approximation Scheme (FPRAS) for computing the Shapley value for any CQ and, in fact, for any union of CQs [20]. Here, we show that the addition of negation changes the complexity picture completely. Recall that an FPRAS for a numeric function \( f \) is a randomized algorithm \( A(x, f, \delta) \), where \( x \) is an input for \( f \) and \( \epsilon, \delta \in (0, 1) \). The algorithm returns an \( \epsilon \)-approximation of \( f(x) \) with probability at least \( 1 - \delta \) in time polynomial in \( x, 1/\epsilon \) and \( \log(1/\delta) \). More formally, for an additive (or absolute) FPRAS we have that:

\[
\Pr[f(x) - \epsilon \leq A(x, f, \delta) \leq f(x) + \epsilon] \geq 1 - \delta.
\]

and for a multiplicative (or relative) FPRAS we have that:

\[
\Pr[f(x)/(1 + \epsilon) \leq A(x, f, \delta) \leq (1 + \epsilon)f(x)] \geq 1 - \delta.
\]

5.1 Additive vs. Multiplicative Approximation

We start by showing that there exists an additive FPRAS for computing the Shapley value for CQ\(^{-}\)s. The additive FPRAS for CQ\(^{-}\)s is a generalization of the additive FPRAS for CQs. We observe that when negated atoms are allowed along with self-joins, a fact \( f \) may change the query result from false to true in one permutation, while changing the query result from true to false in another permutation. For a random permutation \( \sigma \) of the facts in \( D_0 \), the result of \( q(D_0) \cup \sigma(f) \) is a random variable \( x \in \{1, 0, 1\} \). By using the Hoeffding bound for sums of independent random variables in bounded intervals [16], we get an additive FPRAS for computing Shapley\((D,q,f)\) by taking the average value of \( x \) over \( O(\log(1/\delta)/\epsilon^2) \) samples of random permutations.
For CQs, an additive FPRAS is also a multiplicative FPRAS [20]. This is due to the gap property: there exists a polynomial $p$ such that for all databases $D$ and facts $f \in D$ it holds that $\text{Shapley}(D, q, f)$ is either zero or at least $1/p(|D|)$. We will now show that this property does not hold when negation is added to the picture; hence, this approach for obtaining a multiplicative approximation of the Shapley value is no longer valid. As an example, consider the query

$$q() : R(x, y), \neg R(y)$$

and the database $D$ constructed as follows. For every $i \in \{0, \ldots, 2n\}$ we add to $D$ an exogenous fact $S(c_i^0, c_i^0)$. Moreover, for every $i \in \{1, \ldots, n\}$ we add to $D$ an exogenous fact $R(c_i^0)$ and an endogenous fact $R(c_i^n)$, and for every $i \in \{0, n+1, \ldots, 2n\}$ we add an endogenous fact $R(c_i^n)$. We will show that the fact $f = R(c_0^n)$ does not satisfy the gap property.

First, note that $D_x \models q$ since for every $i \in \{1, \ldots, n\}$, there is a homomorphism $h$ from $q$ to $D$, where $h(x) = c_i^0$ and $h(y) = c_i^n$. For the fact $f$ to change the query result from false to true, we first need to add all the endogenous facts of the form $R(c_i^n)$ in $D$ to a permutation. Moreover, the first endogenous fact of the form $R(c_i^n)$ will be added to the query resulting in the query result from false to true, and no fact could change it back to false; hence, the fact $f$ has to appear before all these facts in a permutation.

All in all, there is exactly one subset $E \subseteq D_n$, such that $(D_x \cup E) \models q$ and $(D_x \cup E \cup \{f\}) \models q$. We have that $|E| = n$ and $|D_n| = 2n + 1$; thus, we conclude the following.

$$|\text{Shapley}(D, q, f)| = \frac{n!n!}{(2n + 1)!} \leq 2^n = 2^{-\Theta(|D|)}$$

We can generalize this result and show that the gap property does not hold for any “natural” CQ with negation and without constants.

**Theorem 5.1.** Let $q$ be a satisfiable CQ with at least one negated atom. Assume that $q$ has no constants, and that $q$ is positively connected. There is a sequence $(D_n)_{n=1}^\infty$ of databases and a fact $f$ such that $|D_n| = \Theta(n)$ and $0 < |\text{Shapley}(D_n, q, f)| \leq 2^{-\Theta(n)}$.

Note that by “positively connected” we mean that the positive atoms of $q$ are connected (i.e., every two variables of $q$ are connected in the Gaifman graph through positive atoms). The proof of Theorem 5.1 is nontrivial and, as usual, we give it in the Appendix.

Theorem 5.1 implies that we need at least $2^{\Omega(|D|)}$ samples for a multiplicative approximation of the additive one. This does not mean that there is no multiplicative approximation for CQ$^-$'s; however, we will show that there are CQ$^-$'s for which a multiplicative approximation does not exist at all (under conventional complexity assumptions).

### 5.2 Hardness of Multiplicative Approximation

We now explore the complexity of computing a multiplicative approximation for the Shapley value through a connection to the problem of relevance to the query.

**Definition 5.2 (Relevance).** Let $q$ be a Boolean query and $D$ a database. A fact $f \in D_n$ is relevant to $q$ if $q(D_x \cup E) \neq q(D_x \cup E \cup \{f\})$ for some $E \subseteq D_n$; we then say that $f$ is positively (resp., negatively) relevant to $q$ if $q(D_x \cup E \cup \{f\})$ is true (resp., false).

This problem of determining whether a fact is relevant to a query is strongly related to the approximation problem, as we cannot obtain a multiplicative approximation in cases where we cannot decide if the Shapley value is zero or not. In turn, deciding on zeroeness is related to the relevance problem. Clearly, if Shapley$(D, q, f) \neq 0$, then $f$ is relevant to $q$. However, it may be the case that $f$ is relevant to $q$ but Shapley$(D, q, f) = 0$, as the following example shows.

**Example 5.3.** Consider the query $q() : R(x, y), \neg R(y, x)$ and the database $(\{R(1, 2), R(2, 1)\})$ where both facts are endogenous. The fact $R(1, 2)$ is positively relevant for $E = \emptyset$, and it is negatively relevant for $E = \{R(2, 1)\}$. Therefore, the number of permutations where $f$ changes the query result from false to true is equal to the number of permutations where $f$ changes the result from true to false and we have that Shapley$(D, q, f) = 0$.

Nevertheless, there are cases where the relevance problem coincides with the problem of deciding whether the Shapley value is zero. The Shapley value of a relevant fact $f$ can be zero if and only if $f$ is both positively and negatively relevant. This may be the case if and only if $f$ belongs to a relation that appears both as a positive and a negative atom in the query. We call a relation symbol polarity consistent if it appears in $q$ only in positive atoms or only in negative atoms. A fact over a polarity-consistent relation symbol is relevant to $q$ if and only if Shapley$(D, q, f) \neq 0$.

**Example 5.4.** Consider again the queries of our running example (Example 2.2). Clearly, in the queries $q_1$ and $q_2$, every relation is polarity consistent, as the queries are self-join-free. The same holds for the query $q_3$, as $\text{Adv}$ and $\text{Reg}$ occur only in positive atoms while $\text{TA}$ occurs only in negative atoms. The query $q_4$, on the other hand, contains both polarity-consistent relations (i.e., $\text{Adv}$) and relations that occur in both positive and negative atoms (i.e., $\text{TA}$ and $\text{Reg}$). In this case, a fact $f$ in the relation $\text{Adv}$ is relevant to $q_4$ if and only if Shapley$(D, q_4, f) > 0$. However, for a fact $f$ in $\text{TA}$ it may be the case that $f$ is relevant to $q_4$, while Shapley$(D, q_4, f) = 0$.

It is straightforward to show that the relevance to a CQ without negation can be decided in polynomial time. The problem is known to be NP-complete for Datalog programs with recursion [4]. We now show that there exists a CQ$^-$ $q$ containing a polarity-consistent relation $T$, such that the relevance of a $T$-fact to $q$ is NP-complete. (Hence, so is the problem of deciding if the Shapley value is zero.)

Consider the following CQ$^-$:

$$q_{\text{RST} \rightarrow R}() : T(z), \neg R(x), \neg R(y), R(z), R(w), S(x, y, z, w)$$

We prove the following.

**Proposition 5.5.** Deciding whether $f \in T^D$ is relevant to $q_{\text{RST} \rightarrow R}$, given $D$ and $f$, is NP-complete.

**Proof. (Sketch)** The proof, given in the Appendix, is by a reduction from the satisfiability problem for $(2^*, 2^-, 4^-)$-CNF formulas, which are formulas of the form $c_1 \land \cdots \land c_w$ where each clause $c_i$ is either of the form $(x_j \lor x_k)$ or $(\neg x_j \lor \neg x_k)$ or $(x_j \lor x_k \lor \neg x_r \lor \neg x_p)$. We prove that this problem is NP-complete in the Appendix. We
reduce this problem to the relevance problem for a fact \( f \) in the relation \( T \). Figure 4 illustrates the database constructed in the proof of Proposition 5.5 for the formula \((x_1 \lor x_2) \cap (\neg x_1 \lor \neg x_3) \land (x_3 \lor x_4 \lor \neg x_1 \lor \neg x_2)\). The gray facts are exogenous. We now explain the general idea of the proof using this example. Given a formula \( \varphi \), we first add to \( D \) an endogenous fact \( R(i) \) and an exogenous fact \( T(i) \) for every \( i \in \{1, \ldots, n\} \) (where \( n \) is the number of variables used in \( \varphi \)). Then, for every clause of the form \((x_j \lor x_i)\) we add an exogenous fact \( S(i,j,a,a) \) to \( D \) (e.g., the fact \( S(1, 2, a, a) \) in the database of Figure 4 represents the clause \((x_1 \lor x_2) \). For every clause of the form \((\neg x_i \lor \neg x_j)\) we add an exogenous fact \( S(b,b,i,j) \) to \( D \) (e.g., the fact \( S(b,b,1,3) \) in the database of Figure 4 represents the clause \((\neg x_1 \lor \neg x_3)\)). For every clause of the form \((x_k \lor x_r \lor \neg x_i \lor \neg x_j)\) we add an exogenous fact \( S(k,r,i,j) \) to \( D \) (e.g., the fact \( S(3, 4, 1, 2) \) in the database of Figure 4 represents the clause \((x_3 \lor x_4 \lor \neg x_1 \lor \neg x_2)\)). We also add to \( D \) the exogenous facts \( R(a) \) and \( T(a) \).

Next, we add an endogenous fact \( f = T(c) \) to \( D \) and our goal is to decide whether \( f \) is relevant. For \( f \) to change the query result in any permutation, we also add the exogenous facts \( R(c) \) and \( S(d, d, c, c) \); thus, for every \( E \subseteq D_n \), it holds that \((D_x \cup E \cup \{ f \}) \models \varphi_{\text{RST-R}}\). We show that \( f \) is relevant to \( \varphi_{\text{RST-R}} \) if and only if the formula \( \varphi \) is satisfiable. First, note that \( D_x \models \varphi_{\text{RST-R}} \). In the example of Figure 4, this is due to the existence of the facts \( S(1, 2, a, a), R(a) \) and \( T(a) \) and the absence of the fact \( R(c) \) in \( D_x \). We can assume that every \((2^*, 2^*, 4^*)\)-CNF formula has a clause of the form \((x_j \lor x_i)\) (hence, an exogenous fact of the form \( S(i,j,a,a) \) always exists in \( D_x \), since the satisfiability problem is trivial for formulas that do not contain such a clause—the zero assignment satisfies all of them. Hence, for the fact \( f \) to change the query result in a permutation, we first need to add a subset \( E \) of endogenous facts of the form \( R(i) \) such that \((D_x \cup E) \not\models \varphi_{\text{RST-R}}\). We show that the existence of a satisfying assignment \( z \) implies that such a subset \( E \) exists (formally, \( E = \{R(i) \mid z(x_i) = 1\} \)). On the other hand, if \( \varphi \) is not satisfiable, then such \( E \) does not exist. The formula of our example is satisfiable (e.g., by the assignment \( z \) such that \( z(x_1) = z(x_2) = 0 \) and \( z(x_3) = \neg z(x_3) = 1 \)), and the reader can verify that indeed for \( E = \{R(2), R(3)\} \) we have that \((D_x \cup E) \not\models \varphi_{\text{RST-R}}\) while \((D_x \cup E \cup \{ f \}) \models \varphi_{\text{RST-R}}\).}

**Corollary 5.6.** Given a database \( D \) and a fact \( f \in T^D \), deciding whether Shapley\((D, \varphi_{\text{RST-R}}, f) = 0 \) is \( \text{NP} \)-complete.

The existence of a multiplicative FPRAS for \( \text{Shapley} (D, \varphi_{\text{RST-R}}, f) \) would imply the existence of a randomized algorithm that, for every \( \delta \in (0, 1) \), returns zero if \( \text{Shapley}(D, \varphi_{\text{RST-R}}, f) = 0 \) and a value \( \epsilon \neq 0 \) otherwise, with probability at least \( 1 - \delta \). Hence, we could obtain a randomized algorithm for deciding if \( \text{Shapley}(D, \varphi_{\text{RST-R}}, f) = 0 \) from a multiplicative FPRAS for \( \text{Shapley}(D, \varphi_{\text{RST-R}}, f) \), in contradiction to the result of Corollary 5.6.

Note that in Proposition 5.5 (and Corollary 5.6) we consider a fact that belongs to a polarity-consistent relation; however, the query is not polarity-consistent as it contains a relation that appears both in a positive and a negative atom of \( \varphi \) (i.e., the relation \( R \)). What about the cases where every relation of \( \varphi \) is polarity-consistent? We show that the problem of deciding whether the Shapley value is zero can always be solved in polynomial time for polarity-consistent queries. Hence, we conclude that having a non-polarity-consistent relation is a necessary condition for hardness of this problem.

**Proposition 5.7.** Let \( \varphi \) be a polarity-consistent CQ\(^*\). Given a database \( D \) and a fact \( f \), the following decision problems are solvable in polynomial time:

- Is \( f \) relevant to \( \varphi \)?
- Is \( \text{Shapley}(D, \varphi, f) = 0 \)?

Since \( \varphi \) is polarity-consistent, the relevance to \( \varphi \) is the same as the Shapley value being nonzero. Hence, to prove the proposition, we introduce the algorithm IsPosRelevant (depicted as Algorithm 2) for deciding whether a fact \( f \) is positively relevant to \( \varphi \). The algorithm IsNegRelevant for deciding whether a fact is negatively relevant is very similar, and we give it in the Appendix. In the algorithms, we denote by \( \text{Dom}(D) \) the set of constants used in the facts of \( D \). Moreover, we denote by \( \text{Neg}(D_n) \) the set of facts in \( D_n \) that appear in relations associated with negative atoms of \( \varphi \).

In IsPosRelevant, our goal is to decide if there is a subset \( E \subseteq D_n \) such that \((D_x \cup E) \not\models \varphi \) while \((D_x \cup E \cup \{ f \}) \models \varphi \). Hence, we go over all possible mappings \( h \) from the variables of \( \varphi \) to the constants of \( D \), that map at least one positive atom of \( \varphi \) to \( f \). Each such mapping defines a set \( P \) of facts \( f' \in D_n \) such that \( h \) maps a positive atom of \( \varphi \) to \( f' \), and a set \( N \) of facts \( f' \in D_n \) such that \( h \) maps a negative atom of \( \varphi \) to \( f' \). For a mapping \( h \) to be an evidence for the relevance of \( f \), it has to map every positive atom of \( \varphi \) to a fact of \( D \) (and at least one such atom to \( f \) itself) and none of the negative atoms of \( \varphi \) to a fact of \( D_x \) (otherwise, \( h \) is not a homomorphism from \( \varphi \) to \( D \)). Moreover, it should be the case that every fact in \( P \setminus \{ f \} \) and none of the facts in \( N \) appears in the set \( E \) (the set of facts added before \( f \) in a permutation). This ensures that \((D_x \cup E \cup \{ f \}) \models \varphi \).

However, this is not enough, as it may be the case that \((D_x \cup E) \models \varphi \) as well. To make sure that this is not the case, there must exist

---

**Algorithm 2: IsPosRelevant\((D, \varphi, f)\)**

```
for \( h : \text{Vars}(\varphi) \rightarrow \text{Dom}(D) \) do
  if \( h \) maps an atom \( \alpha \in \text{Neg}(\varphi) \) to some \( f' \in D_x \) then
    continue
  if \( h \) maps an atom \( \alpha \in \text{Pos}(\varphi) \) to some \( f' \notin D \) then
    continue
  \( P = \{ f' \in D_n \mid h \) maps an atom \( \alpha \in \text{Pos}(\varphi) \) to \( f' \} \)
  \( N = \{ f' \in D_n \mid h \) maps an atom \( \alpha \in \text{Neg}(\varphi) \) to \( f' \} \)
  if \( f \notin P \) then
    continue
  if \((D_x \cup (P \setminus \{ f \}) \cup (\text{Neg}(D_n) \setminus N)) \not\models \varphi \) then
    return false
return true
```

**Figure 4:** The database constructed in the proof of Proposition 5.5 for \((x_1 \lor x_2) \land (\neg x_1 \lor \neg x_3) \land (x_3 \lor x_4 \lor \neg x_1 \lor \neg x_2)\).
a set $F$ of facts corresponding to negative atoms of $q$ such that $(D_q \cup (P \setminus F) \cup F) \not\models q$ and $F$ does not contain any fact of $N$. Then, for $E' = (E \cup F)$ we have that $(D_q \cup E') \not\models q$ while $(D_q \cup E \cup \{f\}) \models q$. The main observation here is that since $q$ is polarity consistent, every fact corresponds to either positive or negative atoms of $q$, but not both; hence, we can add all the facts in $\text{Neg}_{q}(D_q) \setminus N$ to $F$, and check whether the resulting set satisfies the conditions. If this is not the case, then no subset of $F$ satisfies this condition, and hence cannot be the evidence to the relevance of $f$. The proof of correctness of the algorithm is in the Appendix. The algorithm terminates in polynomial time since the number of mappings from the variables of $q$ to the constants of $D$ is polynomial in the size of $D$ when considering data complexity.

Interestingly, while the relevance problem can be solved in polynomial time for any polarity-consistent CQ, this is no longer the case when considering a union of polarity-consistent CQs. Specifically, we show that the relevance to the UCQ $\text{IsPosRelevant}(q)$ is NP-complete, where:

$$q_1() : = \bigwedge_{i \in [k]} (x_i \lor \neg x_i)$$

$$q_2() : = \bigwedge_{i \in [k]} (T(x_i, \theta), \neg T(x, \theta))$$

$$q_3() : = R(\theta)$$

In particular, we show that it is hard to decide whether the fact $R(\theta)$ is relevant to $q_{\text{SAT}}$.

**Proposition 5.8.** Given a database $D$ and the fact $f = R(\theta)$, deciding whether $f$ is relevant to $q_{\text{SAT}}$ is NP-complete.

The proof of the proposition is by a reduction from the satisfiability problem for 3CNF formulas. Given an input formula $\varphi$, we construct an input database $D$ to our problem by adding a fact $V(i)$ and two facts $T(i, 1)$ and $T(i, \theta)$ for every variable $x_i$, and a fact $C(i, j, k, v_i, v_j, v_k)$ for every clause $(l_i \lor l_j \lor l_k)$ in $\varphi$, where $l_r$ is either $x_r$ or $\neg x_r$ for every $r \in \{i, j, k\}$. If $l_r = x_r$, then $v_r = 0$ and if $l_r = \neg x_r$, then $v_r = 1$. Intuitively, the purpose of the first query is to ensure that the assignment satisfies every clause, the purpose of the second query is to ensure that the assignment assigns at least one value to each variable, and the purpose of the third query is to ensure that the assignment assigns at most one value to each variable. Hence, we show that there exists a satisfying assignment if and only if the fact $R(\theta)$ is (positively) relevant to $q_{\text{SAT}}$.

Since the relation $R$ is polarity-consistent and only occurs as a positive atom in $q_{\text{SAT}}$, we again conclude the following.

**Corollary 5.9.** Given a database $D$ and a fact $f \in R^D$, deciding whether Shapley$(D, q_{\text{SAT}}, f)$ is 0 is NP-complete.

Note that while every individual CQ $q^*$ in the query $q_{\text{SAT}}$ is polarity-consistent, the whole query is not, as the relation $T$ appears as a positive atom in $q_1$ and $q_3$ and as a negative atom in $q_2$. If a UCQ $q^*$ is such that the whole query is polarity-consistent, then the relevance problem is solvable in polynomial time. This is due to the fact that a fact $f$ is relevant to such a UCQ $q$ if and only if it is relevant to at least one of the CQs in $q$. Hence, we can use our algorithms $\text{IsPosRelevant}$ and $\text{IsNegRelevant}$ for every individual CQ $q^*$ in $q$ to decide whether a fact $f$ is relevant to $q$. In this case, we cannot preclude the existence of a multiplicative approximation.

### 6 CONCLUDING REMARKS

We have investigated the complexity of computing the Shapley value for CQs and UCQs with negation. In particular, we have generalized a dichotomy by Livshits et al. [20] to classify the class of all CQs with negation and without self-joins. We further generalized this dichotomy to account for exogenous relations that are allowed to contain only exogenous facts. We have also studied the complexity of approximating the Shapley value in a multiplicative manner. The presence of negation makes this approximation fundamentally harder than the monotonic case, since the gap property (that unifies the additive and multiplicative FPRAS task) no longer holds. We have shown the hardness of approximation by making the connection to the problem of deciding relevance to a query, and by establishing hardness results for that problem.

This work leaves open several immediate directions for future research. In particular, we do not yet have a dichotomy for the class of CQs with self-joins (with or without negation). We know from past research that self-joins may cast dichotomies considerably more challenging to prove [9]. In addition, we have not yet studied the implication of the constraint of endogenous relations as an analogue of the exogenous relations; we believe that this problem tightly relates to the problem of model counting for conjunctive queries that has only recently been resolved [1]. Finally, we leave open some fundamental questions about the algorithmic and proof techniques for Shapley approximation. Is there a multiplicative FPRAS in the absence of the gap property? Are there cases where the relevance problem is tractable but a multiplicative approximation is computationally hard (beyond some ratio)?

A DETAILS FOR SECTION 2

We now provide the missing computations for Example 2.3. If the fact $f_1^T$ does not hold, then $f_2^T$ changes the query result from false to true. Thus, there are five possible subsets of the endogenous facts that can appear before $f_2^T$ in a permutation where $f_1^T$ affects the query result: $\emptyset$, $\{f_1^T\}$, $\{f_2^T, f_1^T\}$, $\{f_2^T, f_3^T, f_1^T\}$, $\{f_4^T, f_2^T, f_1^T\}$. To each one of those subsets we can add the fact $f_3^T$; hence, overall, we have ten possible subsets and we conclude that:

$$\text{Shapley}(D, q_1, f_2^T) = \frac{7! + 2 \cdot 1! \cdot 6! + 3 \cdot 2! \cdot 5! + 3 \cdot 3! \cdot 4! + 4! \cdot 3!}{8!} = \frac{27}{140}$$

As for the fact $f_1^T$, it changes the query result from false to true if both $f_2^T$ and $f_3^T$ appear later in the permutation, and none of the conditions (1) or (3) holds. Hence, the subsets of the endogenous facts that can appear before $f_1^T$ in a permutation are:

$$\emptyset, \{f_1^T\}, \{f_2^T, f_1^T\}, \{f_3^T, f_1^T\}, \{f_2^T, f_3^T, f_1^T\}, \{f_4^T, f_2^T, f_1^T\}$$

and we have that:

$$\text{Shapley}(D, q_1, f_1^T) = \frac{7! + 2 \cdot 1! \cdot 6! + 2! \cdot 5! + 3! \cdot 4! + 3! \cdot 5!}{8!} = \frac{27}{140}$$

The same calculations hold for the fact $f_2^T$.

Finally, adding $f_1^T$ to a permutation before $f_2^T$ would change the query result from false to true, unless conditions (2) or (3) hold. In this case, there is a much larger number of subsets of facts that can appear before $f_1^T$ in a permutation where it changes the query result. We divide these subsets to four groups:

- Subsets without any fact from $R_2g$, that is, all subsets of $\{f_1^T, f_3^T, f_4^T\}$.
- Subsets where the only possible facts from $R_2g$ are $f_2^T, f_3^T$. In this group we have: $\{f_2^T, f_1^T\}$, $\{f_2^T, f_1^T\}$, $\{f_2^T, f_3^T, f_1^T\}$, $\{f_2^T, f_3^T, f_1^T\}$. To each of these subsets we can add a subset of the facts $\{f_2^T, f_3^T, f_1^T\}$.
- Subsets that include only the fact $f_3^T$ from $R_2g$. Here we have the subset $\{f_3^T, f_1^T\}$ and we can add to it every subset of $\{f_1^T, f_3^T\}$.
- Subsets that contain the fact $f_3^T$ and at least one of $f_2^T, f_2^T$, that is, $\{f_2^T, f_2^T, f_1^T\}$, $\{f_2^T, f_2^T, f_1^T\}$, and $\{f_2^T, f_2^T, f_1^T\}$.

To each one of these subsets we can add the fact $f_3^T$. Overall we have thirty possible subsets, and we conclude that:

$$\text{Shapley}(D, q_1, f_3^T) = \frac{7! + 3! \cdot 1! \cdot 6! + 3! \cdot 1! \cdot 6! + 3! \cdot 1! \cdot 6! + 3! \cdot 1! \cdot 6!}{8!} = \frac{13}{42}$$

The same calculations hold for Shapley$(D, q_1, f_3^T)$.

B DETAILS FOR SECTION 3

In this section, we provide the proofs of the lemmas used in the proof of hardness of Theorem 3.1. For convenience, we give the theorem here again.

Theorem 3.1. Let $q$ be a CQ without self-joins. If $q$ is hierarchical, then Shapley$(D, q, f)$ can be computed in polynomial time, given $D$ and $f$. Otherwise, its computation is $\text{FP}^{#P}$-complete.

We start by proving the positive side of the theorem.

3Recall that $\text{FP}^{#P}$ is the class of problems that can be solved in polynomial time with an oracle to a $\#P$-complete problem.

Lemma 3.2. Let $q$ be a hierarchical CQ without self-joins. There is a polynomial-time algorithm for computing the number $\text{Sat}(D, q, k)$ of $k$-subsets $E$ of $D_N$, such that $(D_N \cup E) \models q$, given $D$ and $k$.

Proof. The algorithm CntSat of Livshits et al. [20] for computing $\text{Sat}(D, q, k)$ is a recursive algorithm that reduces the number of variables in the query with each recursive call. If there is a variable $x$ that occurs in every atom of $q$ (i.e., a root variable), then the problem is solved using dynamic programming, by considering every possible value of $x$. If no variable occurs in all atoms, then the query can be split into two disjoint sub-queries, in which case the problem is solved separately for each one of them. The treatment of these two cases applies to any hierarchical CQ as it only relies on the hierarchical structure of the query; however, the treatment of the base case, when no variables occur in $q$, does not apply to queries with negation, and we now explain how it should be modified.

If at least one atom of $q$ does not correspond to any fact of $D$, then CntSat will return 0, as $D \not\models q$. This will also be the case if $k < |A|$ or $k \geq |D_N|$, where $A = \text{Atoms}(q) \cap D_N$. In any other case, the algorithm will return $(\frac{|D_N - |A|)}{k - |A|})$ which is the number of possibilities to select $k - |A|$ facts among those in $D_N \setminus A$ (as every fact of $A$ should be selected to satisfy $q$). By modifying the base case in the following way, we ensure that the algorithm returns $\text{Sat}(D, q, k)$ for a CQ. The algorithm will return 0 in one of the following cases: (a) at least one of the positive atoms of $q$ does not appear as a fact of $D$, (b) at least one of the negative atoms of $q$ appears as a fact of $D$, or (c) $k \leq |A|$ or $k \geq |D_N|$ where $A = \text{Pos}(q) \cap D_N$. In any other case, the result will be $(\frac{|D_N - |A|)}{k - |A|})$. It is rather straightforward that the modified algorithm will indeed return $\text{Sat}(D, q, k)$ in polynomial time, based on the correctness and efficiency of CntSat.

Next, we prove the hardness side of the theorem. First, we prove hardness for the basic non-hierarchical self-join-free queries, and then we reduce these problems to the problem of computing Shapley$(D, q, f)$ for any non-hierarchical self-join-free CQ $q$. We start by proving the following.

Lemma 3.3. If $q$ is one of $q_{RS-T}$, $q_{RS-Str}$, or $q_{RS-T}$, then computing Shapley$(D, q, f)$ is $\text{FP}^{#P}$-complete.

We prove the lemma separately for each one of the queries. We start with the query $q_{RS-T}$.

Lemma B.1. Computing Shapley$(D, q_{RS-T}, f)$ is $\text{FP}^{#P}$-complete.

Proof. We construct a reduction from the problem of computing Shapley$(D, q_{RS-T}, f)$ to that of computing Shapley$(D, q_{RS-T}, f)$.

We make the following assumptions on the input database $D$ to the first problem: (a) every fact in $S$ is exogenous, and (b) for every $T(a, b)$ in $D$, it holds that both $R(a)$ and $T(b)$ are in $D$ as well. The database used in the proof of hardness for $\text{qRS-T}$ [20] satisfies these properties; hence, computing Shapley$(D, q_{RS-T}, f)$ for such an input is $\text{FP}^{#P}$-complete.

Let $D$ be such database, and let $f \in D_N$. Assume, without loss of generality, that $f = R(\bar{q})$ (the proof for a fact $f$ in $T$ is symmetric).

Let:

$$P_1 = \{ \sigma \mid \sigma \in \Pi_D, (\sigma_f \cup D) \models q_{RS-T}, (\sigma_f \cup D) \models \{f\} \}$$
$P_2 = \{ (a \mid \sigma \in \Pi \Delta_x, (\sigma f \cup \Delta_x) \models q_{RS,-T}, (\sigma f \cup \Delta_x \cup \{ f \}) \not\models q_{RS,-T} \}$

Recall that $\Pi \Delta_x$ is the set of all possible permutations of the endogenous facts, and $\sigma f$ is the set of facts that appear before $f$ in the permutation $\sigma$. That is, $P_1$ and $P_2$ are the sets of all permutations where $f$ changes the query result from false to true w.r.t. $q_{RS,T}$ and $q_{RS,-T}$, respectively. We claim that $|P_1| = |P_2|$ due to a bijection that exist between the two sets.

Let $g$ be a function defined as follows:

$$g : P_1 \rightarrow P_2, \quad g(\sigma) = \sigma^R$$

where $\sigma^R$ is the permutation $\sigma$ in reversed order (i.e., $\sigma_i = \sigma_{n-i+1}$ for all $i = \{1, 2, ..., n\}$, where $n = |\Pi \Delta_x|$). First, we prove that if $\sigma \in P_1$ then $g(\sigma) \in P_2$. If $f$ changes the query result from false to true in $\sigma$, then for every $S(a, b) \in \Delta_x$, at least one of the facts $R(a), T(b)$ is not in $D_x \cup \sigma f$, and there is at least one fact $T(c)$ in $D_x \cup \sigma f$ such that $S(\emptyset, c) \in D_x$. According to our assumption, for every $S(a, b) \in \Delta_x$ both $R(a)$ and $T(b)$ exist in $D$; hence, at least one of those is in $\sigma^R$.

Moreover, there is at least one fact $T(c)$, which is not in $D_x \cup \sigma^R$, such that $S(\emptyset, c) \in \Delta_x$. We conclude that $(D_x \cup \sigma f) \models q_{RS,-T}$ because $S(\emptyset, c)$ satisfies $q_{RS,-T}$ and $T(c) \notin (D_x \cup \sigma f)$. Moreover, since for every fact $S(a, b) \in \Delta_x$ for $a \neq \emptyset$ at least one of $R(a)$ or $T(b)$ is in $D_x \cup \sigma f$, we have that $(D_x \cup \sigma f \cup \{ f \}) \models q_{RS,-T}$, and $g(\sigma) \in P_2$.

Next, we prove that the function is injective and surjective.

- **Injectivity**: Let $\sigma_1, \sigma_2 \in P_1$ such that $\sigma_1 \neq \sigma_2$. It follows directly that $\sigma^R \neq \sigma^R$.

- **Surjectivity**: Let $\sigma \in P_2$. Since $(D_x \cup \sigma f) \models q_{RS,-T}$, it holds that for every $S(a, b) \in \Delta_x$ such that $a \neq \emptyset$, at least one of $R(a)$, $T(b)$ is in $D_x \cup \sigma f$. In addition, since $(D_x \cup \sigma f \cup \{ f \}) \not\models q_{RS,-T}$, there is a fact $S(\emptyset, c) \in \Delta_x$ such that $T(c)$ is not in $D_x \cup \sigma f$. Observe that $\sigma_R \in P_1$, for every $S(a, b) \in \Delta_x$ such that $a \neq \emptyset$, at least one of $R(a)$, $T(b)$ is not in $D_x \cup \sigma^R$, and there is a fact $S(\emptyset, c) \in \Delta_x$ such that $T(c)$ is in $D_x \cup \sigma^R$. Thus $f$ changes the query result from false to true w.r.t. $q_{RS,T}$ in $\sigma^R$. Since $\sigma^R = \sigma$, we get that $g(\sigma^R) = \sigma$.

Thus, by the definition of the Shapley value we obtain that:

$$Shapley(D, q_{RS,T}, f) = \frac{|P_1|}{n!} = \frac{|P_2|}{n!} = -Shapley(D, q_{RS,-T, f})$$

and that concludes our proof.

Next, we give the proof of hardness for $q_{RS,-T}$.

**Lemma B.2.** *Computing Shapley(D, q_{RS,-T}, f) is $FP^{#P}$-complete.*

**Proof.** We show a reduction from the known $\#P$-complete problem of computing $|S(g)|$—the number of independent sets in a bipartite graph $g$. Given an input graph $g = (A \cup B, E)$, where $A$ and $B$ are the disjoint sets of vertices in $g$, we define the following set:

$$S(g) := \{ A' \cup B' \mid A' \subseteq A, B' \subseteq B, \forall (a, b) \in E (a \in A' \Rightarrow b \in B') \}$$

That is, $S(g)$ contains all subsets of the vertices in $g$, such that if a vertex from $A$ is in the subset, all of its neighbours from $B$ are in the subset as well. Note that a subset in $S(g)$ may include additional vertices from $B$ that not connected to any vertex from $A$ in the subset. We denote by $S(g, k)$ the set of all $E \in S(g)$ such that $|E| = k$.

Given a bipartite graph $g = (A \cup B, E)$, where $|A| = m, |B| = n$, and $N = m + n$ such that none of the vertices in $g$ is isolated, we build a database $D^P$ which consists of the following facts: an endogenous fact $R(a)$ for every vertex $a \in A$, an endogenous fact $T(b)$ for every vertex $b \in B$, an exogenous fact $S(a, b)$ for every edge $(a, b) \in E$, and another endogenous fact $T(c)$ for a fresh constant $\emptyset$. In addition, for every $a \in A, D^P$ will contain the exogenous fact $S(a, \emptyset)$. We will compute the Shapley value for the fact $f = T(\emptyset)$.

(In fact, we will compute $1 - Shapley(D^P, q_{RS,-T, f})$.)

There are two types of permutations $\sigma \in \Pi \Delta_x$ for which it holds that $q_{RS,-T}(D^P \cup \sigma f) = q_{RS,-T}(D^P \cup \sigma f \cup \{ f \})$ (i.e., permutations where $f$ does not change the result of $q_{RS,-T}$):

Observe that $D'_n = D_n$, we define two sets of permutations:

$$P_1 := \{ \sigma \in \Pi \Delta_x \mid (D_x \cup \sigma f) \not\models q_{RS,T}, (D_x \cup \sigma f \cup \{ f \}) \models q_{RS,T} \}$$

$$P_2 := \{ \sigma \in \Pi \Delta_x \mid (D'_x \cup \sigma f) \not\models q_{RS,T}, (D'_x \cup \sigma f \cup \{ f \}) \models q_{RS,T} \}$$

We prove that $P_1 = P_2$ by showing a mutual inclusion between the sets:

$$P_1 \subseteq P_2: \text{Let } \sigma \in P_1. \text{ Since } (D_x \cup \sigma f) \not\models q_{RS,T}, \text{ for every pair of facts } R(a), T(b) \in \sigma f, \text{ we have that } S(a, b) \in D_x. \text{ Moreover, since } (D_x \cup \sigma f \cup \{ f \}) \models q_{RS,T}, \text{ there is a fact } S(\emptyset, c) \in D_x \text{ such that } T(c) \in \sigma f. \text{ By the definition of } D'_x, \text{ we have that } S(a, b) \in D'_x \text{ for every pair of facts } R(a), T(b) \in \sigma f; \text{ hence, } (D'_x \cup \sigma f) \not\models q_{RS,-T}. \text{ We also have that } S(\emptyset, c) \notin D'_x \text{ (while } T(c) \in \sigma f), \text{ and we conclude that } (D'_x \cup \sigma f \cup \{ f \}) \not\models q_{RS,-T}$

$$P_2 \subseteq P_1: \text{Let } \sigma \in P_2. \text{ For every } R(a), T(b) \in \sigma f, \text{ there is a fact } S(a, b) \in D'_x \text{, and there is also a fact } T(c) \in \sigma f \text{ such that } S(\emptyset, c) \notin D'_x. \text{ Thus, it holds that for every pair of facts } R(a), T(b) \in \sigma f, \text{ the fact } S(a, b) \text{ does not belong to } D_x \text{ by the definition of } D'_x, \text{ so } R(a), T(b) \text{ cannot be a part of any answer to } q_{RS,T}, \text{ and overall } (D_x \cup \sigma f) \not\models q_{RS,T}. \text{ Moreover, } S(\emptyset, c) \in D_x, \text{ so the set of facts } \{ R(\emptyset), S(\emptyset, c), T(c) \} \text{ satisfies } q_{RS,T}, \text{ and we conclude that } (D'_x \cup \sigma f \cup \{ f \}) \models q_{RS,T}$

Finally, we deduce that:

$$Shapley(D, q_{RS,T}, f) = \frac{|P_1|}{n!} = \frac{|P_2|}{n!} = Shapley(D', q_{RS,-T}, f)$$

where $n = |D_n| = |D'_n|$. \qed
(1) \((D_0^R \cup \sigma_f) \not\subseteq \text{qrs-T}\) and \((D_0^\sigma \cup \sigma_f \cup \{f\}) \not\subseteq \text{qrs-T}\). In this case, no fact from \(R\) is in \(\sigma_f\). Otherwise, there is \((R,a) \in \sigma_f\) such that \((R,a), (S,a, \emptyset)\) is an answer to \(\text{qrs-T}\), based on the construction of \(D_0^R\), in which case \((D_0^R \cup \sigma_f) \subseteq \text{qrs-T}\). Adding \(f\) cannot form a new answer to the query. The number of permutations that satisfy this property is \(P_{0 \rightarrow 0} = \frac{(N+1)!}{m+1}\) since each of the \(m+1\) facts in \(R^2 \cup \{f\}\) has an equal chance to be the first (among these facts) to appear in a permutation, and we are interested in the permutations where \(f\) appears before any fact in \(R^2\).

(2) \((D_0^R \cup \sigma_f) \subseteq \text{qrs-T}\) and \((D_0^\sigma \cup \sigma_f \cup \{f\}) \subseteq \text{qrs-T}\). Here, we observe that \(F = \{a | (R,a) \in \sigma_f\} \cup \{b | T(b) \in \sigma_f\}\) is a subset of vertices in \(g\) such that \(F \notin S(g)\). Otherwise, we get that for every \(S(a,b) \in D_0^R\) if \((R,a) \in \sigma_f\) then \(T(b) \in \sigma_f\), by the definition of \(S(g)\). Therefore, none of the pairs \((R,a), (S,a,b) \in (D_0^\sigma \cup \sigma_f)\) is an answer to \(\text{qrs-T}\), since \(T(b) \in \sigma_f\) as well. Hence, every pair of facts from \(R\) and \(\sigma_f\) satisfies \(\text{qrs-T}\) if \(a \notin \{0\}\) and \(\{b | T(b) \in \sigma_f\}\) must be such that \(F \notin S(g)\) or, otherwise, there is \((S,a,b) \in D_0^R\) such that \((R,a) \in \sigma_f\) and \(T(b) \notin \sigma_f\), which implies that \((D_0^\sigma \cup \sigma_f) \subseteq \text{qrs-T}\), in contradiction to our assumption. The number of such permutations is: \(P_{0 \rightarrow 0} = \sum_{k=0}^{N} |S(g,k)| \cdot k! \cdot (N-k+r)!\).

Hence, we have that:

Shapley\((D^R, q_{\text{qrs-T}}, f)\) = 1 - \(\frac{P_{r \rightarrow 0} + P_{r \rightarrow 1}}{(N + r + 1)!}\) = 1 - \(\frac{P_{r \rightarrow 1} \cdot m_r + P_{r \rightarrow 0}}{(N + r + 1)!}\)

We get that:

\(P_{r \rightarrow 0} = (1 - \text{Shapley}(D^R, \text{qrs-T}, f)) \cdot (N + r + 1)! - P_{r \rightarrow 1} \cdot m_r = \sum_{k=0}^{N} |S(g,k)| \cdot k! \cdot (N-k+r)!\)

(Recall that \(P_{r \rightarrow 1}\) can be computed from the Shapley value of the fact \(T(\emptyset)\) in the instance \(D^0\).) As a consequence, we get a system of \(N+1\) equations:

\[
\begin{pmatrix}
0!(N+1)! & 1!1! & \ldots & N!1! & |S(g,0)|
0!(N+2)! & 1!(N+1)! & \ldots & N!2! & |S(g,1)|
\vdots & \vdots & \ddots & \vdots & \vdots
0!(2N+1)! & 1!(2N)! & \ldots & N!(N+1)! & |S(g,N)|
\end{pmatrix}
= \begin{pmatrix}
(1 - \text{Shapley}(D^1, \text{qrs-T}, f)) \cdot (N + 2)! - P_{1 \rightarrow 1} \cdot m_1
(1 - \text{Shapley}(D^2, \text{qrs-T}, f)) \cdot (N + 3)! - P_{1 \rightarrow 1} \cdot m_2
\vdots
(1 - \text{Shapley}(D^{N+1}, \text{qrs-T}, f)) \cdot (2N+2)! - P_{1 \rightarrow 1} \cdot m_{N+1}
\end{pmatrix}
\]

This is the same system of equations that Livshits et al. obtained in the hardness proof for \(\text{qrs-T}\). There, they prove that the determinant of the coefficient matrix is not zero; hence, this system is solvable in polynomial time, providing us the with the value of \(|S(g)| = \sum_{k=0}^{N} |S(g,k)|\).

Finally, it is left to prove that \(|S(g)| = |IS(g)|\). For that purpose, we define a bijection between the two sets, \(h : IS(g) \rightarrow S(g)\), as follows: Let \((A' \cup B') \in IS(g)\). Then, \(h(A' \cup B') = A' \cup (B \setminus B')\). Note that for every \((a,b) \in E\) we have that if \(a \in A'\) then \(b \notin B'\), hence, for every \((a, b) \in E\) it holds that if \(a \in A'\) then \(b \notin B'\). Hence, if \((A' \cup B') \in IS(g)\), then \((A' \cup (B \setminus B')) \in S(g)\).

Injectivity: Let \(I_1 = (A'_1 \cup B'_1)\) and \(I_2 = (A'_2 \cup B'_2)\) be two distinct independent sets of \(g\) (i.e., \(I_1, I_2 \in IS(g)\)). At least one of the following holds: \(A'_i \neq A'_j\) or \(B'_i \neq B'_j\). Clearly in both cases we have that \(h(I_1) \neq h(I_2)\) as well.

Surjectivity: Let \(E = (A' \cup B')\) be a subset of vertices in \(S(g)\). Consider the subset \(I = (A' \cup (B \setminus B'))\). By the definition of \(S(g)\), for every \((a,b) \in E\) we have that if \(a \in A'\) then \(b \notin B'\). Therefore,
for every \((a, b) \in E\) it holds that if \(a \in A'\) then \(b \notin (B \setminus B')\). Then, we conclude that \(f \in IS(q)\) by definition. It holds that \(h(I) = (A' \cup (B \setminus B')) = (A' \cup B') = E\); thus, the function \(h\) is surjective.

To conclude, we constructed a reduction from the problem of computing \(|IS(q)|\) to that of computing Shapley\((D, q_{RS-T}, f)\); hence, computing Shapley\((D, q_{RS-T}, f)\) is \(FP^{P,P}\)-complete.

Finally, we show that for any non-hierarchical self-join-free \(CQ^n\) \(q\) computing Shapley\((D, q, f)\) is \(FP^{P,P}\)-complete, using a reduction from the problem of computing Shapley\((D, q', f')\) where \(q'\) is one of queries \(q_{ST}, q_{RS-T}, q_{RS-ST}\), or \(q_{RS-T}\), depending on the polarity of the atoms in the non-hierarchical triplet in \(q\).

**Lemma B.4.** If \(q\) is a non-hierarchical \(CQ^n\) without self-joins, then computing Shapley\((D, q, f)\) is \(FP^{P,P}\)-complete.

**Proof.** Every non-hierarchical self-join-free \(CQ^n\) contains three atoms \(\alpha_x, \alpha_y, \alpha_{x,y}\) where \(x, y \in \text{Vars}(q)\), such that \(\alpha_x \in A_x \setminus A_y\), \(\alpha_y \in A_y \setminus A_x, \alpha_{x,y} \in A_x \cap A_y\). We argue that \(q\) satisfies another property: if there is a non-hierarchical triplet \(\alpha_x, \alpha_y, \alpha_{x,y}\) where \(\alpha_x\) and \(\alpha_y\) are both positive or both negative, then there is another non-hierarchical triplet \(\alpha'_x, \alpha'_y, \alpha'_{x,y}\) where \(\alpha'_x\) and \(\alpha'_y\) are both positive or both negative. Assume, without loss of generality, that \(\alpha_x\) is negative. Since \(q\) is safe, there is a positive atom \(\alpha'_x\) such that \(\alpha'_x \in A_x\). If there exists such an atom \(\alpha'_x\) such that \(\alpha'_x \in A_x \cap A_y\), the triplet \(\alpha_x, \alpha'_x, \alpha_{x,y}\) satisfies the property. Otherwise, if \(\alpha'_x\) is positive, the triple \(\alpha'_x, \alpha_{x,y}, \alpha'_y\) satisfies the property. Finally, if every \(\alpha'_x\) such that \(\alpha'_x \in A_x \& A_y\), and \(\alpha_y\) is negative, since \(q\) is safe, we have another positive atom \(\alpha'_x \in A_y \setminus A_x\) and \(\alpha'_x, \alpha_{x,y}, \alpha'_y\) is a non-hierarchical triplet satisfying the property.

Let \(\alpha_x, \alpha_y, \alpha_{x,y}\) be non-hierarchical triplets of \(q\) that satisfies the above property. We construct a reduction from the problem of computing Shapley\((D', q', f')\) where \(q'\) is one of \(q_{ST}, q_{RS-T}, q_{RS-ST}\), or \(q_{RS-T}\) computing Shapley\((D, q, f)\). We have already established that computing Shapley\((D', q', f')\) for each of these queries is \(FP^{P,P}\)-complete; hence, we conclude that Shapley\((D, q, f)\) is \(FP^{P,P}\)-complete for any non-hierarchical self-join-free \(CQ^n\). We present the four reductions simultaneously, as they all work in a very similar way.

Depending on the polarity of the atoms in the non-hierarchical triplet of \(q\) satisfying the property indicated above, we select one of the four reductions (if there are multiple triplets satisfying this property, we choose one randomly):

1. If all three atoms are positive, we reduce from computing Shapley\((D', q_{ST}, f')\).
2. If \(\alpha_{x,y}\) is positive while the other two atoms are negative, we reduce from computing Shapley\((D', q_{RS-T}, f')\).
3. If \(\alpha_{x,y}\) is negative while the other two atoms are positive, we reduce from Shapley\((D', q_{RS-ST}, f')\).
4. If \(\alpha_{x,y}\) is negative, and exactly one of \(\alpha_x, \alpha_y\) is positive, we reduce from Shapley\((D', q_{RS-T}, f')\).

The idea is very similar to the corresponding proof in [20]. The main difference is in the construction of the database \(D'\), as \(q\) may contain negative atoms. We use the atom \(\alpha_x\) to represent the atom \(R(x)\) (or \(-R(x)\)) in \(q'\), the atom \(\alpha_y\) to represent the atom \(T(y)\) (or \(-T(y)\)) in \(q'\), and the atom \(\alpha_{x,y}\) to represent the atom \(S(x, y)\) (or \(-S(x, y)\)) in \(q'\). For every fact \(R(a)\) in \(D\) (which is the input to the first problem), we insert to the relation \(R_{\alpha_x}\) in \(D'\) (the input to our problem) a fact obtained by mapping the variable \(x\) in \(\alpha_x\) to \(a\) and the rest of the variables to a constant \(\circ\). Similarly, for every fact \(T(b)\) in \(D\), we insert to the relation \(R_{\alpha_y}\) in \(D'\) a fact obtained by mapping the variable \(y\) in \(\alpha_y\) to \(b\) and the rest of the variables to a constant \(\circ\). Each such fact \(f' \in D'\) will be endogenous if and only if the fact \(f\) it was generated from is endogenous. Finally, for every fact \(S(a, b)\) and a positive atom \(x\) in \(q\) that is not one of \(\alpha_x, \alpha_y\), or \(\alpha_{x,y}\), we insert to the relation \(R_a\) in \(D'\) every exogenous fact obtained by mapping the variable \(x\) in \(a\) to \(a\), the variable \(y\) to \(b\), and the rest of the variables to \(\circ\). We also add to the relation \(R_{\alpha_{x,y}}\) in \(D'\) every exogenous fact obtained by such a mapping of the variables in \(\alpha_{x,y}\).

Note that \(|D_n| = |D'_n|\); hence, the total number of permutations of the endogenous facts is equal for both databases, and we only need to show that for every fact \(f \in D_n\), the number of permutations of the facts in \(D_n\) where \(f\) changes the result of \(q'\) is equal to the number of permutations of the facts in \(D_n\) where \(f'\) (which is the fact generated from \(f\)) changes the result of \(q\). We can then conclude that Shapley\((D, q', f)\) = Shapley\((D', q', f')\).

When considering the fact \(S(a, b)\) in the construction of \(D'\), we have created a mapping \(h\) from the variables of \(q\) such that \(h(x) = a, h(y) = b, h(w) = \circ\) for the rest of the variables, and we have added all the resulting facts, associated with positive atoms that are not one of \(\alpha_x, \alpha_y, or \alpha_{x,y}\, to \(D'\) as exogenous facts). Moreover, the relations in \(D'\) associated with negative atom of \(q\) (except \(\alpha_{x,y}\)) are empty and do not affect the query result. Finally, it holds that \(S(a, b) \in D_n\) if and only if the fact \(f\) obtained from it using the atom \(\alpha_{x,y}\) is in \(D'_n\). Hence, a subset \(E\) of \(D_n\) is such that there is a homomorphism mapping every positive atom and none of the negative atoms of \(q\) to \(E \cup D_k\) (that is, \((E \cup D_k)) \models q\) if and only if the subset \(E'\) of \(D'_n\) contains for each fact \(f \in E\) the corresponding fact \(f' \in D'\) is such that there is a homomorphism mapping every positive atom and none of the negative atoms of \(q\) to \(E' \cup D'_k\) (that is, \((E' \cup D'_k)) \models q\). Therefore, a permutation \(\sigma\) of the facts in \(D_n\) and a fact \(f \in D_n\) satisfies \(q'(D_x \cup \sigma_f) \neq q'(D_x \cup \sigma_f \cup \{f\})\) if and only if the corresponding permutation \(\sigma'\) of the facts in \(D'_n\) and the corresponding fact \(f' \in D_n\) satisfies \(q(D'_x \cup \sigma_{f'}) \neq q(D'_x \cup \sigma_{f'} \cup \{f'\})\), and that concludes our proof.

Next, we provide an insight into the complexity of the problem for \(CQ^n\)’s with self-joins. Theorem 3.1 does not provide us with any information about the complexity of computing the Shapley value for the query \(\text{UNEMPLOYED}(x), \text{MARRIED}(x, y), \text{UNEMPLOYED}(y)\) asking whether there is a married couple where both spouses are unemployed, or for the query \(\neg\text{CITIZEN}(x), \text{MARRIED}(x, y), \neg\text{CITIZEN}(y)\) asking if there are two married people such that none of them is a citizen. The following result implies that computing the Shapley value for both queries is \(FP^{P,P}\)-complete.

**Theorem B.5.** Let \(q\) be a polarity-consistent \(CQ^n\) containing a non-hierarchical triplet \((\alpha_x, \alpha_{x,y}, \alpha_y)\) such that the relation \(R_{\alpha_x}\) occurs only once in \(q\). Then, computing Shapley\((D, q, f)\) is \(FP^{P,P}\)-complete.

To prove the theorem, we construct a reduction from the problem of computing Shapley\((D, q', f)\) where \(q'\) is one of \(q_{ST}, q_{RS-T}, q_{RS-ST}\) (depending on the polarity of the atoms \(\alpha_x\) and \(\alpha_y\), under the following assumptions: (1) all the facts of \(S\) are exogenous, and (2) for every fact \(R(a)\) in \(D\), both facts \(R(a)\) and \(T(1)\) are in
The instances constructed in the proofs of hardness for all three queries satisfy these conditions; hence, the problems remain hard under these assumptions. We also assume for simplicity that the set of values used in the facts of $\mathcal{D}^D$ and the set of values used in the facts of $\mathcal{T}^D$ are disjoint.

The idea is very similar to the construction in the proof of Lemma B.4, with the main difference being the treatment of the negative atoms in $\mathcal{q}$. Moreover, the relation $\alpha$ to the constants of $\mathcal{f}$ that maps the variable $x$ to a value from the domain of $\mathcal{D}^D$, the variable $y$ to a value from the domain of $\mathcal{T}^D$, and the rest of the variables to $\emptyset$. If $h'$ maps $\beta$ to $f$, then there is also a homomorphism from $\beta$ to $\alpha$ (and from $\alpha$ to $\beta$) where $x$ is mapped to itself. We conclude that $h'$ maps the atom $\alpha$ to the fact $f$. From the construction of $\mathcal{D}'$, we have that $R(a) \in \mathcal{E}$, which is a contradiction to the fact that $R$ appears as a negative atom in $q'$ and $(\mathcal{D}_n \cup \mathcal{E}) \models q'$.

Next, we prove the following.

**Lemma B.7.** Let $E \subseteq D_n$ and let $E'$ be the set of corresponding facts in $\mathcal{D}'_n$. If $(\mathcal{D}_n \cup \mathcal{E}) \not\models q'$ then $(\mathcal{D}_n' \cup \mathcal{E}'') \not\models q$.

Proof. Let us assume, by way of contradiction, that $(\mathcal{D}_n' \cup \mathcal{E}'') \models q$. Then, there is a mapping $h$ from the variables of $q$ to the domain of $\mathcal{D}'$ that maps every positive atom and none of the negative atoms of $q$ to a fact in $\mathcal{D}_n' \cup \mathcal{E}'$. In particular, the atom $\alpha$, is mapped to a fact of $\mathcal{D}_n' \cup \mathcal{E}'$ and if only if it is positive. From the construction of $\mathcal{D}'$ and the uniqueness of the atom (i.e., the fact that its relation does not appear in another atom of $q$), we have that if $\alpha$, is positive, then $h$ maps $\alpha$, to a fact of $\mathcal{D}_n'$ if and only there exists a fact $S(1, a)$ in $D$ such that $h(x) = a$ and $h(y) = 1$. If $\alpha$, is negative, then $h$ does not map $\alpha$, to a fact of $\mathcal{D}_n'$ if and only there exists a fact $S(1, a)$ in $D$ such that $h(x) = a$ and $h(y) = 1$.

We claim that the mapping $h$ is such that every positive atom and none of the negative atoms of $q'$ is mapped to a fact of $\mathcal{D}_n' \cup \mathcal{E}'$, which is a contradiction to the fact that $(\mathcal{D}_n \cup \mathcal{E}) \not\models q$. We have already established, that there exists an exogenous fact $S(1, a)$ in $\mathcal{D}_n$ and it holds that $h(x) = a$ and $h(y) = 1$. It is only left to show that the fact $R(a)$ belongs to $\mathcal{E}$ if and only if $R$ occurs as a positive atom in $q'$, and, similarly, the fact $T(1)$ belongs to $\mathcal{E}$ if and only if $T$ occurs as a positive atom in $q'$.

If $\alpha$, is a positive atom, then there is a fact $f$ in the relation $\mathcal{R}_\alpha$, obtained from $\alpha$, by mapping the variable $x$ to the value $a$ and the rest of the variables to the value $\emptyset$. In this case, the relation $R$ also appears in $q'$ as a positive atom and the fact $f' = R(a)$ corresponding to $f$ appears in $E$. If $\alpha$, is a negative atom (in which case, the relation $R$ occurs in $q'$ as a negative atom), then the fact $f$ does not appear in $E'$ (or, otherwise, $\mathcal{D}_n' \cup \mathcal{E}'$ will not satisfy $q$), which implies that the fact $f'$ does not appear in $E$. We can similarly show that the fact $T(1)$ appears in $E$ if and only if its corresponding fact appears in $E'$, and that concludes our proof.

Lemmas B.6 and B.7 imply that the fact $f$ changes the result of $q'$ in a permutation $\sigma$ of $\mathcal{D}_n$ if and only if the fact $f'$ changes the result of $q$ in a permutation $\sigma'$ of $\mathcal{D}_n'$. Since the total number of permutations of the facts in $\mathcal{D}_n$ and $\mathcal{D}_n'$ is equal, we conclude that indeed $\text{Shapley}(\mathcal{D}, q', f) = \text{Shapley}(\mathcal{D}', q, f')$.

### C DETAILS FOR SECTION 4

We start by proving the hardness side of the theorem. Let $\mathcal{S}_X$ be a schema and let $q$ be a self-join-free CQ$^*$ that contains a non-hierarchical path. Similarly to the proof of Theorem B.3, we construct a reduction from the problem of computing Shapley($\mathcal{D}, q', f$) where $q'$ is one of $\mathcal{q}_{\mathcal{RST}}, \mathcal{q}_{\mathcal{RS}-\mathcal{T}}$ or $\mathcal{q}_{\mathcal{RS}-\mathcal{T}}$ to that of computing Shapley($\mathcal{D}, q, f$). We again assume that in the input to the first problem all the facts of $\mathcal{S}$ are exogenous, and for every fact $S(a, 1)$...
in $D$, both facts $R(a)$ and $T(1)$ are in $D$. We also assume that the set of values used in the facts of $R^D$ and the set of values used in the facts of $T^D$ are disjoint.

Since $q$ has a non-hierarchical path, there exist two atoms $\alpha_x$ and $\alpha_y$ in $q$ and two variables $x, y$, such that $R_{\alpha_x} \notin X$ and $R_{\alpha_y} \notin X$, the variable $x$ occurs in $\alpha_x$ but not in $\alpha_y$ and the variable $y$ occurs in $\alpha_y$ but not in $\alpha_x$. Moreover, there exists a path $x = v_1, \ldots, v_n = y$ in the graph obtained from the Gaifman graph $G(q)$ of $q$ by removing every variable in $\text{Vars}(\alpha_x) \cup \text{Vars}(\alpha_y)$ \{ $x, y$}. The idea is the following. We use the atoms $\alpha_x$ and $\alpha_y$ to represent the atoms $\neg R(x)$ and $\neg T(y)$ in $q$, respectively, and we use the non-hierarchical path to represent the connections between them (i.e., the atom $S(x, y)$). If $\alpha_x$ and $\alpha_y$ are both positive, the reduction is from the problem of computing Shapley$(D, q_{\text{RS} \cup T}, f)$, and if only one atom is positive while the other is negative, the reduction is from computing Shapley$(D, q_{\text{RS} \cup T}, f)$, except if $q$ is the negation of a fact, and if one atom is positive while the other is negative, the reduction is from computing Shapley$(D, q_{\text{RS} \cup T}, f)$. Formally, given an input database $D$ to the first problem, we build a database $D'$ in the following way. For every fact $f = R(a)$ we assign the value $a$ to the variable $x$ in $\alpha_x$ and the value $\varnothing$ to the rest of the variables, and we add the corresponding fact $f'$ to the relation $R_{\alpha_x}$ in $D'$. The fact $f'$ will be endogenous if and only if $f$ is endogenous. Similarly, for every fact $f = T(1)$ we assign the value $1$ to the variable $y$ in $\alpha_y$ and the value $\varnothing$ to the rest of the variables, and we add the corresponding fact $f'$ to the relation $R_{\alpha_y}$ in $D'$. Again, the fact $f'$ will be endogenous if and only if $f$ is endogenous. Next, for every fact $S(a_1)$ in $D$ and atom $\alpha_q$ in $\alpha_q$ that is not one of $\alpha_x$ or $\alpha_y$, we assign the value $a$ to the variable $x$, the value $1$ to the variable $y$, the value $(a, 1)$ to the variables $v_1, \ldots, v_n$ along the non-hierarchical path, and the value $\varnothing$ to the rest of the variables, and we add the corresponding exogenous fact to the relation $R_{\alpha_q}$ in $D'$ if we have not added this fact to $D'$ already. Note that $|D_n| = |D'_n|$.

Now, given the database $D'$ we construct a database $D''$ which will be the input to our problem in the following way. We first copy all the endogenous facts from $D'$ to $D''$. Then, for every relation $R$ in $D'$ corresponding to a positive atom of $q$, we copy every exogenous fact from $R^D$ to $R^{D'}$. For every relation $R$ in $D'$ corresponding to a negative atom of $q$, we add to $R^{D'}$ every exogenous fact over the domain of $D'$ if and only if it does not occur in $R^{D'}$ (i.e., $R^{D''} = R^{D'}$). Note that since we did not change the endogenous facts, we have that $|D_n| = |D'_n| = |D''_n|$.

We will now prove that for every endogenous fact $f_1$ in $D$ and its corresponding fact $f_2$ in $D''$ it holds that Shapley$(D, q', f_1) = \text{Shapley}(D'', q, f_2)$ (recall that $q'$ is one of $q_{\text{RS} \cup T}, q_{\text{RS} \cup T}$). We start by proving the following.

**Lemma C.1.** Let $E \subseteq D_n$ and let $E''$ be the set of corresponding facts in $D''_n$. If $(D_x \cup E) \models q'$ then $(D''_x \cup E'') \models q$.

**Proof.** Since $(D_x \cup E) \models q'$ there is a mapping $h$ from the variables of $q'$ to the domain of $D$ where $h(x) = a$ for some value $a$ from the domain of $R^D$ and $h(y) = 1$ for some value $1$ from the domain of $T^D$ such that $h$ maps every positive atom and none of the negative atoms of $q'$ to a fact of $D_x \cup E$. We claim that the mapping $h'$ such that $h'(x) = a, h'(y) = 1, h'(z) = (a, 1)$ for every variable along the non-hierarchical path, and $h'(w) = \varnothing$ for the rest of the variables, maps every positive atom and none of the negative atoms of $q$ to facts of $D''_x \cup E''$; hence $(D''_x \cup E'') \models q$.

When considering the fact $S(a, 1)$ in the construction of $D'$, we have created a mapping $h'$ from the variables of $q$ such that $h'(x) = a, h'(y) = 1, h'(z) = (a, 1)$ for every variable along the non-hierarchical path, and $h'(w) = \varnothing$ for the rest of the variables, and we have added all the resulting facts (associated with atoms that are not one of $\alpha_x$ or $\alpha_y$) to $D'$ (as exogenous facts). When constructing $D''$ we have removed every such fact if it was generated from a negative atom of $q$. Hence, $h'$ is a mapping from the the variables of $q_{\{\alpha_x, \alpha_y\}}$ (which is the query obtained from $q$ by removing the atoms $\alpha_x$ and $\alpha_y$) to the domain of $D''$ such that every positive atom and none of the negative atoms of $q$ appears as a fact in $D''_x$. Moreover, it holds that $R(a) \in D_n$ if and only if $h'(\alpha_x) \in D''_n$ and similarly $T(1) \in D_n$ if and only if $h'(\alpha_y) \in D''_n$. There, $(D''_x \cup E'')$ indeed satisfies $q$ and that concludes our proof.

Next, we prove the following.

**Lemma C.2.** Let $E \subseteq D_n$ and let $E''$ be the set of corresponding facts in $D''_x$. If $(D_x \cup E) \not\models q$ then $(D''_x \cup E'') \not\models q$.

**Proof.** Assume, by way of contradiction, that $D''_x \cup E''$ satisfies $q$. Hence, there is a mapping $h$ from the variables of $q$ to the domain of $D''$ such that every positive atom and none of the negative atoms of $q$ is mapped into a fact in $D''_x \cup E''$. We now look at the non-hierarchical path $x = v_1 = \cdots = v_n = y$ in the Gaifman graph of $q$. From the construction of $D'$, every fact $f \in D'$ in a relation corresponding to an atom $\alpha_q$ that uses both $x$ and $v_1$ is obtained from $a$ by mapping the variable $x$ to some value $c_1$ and the variable $v_1$ to some value $(c_1, c_2)$ such that $S(c_1, c_2)$ is in $D$. If $a$ is positive, then $D''$ also contains only such facts, and if $a$ is negative, then $D''$ does not contain only such facts. Using an atom $\alpha'$ containing the variables $y$ and $v_n$, we can show, in a similar way, that $h(c_n) = (d_1, d_2)$ for some values $d_1, d_2$ such that $S(d_1, d_2)$ is in $D$. Finally, every two consecutive variables $v_i, v_{i+1}$ in the non-hierarchical path occur together in at least one atom $\alpha_q$ of $q$, and from the construction of $D''$, it holds that if $\alpha_q$ is positive, then $R_{\alpha_q}$ contains only facts where both $v_i$ and $v_{i+1}$ are mapped to the same value, and if $\alpha_q$ is negative, then these are the only facts that are not in $R_{\alpha_q}$; hence, we have that $h(v_i) = h(v_{i+1})$ and we conclude that $c_1 = d_1$ and $c_2 = d_2$, and the mapping $h$ assigns some value $(a, 1)$ to every variable along the non-hierarchical path, such that $S(a, 1)$ is in $D$.

When constructing the database $D'$, we have only assigned the value $(a, 1)$ to variables if there exists an exogenous fact $S(a, 1)$ in $D$. Hence, we have established that such a fact exists in $D$. Moreover, it holds that $(R(a) \in E$ if and only if $h(\alpha_x) \in E''$ and similarly $T(1) \in E$ if and only if $h(\alpha_y) \in E''$. In all cases, the restriction of $h$ to the variables $x$ and $y$ maps every positive atom and none of the negative atoms of $q''$ to $D_x \cup E$; thus, $(D_x \cup E) \models q'$, which is a contradiction to our assumption.

The remainder of the proof is rather straightforward based on these two lemmas. The total number of permutations of the facts in $D_n$ and $D''_x$ is equal, and the lemmas prove that the number of permutations where $f$ changes the result of $q''$ in $D'$ is equal to the number of permutations where it changes the result of $q$ in $D'$; hence, we conclude that Shapley$(D, q'', f) = \text{Shapley}(D', q, f)$.
Next, we provide the missing proofs for the lemmas used in the proof of the positive side of Theorem 4.3. First, we prove that we can replace every negated atom of $q$ corresponding to an exogenous relation of $D$ by a positive atom and the corresponding relation in $D$ by its complement relation, without affecting the Shapley value.

**Lemma C.3.** Let $q$ be a self-join-free $CQ^*$, and let $\alpha \in (\text{Atoms}(q) \setminus \text{Neg}(q))$. Then, computing Shapley($D$, $q$, $f$) can be reduced to computing Shapley($D'$, $q'$, $f$), where $q'$ is obtained from $q$ by substituting $\alpha$ with $\overline{\alpha}$, and $D'$ is obtained from $D$ by substituting $R^D_{\alpha}$ with $\overline{R^D_{\alpha}}$.

**Proof.** Note that the difference between $D$ and $D'$ is restricted to the exogenous facts; thus, we have that $D_n = D'_n$. Moreover, for every $E \subseteq D_n$, it holds that $(D_n \cup E) \models q$ if and only if $(D'_n \cup E) \models q'$. This is rather straightforward from the construction of $D'$. If $(D_n \cup E) \models q$, then there is a homomorphism $h$ from the variables of $q$ to the constants of $D$ that does not map $\alpha$ to any fact of $R^D_{\alpha}$ (since $\alpha$ is a negated atom); hence, it maps $\overline{\alpha}$ to a fact of $\overline{R^D_{\alpha}}$. Every other atom $\beta$ of $q$ also occurs in $q'$ and we have not changed the relations corresponding to other atoms; thus, $h$ maps $\beta$ to a fact of $(D_n \cup E)$ if and only if it maps $\beta$ to a fact of $(D'_n \cup E)$, and we conclude that $h$ maps every positive atom and none of the negative atoms of $\alpha$ to a fact of $(D'_n \cup E)$.

The proof of the second direction is very similar. If $(D'_n \cup E) \models q'$, then there is a homomorphism $h$ from the variables of $\alpha'$ to the constants of $D'$ that maps $\overline{\alpha}$ to a fact of $\overline{R^D_{\alpha}}$; hence, it does not map $\alpha$ to a fact of $R^D_{\alpha}$. Again, since the rest of the atoms are unchanged in $q'$, we conclude that $h$ maps every positive atom and none of the negative atoms of $q$ to a fact of $(D_n \cup E)$. We conclude that the total number of permutations is equal in both databases, and the number of permutations where $f$ changes the query result is equal as well; hence, Shapley($D$, $q$, $f$) = Shapley($D'$, $q'$, $f$). □

Next, we prove that we can combine all the exogenous atoms of $q$ in a connected component of $g_k(q)$ into a single exogenous atom, without affecting the Shapley value. Recall that from now on we assume (based on Lemma C.3) that every atom of $q$ corresponding to an exogenous relation of $D$ is positive.

**Lemma 4.4.** Computing Shapley($D$, $q$, $f$), given $D$ and $f$, can be efficiently reduced to computing Shapley($D'$, $q'$, $f$) for a $CQ^*$ $q'$ without self-joins such that: (1) every exogenous variable of $q'$ occurs in a single atom, and (2) $q'$ does not have any non-hierarchical path.

**Proof.** Let $C$ be a connected component of $g_k(q)$, and let the set $\{a_1, \ldots, a_k\}$ be the set of (exogenous) atoms in $C$. Let $q'$ be the query obtained from $q$ by replacing all the atoms of $C$ with a single atom $a_C$, such that $\text{Vars}(a_C) = \bigcup_{i \in \{1, \ldots, k\}} \text{Vars}(a_i)$. Observe that since $C$ is a connected component of $g_k(q)$, none of the exogenous variables occurring in $a_C$ also occurs in another atom of $q'$. Let $D'$ be the database obtained from $D$ by replacing the exogenous relations $R_{a_1}, \ldots, R_{a_k}$ with a single exogenous relation $R_{a_C}$ consisting of the set of answers to the query $q_C(x) : a_1, \ldots, a_k$ on the database $D$ (where every variable of $a_1, \ldots, a_k$ occurs in $x$). That is, the facts in the relation $R_{a_C}$ are obtained by an inner join between the relations $R^D_{a_1}, \ldots, R^D_{a_k}$, where the relations are joined according to the variables of the corresponding atoms.

Since we have only changed the exogenous relations in $D$ to obtain $D'$, we have that $D'_n = D_n$. We now prove that for every $E \subseteq D_n$, it holds that $(D_n \cup E) \models q$ if and only if $(D'_n \cup E) \models q'$, which implies that Shapley($D$, $q$, $f$) = Shapley($D'$, $q'$, $f$) for every endogenous fact $f$. Let $E \subseteq D_n$. If $(D_n \cup E) \models q$, then there is a homomorphism $h$ from $q$ to $D_n \cup E$. Note that the only negative atoms of $q$ are atoms corresponding to non-exogenous relations; hence, if $h$ does not map any negative atom of $q$ to a fact of $D_n \cup E$, it also does not map any negative atom of $q'$ to a fact of $D'_n \cup E$. As for the positive atoms, the homomorphism $h$ maps every positive atom of $q$ and, in particular, the atoms $a_1, \ldots, a_k$ of the connected component $C$, to facts of $D_n \cup E$. Assume that $h(u) = v_C$ for every variable in $a_1, \ldots, a_k$. By the definition of $q_C$, the tuple $(v_{u_1}, \ldots, v_{u_k})$ (where $v_{u_1}, \ldots, v_{u_k}$ are the variables occurring in $a_1, \ldots, a_k$) is an answer to $q_C$ and appears in $R^D_{a_C}$. Hence, the atom $a_C$ in $q'$ is mapped to a fact of $D'_n \cup E$. Every positive atom of $q$ that is not one of $a_1, \ldots, a_k$ also occurs in $q'$ and it is mapped to a fact of $D_n \cup E$ that also appears in $D'_n \cup E$; hence, we conclude that $h$ is a homomorphism from $q'$ to $D'_n \cup E$.

Similarly, if we assume that $(D'_n \cup E) \models q'$, then there is a homomorphism $h$ from $q'$ to $D'_n \cup E$. Every atom $\alpha \in (\text{Atoms}(q) \setminus \{a_1, \ldots, a_k\})$ occurs in both $q$ and $q'$, and the relation $R_{a_C}$ is the same in $D$ and $D'$; thus, every such $\alpha$ is mapped to a fact of $D_n \cup E$ if and only if it is mapped to a fact of $D'_n \cup E$. Since every fact in $R^D_{a_C}$ is an answer to $q_C$ on the database $D$, if the atom $a_C$ of $q'$ is mapped by $h$ to a fact $R_{a_C}(v_{u_1}, \ldots, v_{u_k})$ in $D'_n$, then every atom $\alpha$ in $\alpha$ is mapped by $h$ to a fact $R_{a_C}(v_{u_1}, \ldots, v_{u_k})$ in $D$ where $(v_{u_1}, \ldots, v_{u_k})$ is the set of variables occurring in $a_1$, as if such a fact did not exist, we would never obtain the tuple $(v_{u_1}, \ldots, v_{u_k})$ as an answer to $q_C$ on $D$. Hence, we have that $(D_n \cup E) \models q$, as evidenced by $h$.

The above argument holds for every connected component of $g_k(q)$; hence, we can replace every connected component with a single atom in $q$ and change the database $D$ accordingly. This will result in a query $q'$ where every exogenous variable occurs exactly once and that concludes our proof. We finish this proof by showing that $q'$ does not have a non-hierarchical path.

Let us assume, by way of contradiction, that the query $q'$ has a non-hierarchical path induced by the atoms $a_1$ and $a_2$. Hence, in the Gaifman graph of $q'$, there is a path $x = v_1 \cdots v_n = y$ that does not pass through the variables of $a_1$ and $a_2$. We claim that there is also a non-hierarchical path induced by $a_1$ and $a_2$ in $q$, in contradiction to the fact that $q$ does not have a non-hierarchical path. Let $v_i, v_{i+1}$ be two consecutive variables in the path. If $v_i$ and $v_{i+1}$ occur together in a non-exogenous atom of $q'$, then they occur together in the same non-exogenous atom of $q$, and $v_i, v_{i+1}$ are also connected in the Gaifman graph of $q$. Otherwise, $v_i, v_{i+1}$ occur together in an exogenous atom of $q'$, which exogenous atom represents a connected component $\{a_1, \ldots, a_k\}$ in $g_k(q)$. Let $a_C$ be the atom where the variable $v_i$ occurs and let $a_D$ be the variable where the variable $v_{i+1}$ occurs. By the definition of $g_k(q)$, there is a path $u_1 \cdots u_m$ between $a_1$ and $a_2$ such that $u_i \in a_1, u_m \in a_2$, and every $u_k$ is an exogenous variable (hence, it does not occur in $a_1$ or $a_2$). We conclude that the Gaifman graph of $q$ contains the path $v_i = u_1 \cdots u_m = v_{i+1}$ that does not pass through the variables of $a_1$ or $a_2$. Therefore, there is a non-hierarchical path between $x$ and $y$ in $q$, and that concludes our proof. □
In the next lemma we will use the following notation. For an atom \( \alpha \in \text{Atoms}(q) \), a variable \( \upsilon \in \text{Vars}(\alpha) \) and a fact \( f \in R^D_{\alpha} \), we denote by \( f[\upsilon] \) the value of the fact \( f \) in the attribute of \( R^D_{\alpha} \) corresponding to the position of \( \upsilon \) in \( \alpha \). For example, for \( \alpha = R(x, y, z) \), we denote by \( f[y] \) the value of the fact \( f \) in the second attribute of \( R^D \).

**Lemma 4.8.** Computing Shapley\((D, q, f)\) can be efficiently reduced to computing Shapley\((D', q', f)\) for a CQ\(^\neg\) \( q' \) without self-joins such that: (1) for every \( \alpha \in \text{Atoms}(q') \) there exists \( \alpha' \in \text{Atoms}(q') \) for which \( \text{Vars}(\alpha) = \text{Vars}(\alpha') \), and (2) \( q' \) does not have any non-hierarchical path.

**Proof.** As shown in Lemma 4.6, we can reduce the problem of computing Shapley\((D, q, f)\), given \( D \) and \( f \), to that of computing Shapley\((D', q', f)\) where \( q' \) is such that every exogenous variable occurs in a single atom of \( q' \). This means that every connected component of \( g(q') \) contains a single atom. Moreover, we have that \( q' \) does not have a non-hierarchical path. For convenience, from now on, we refer to the query \( q' \) simply as \( q \) and to the database \( D' \) simply as \( D \), as we do not rely on the original query and database in our proof. We show that we can further reduce the problem of computing Shapley\((D, q, f)\) to that of computing Shapley\((D', q', f)\), where for every \( \alpha \in \text{Atoms}(q') \) there is \( \alpha' \in \text{Atoms}(q') \) such that \( \text{Vars}(\alpha) = \text{Vars}(\alpha') \). We will do that by first removing the exogenous variables of \( q \) and then adding to every exogenous atom all the variables occurring in the non-exogenous atom that "contains" it.

Let \( \alpha \in \text{Atoms}(q) \). Lemma 4.4 implies that there exists \( \beta \in \text{Atoms}(q) \) such that \( \text{Vars}(\alpha) \subseteq \text{Vars}(\beta) \). We generate the query \( q' \) in two steps. First, we remove from \( \alpha \) every exogenous variable, and obtain a new atom \( \alpha' = R^\alpha(x_1, \ldots, x_n) \), where \( x_1, \ldots, x_n \) are the non-exogenous variables in \( \alpha \). Then, we replace the relation \( R^\alpha \) in \( D \) with the relation \( R^\alpha \) consisting of the set of answers to the query \( q(x_1, \ldots, x_n) \) on \( D \). In the next step, we obtain an atom \( \alpha'' \) by adding to \( \alpha' \) every variable in \( \text{Vars}(\beta) \setminus \text{Vars}(\alpha) \). That is, if \( \{v_1, \ldots, v_m\} \) is the set of variables occurring in \( \beta \) but not in \( \alpha \), then \( \alpha'' = R^\alpha(x_1, \ldots, x_n, v_1, \ldots, v_m) \). Then, we obtain the relation \( R^D_{\alpha''} \) from \( R^D_{\alpha'} \) in the following way. From every \( f = R^\beta(c_1, \ldots, c_n) \in R^D_{\alpha''} \), we generate \(|\text{Dom}(D)|\) facts of the form \( f = R^\alpha(c_1, \ldots, c_m, d_1, \ldots, d_m) \in \text{Dom}(D) \), where \( d_1, \ldots, d_m \in \text{Dom}(D) \), and add all of them to \( R^D_{\alpha''} \). We denote by \( q' \) the query obtained from \( q \) by replacing the atom \( \alpha \) with the atom \( \alpha'' \), and by \( D' \) the database obtained from \( D \) by replacing the relation \( R^\alpha \) with the relation \( R^\alpha '' \). Note that \( D_n = D_n' \).

Next, let \( E \subseteq D_n \) such that \((D'_n \cup E) \models q' \), as evidenced by a homomorphism \( h \). Again, every atom \( \beta \) of \( q' \) that is not \( \alpha'' \) also appears in \( q \), and \( h \) maps \( \beta \) to a fact of \( D \cup E \) if and only if it maps \( \beta \) to a fact of \( D' \cup E \). As for the atom \( \alpha'' \), the homomorphism \( h \) maps it to a fact \( f' \in R^D_{\alpha''} \). Assume that \( f' = R^\alpha''(c_1, \ldots, c_m) \). From the construction of \( D' \), we have that there exists a fact \( f \) in \( R^D_{\alpha} \) such that \( f[i] = c_i \) for every \( i \in \{1, \ldots, n\} \). Assume that the exogenous variables in \( \alpha \) are \( u_1, \ldots, u_k \), and \( f[u_j] = d_j \) for every \( j \in \{1, \ldots, r\} \). Then, if we extend the mapping \( h \) to a mapping \( h' \) such that \( h'(x) = h(x) \) for every non-exogenous variable \( x \in \alpha \) and \( h'(u_j) = d_j \) for every exogenous variable \( u_j \) in \( \alpha \), then \( h' \) will map the atom \( \alpha \) in \( q \) to the fact \( f \). Note that this extension does not affect any other atom of \( q \) since the exogenous variables of \( \alpha \) do not occur in any other atom of \( q \). Hence, the mapping \( h' \) is a homomorphism from \( q \) to \( D \cup E \), and \((D \cup E) \models q \).

We can repeat this process for every exogenous atom of \( q \) and obtain a query \( q' \) satisfying the property of the lemma, such that Shapley\((D, q, f) \) \( \models \) Shapley\((D', q', f) \) for every \( f \in D_n \). Finally, we prove that \( q' \) does not have a non-hierarchical path. Let us assume, by way of contradiction, that \( q' \) has a non-hierarchical path induced by the atoms \( \alpha_1 \) and \( \alpha_2 \). Hence, in the Gaifman graph of \( q' \), there is a path \( x = v_1 \cdots v_n - y \) that does not pass through the variables of \( \alpha_1 \) and \( \alpha_2 \). We claim that the same path exists in the Gaifman graph of \( q \), in contradiction to the fact that \( q \) does not have a non-hierarchical path. Let \( v_i, v_{i+1} \) be two consecutive variables in the path. If \( v_i, v_{i+1} \) occur together in a non-exogenous atom of \( q' \), then they occur together in the same non-exogenous atom of \( q \), and \( v_i, v_{i+1} \) are also connected in the Gaifman graph of \( q \). Otherwise, \( v_i, v_{i+1} \) occur together in an exogenous atom of \( q' \). Since there are no exogenous variables in \( q' \), both \( v_i \) and \( v_{i+1} \) occur in non-exogenous atoms of \( q \). Moreover, since for every exogenous atom \( \alpha \) in \( q \) there exists a non-exogenous atom \( \alpha'' \) of \( q' \) such that \( \text{Vars}(\alpha) = \text{Vars}(\alpha'') \), we again conclude that \( v_i, v_{i+1} \) occur together in the same non-exogenous atom of \( q \), and \( v_i, v_{i+1} \) are also connected in the Gaifman graph of \( q \).

\[ \square \]

### D. Details for Section 5

We now prove that the "gap property" does not hold for CQ\(^\neg\)\(s\).

**Theorem 5.1.** Let \( q \) be a satisfiable CQ\(^\neg\) with at least one negated atom. Assume that \( q \) has no constants, and that \( q \) is positively connected. There is a sequence \( \{D_n\}_{n=0}^\infty \) of databases and a fact \( f \) such that \(|\text{Dom}(D_n)| = \Theta(n) \) and \( 0 < |\text{Shapley}(D_n, q, f)| \leq e^{-\Theta(n)} \).

**Proof.** Since \( q \) is satisfiable, there exists a minimal database \( D \) such that \( D \models q \). Now, we start adding facts to the relations corresponding to negated atom of \( q \), one by one. Clearly, at some point, we will obtain a database \( D' \) that does not satisfy the query. Let \( f \) be the last fact added to \( D' \). We have that \((D' \setminus \{f\}) \models q \) but \( D' \not\models q \). Let \( D_n \) be a minimal database that satisfies this property. We create \( n \) copies \( D_1, \ldots, D_n \) of \( D_n \), such that \((\text{Dom}(D_1) \cap \text{Dom}(D_2)) = \emptyset \) for all \( i, j \in \{1, \ldots, n\} \) (this is possible since \( q \) has no constants). We denote by \( f_i \) the fact for which \((D_1 \setminus \{f_i\}) \models q \) for every \( i \in \{1, \ldots, n\} \). Next, let \( D'_n \) be a minimal database such that \( D'_n \not\models q \) and let \( f' \) be a fact in \( D'_n \). Since \( D'_n \) is minimal, we have that \((D'_n \setminus \{f'\}) \not\models q \). We create \( n + 1 \) copies \( D_0, D_{n+1}, \ldots, D_{2n} \) of \( D'_n \),
such that \((\text{Dom}(D_i) \cap \text{Dom}(D_j)) = \emptyset\) for all \(i, j \in \{0, \ldots, 2n\}\). We again denote by \(f_i\) the fact for which \((D_i \setminus \{f_i\}) \not\models q\) for every \(i \in \{0, n + 1, \ldots, 2n\}\). Finally, we construct a database \(D\) by taking the union of the databases \(D_0, \ldots, D_{2n}\). Every fact in \(D\) except for \(\{f_0, \ldots, f_{2n}\}\) will be exogenous. We will show that the fact \(f_0\) does not satisfy the gap property.

Note that \(D_i \models q\) since there is a homomorphism \(h\) from \(q\) to \((D_i \setminus \{f_i\})\) (and, in fact, to every \((D_i \setminus \{f_i\})\) for \(i \in \{1, \ldots, n\}\)), and we claim that the same \(h\) is a homomorphism from \(q\) to \(D\). Since \(q\) has safe negation, every variable in every negated atom of \(q\) also occurs in a positive atom of \(q\). Hence, if \(h\) maps a negated atom of \(q\) to a fact \(f \in D\), every value \(v\) in \(f\) is such that \(v \in \text{Dom}(D_i)\), and we have that \(f \in (D_i \setminus \{f_i\})\). This is a contradiction to the fact that \(h\) is a homomorphism from \(q\) to \((D_i \setminus \{f_i\})\).

Next, we prove that \((D_k \cup \{f_1, \ldots, f_n\}) \not\models q\). Assume, by way of contradiction, that this is not the case. Then, there is a homomorphism \(h\) from \(q\) to \(D_k \cup \{f_1, \ldots, f_n\}\). Assume that \(h\) maps the positive atoms of \(q\) to the facts \(g_1, \ldots, g_m\). Clearly, it cannot be the case that \(\{g_1, \ldots, g_m\} \subseteq D_i\) for some \(i \in \{1, \ldots, n\}\). This holds true since \((D_i \setminus \{f_i\})\) has a homomorphism \(h\) from \(q\) to \(D\). Since \(q\) is positive connected, the atoms \(x\) and \(y\) are connected. Thus, there is a path \(x = v_1, \ldots, v_t = y\) in the Gaifman graph of \(q\) from every variable \(x\) to every variable \(y\) in \(\beta\) such that all the atoms along the edges of the path are positive. Let \(x, y\) be arbitrary such variables. Since \(g_i \in D_k\), it holds that \(h(x) = c_x\) such that \(c_x \in \text{Dom}(D_k)\). Moreover, since \(g_i \in D_k\), it holds that \(h(y) = c_y\) such that \(c_y \in \text{Dom}(D_k)\). Since every two consecutive variables \(v_i, v_{i+1}\) in the path occur together in some positive atom, from the construction of \(D\), we have that \(h(v_i)\) and \(h(v_{i+1})\) are also both \(c_x\) and \(c_x\) in \(\text{Dom}(D_k)\) for some \(p \in \{0, \ldots, 2n\}\). \(v_i\) is the first variable in the path such that \(h(v_i) \not\in \text{Dom}(D_k)\). There exists such \(v_i\) since \(h(y) \not\in \text{Dom}(D_k)\). Then, we have that \(h(v_{i+1})\) is \(c_x\) in \(\text{Dom}(D_k)\) and \(h(v_i)\) is \(c_y\) in \(\text{Dom}(D_k)\) and we get a contradiction.

We have established that \((D_k \cup \{f_1, \ldots, f_n\}) \not\models q\). We will now prove that \((D_k \cup E) \not\models q\) for every \(E \subset D\) such that \(\{f_1, \ldots, f_n\} \not\in E\). Let \(f_i \in E\) such that \(i \in \{1, \ldots, n\}\). Let \(h\) be a homomorphism from \(q\) to \(D_k \cup E\). \(h\) is a homomorphism from \(q\) to \(D_k \cup E\). \(h\) is a homomorphism from \((D_k \setminus \{f_i\})\) (recall that \((D_k \setminus \{f_i\})\) \not\models q\). \(h\) maps a negated atom of \(q\) to a fact \(f \in (D_k \cup E)\) even \(f\) is such that \(v \in \text{Dom}(D_k)\), and we have that \(f \in (D_k \setminus \{f_i\})\). This is a contradiction to the fact that \(h\) is a homomorphism from \((D_k \setminus \{f_i\})\) to \(q\).

Finally, we have that \((D_k \cup E) \not\models q\) for \(E \not\in \emptyset\) we have that \((D_k \cup E) \not\models q\). Let \(f_i \in E\) such that \(i \in \{0, n + 1, \ldots, 2n\}\). Thus, \(D_k \models q\) there is a homomorphism \(h\) from \(q\) to \(D_k\). We claim that \(h\) is a homomorphism from \(q\) to \(D_k \cup E\). Clearly, every positive atom of \(q\) is mapped by \(h\) to a fact of \(D_k \cup E\) (since \(D_k \subseteq (D_k \cup E)\)). Again, since \(q\) has safe negation, we have that if \(h\) maps a negated atom of \(q\) to a fact \(f \in (D_k \cup E)\), then \(f \in D_k\) and we get a contradiction to the fact that \(h\) is a homomorphism from \(q\) to \(D_k\).

We conclude that the fact \(f_0\) must be added in a permutation before any of the facts \(f_{n+1}, \ldots, f_{2n}\) and after all the facts \(f_1, \ldots, f_n\) to affect the query result. Hence, there is exactly one subset \(E\) of endogenous facts in \(D\), containing \(n\) facts, that should appear before \(f\) in a permutation where it changes the query result from false to true; hence, the number of such permutations is \(\frac{2^n n!}{(2n+1)!}\) (as the total number of endogenous facts is \(2n + 1\)).

Finally, since we consider data complexity, we can assume that the size of each \(D_i\) is bounded by some constant \(k\). Hence, the database \(D\) contains \(\theta(n)\) facts. We have that, \(n = \theta(|D|)\) and the Shapley value of \(f\) w.r.t. \(q\) and \(D\) is \(\frac{n!}{(2n+1)!} < \frac{1}{2}\). Overall, we have that:

\[
0 < \text{Shapley}(D, q, f) \leq 2^{-n} = 2^{-\theta(|D|)}
\]

and that concludes our proof.

Next, we prove the following proposition.

**Proposition 5.5.** Deciding whether \(f \in T^D\) is relevant to \(qrst-r\)-given \(D\) and \(f\), \(D\), is NP-complete.

The following lemma states the NP-completeness of \((2^*, 2^*, 4^+)\)-SAT. (We found it easier to prove it directly rather than showing that it falls on the negative side of Schaefer’s dichotomy theorem [28].) As a preface to our proof, we define the \((3*, 2^-)\)-SAT problem: given a monotone 3CNF formula \(\phi\) where every literal is positive, and a monotone 2CNF formula \(\phi'\) where every literal is negative, defined over the same variables as \(\phi\), \(\phi \land \phi'\) satisfiable? We first prove that this problem is NP-complete using a reduction from the 3-colorability problem.\(^3\) Next, we define the \((2^*, 2^*, 4^+)\)-SAT problem, where the input is a conjunction of clauses of the following forms: (a) \((x_i \lor x_j)\), (b) \((\neg x_i \lor \neg x_j)\), or (c) \((x_i \lor x_j)\). We prove that this problem is NP-complete using a reduction from the \((3^*, 2^*)\)-SAT problem. Then, we will construct a reduction from the \((2^*, 2^*, 4^+)\)-SAT problem to that of deciding whether \(f\) is relevant.

**Lemma D.1.** The \((2^*, 2^*, 4^+)\)-SAT problem is NP-complete.

**Proof.** Given an undirected graph \(G = (V, E)\) and a set of three colours \(C = \{c_1, c_2, c_3\}\), we will build a \((3^*, 2^-)\)-CNF formula denoted as \(\phi\). For every \(v \in V\) and every \(c_i \in C\), we introduce a variable \(x_{v,c_i}\). For every vertex \(v \in V\), we introduce a clause \(x_{v,c_1} \lor x_{v,c_2} \lor x_{v,c_3}\). For every edge \((u, v) \in E\) and for every \(c_i \in C\), we introduce a clause \(\neg x_{u,c_i} \lor \neg x_{v,c_i}\). Since every vertex \(v \in V\) is mapped to a single color \(c_i\) in \(C\), and every edge \((u, v) \in G\) satisfies that \(h(u) \neq h(v)\). The correspondence of the reduction is rather clear. If \(G\) has a valid 3-colouring \(h\), if \(h\) is a mapping \(h : V \to C\), such that every vertex \(v \in V\) is mapped to a single color in \(C\), and every edge \((u, v) \in G\) satisfies that \(h(u) \neq h(v)\).
(x_i^C \lor x_j^C \lor x_k^C) is satisfied since h assigns a color to each vertex. Every clause of the form (\neg x_i^C \lor \neg x_j^C) is satisfied since in a valid colouring, two adjacent vertices cannot be mapped to the same color. In addition, h maps every vertex to a single color in C; therefore, each clause of the form (\neg x_i^C \lor \neg x_j^C) is satisfied as well. Overall, we have that \varphi is satisfiable.

Next, assume that \varphi is satisfiable, and let z be a satisfying assignment. We claim that the coloring h defined by h(v) = c_i if z(x_i^C) = 1 is a valid 3-coloring of G. Since all the clauses of the form (x_i^C \lor x_j^C \lor x_k^C) are satisfied, for every vertex v, the assignment z assigns the value 1 to at least one variable x_i^C. Moreover, since the clauses of the form (\neg x_i^C \lor \neg x_j^C) are satisfied, it cannot be the case that z(x_i^C) = z(x_j^C) = 1; hence, h does not map two vertices connected by an edge in G to the same color.

Next, we reduce the (3\textsuperscript{+}, 2\textsuperscript{-})-SAT problem to the (2\textsuperscript{+}, 2\textsuperscript{-}, 4\textsuperscript{-})-SAT problem. Given an input \varphi to the first problem, we build an input \varphi' to the second problem in the following way. Every clause in \varphi of the form (x_i \lor x_j \lor x_k) remains the same in \varphi'. Every clause of the form (x_i \lor x_j \lor x_k) in \varphi is replaced by three clauses in \varphi': (1) (x_i \lor x_j \lor \neg y \lor \neg y), (2) (x_k \lor y), and (3) (\neg x_k \lor \neg y), where y is a new unique variable introduced for every clause in \varphi. We claim that the clause (x_i \lor x_j \lor x_k) is satisfiable if and only if the formula (x_i \lor x_j \lor \neg y \lor \neg y) \land (x_k \lor y) \land (\neg x_k \lor \neg y) is satisfiable. This holds true since in every satisfying assignment z to the original clause, we either have that z(x_i) = 1, in which case we satisfy the new formula by defining y = 0, or we have that z(x_k) = 0, in which case z(x_i) = 1 = z(x_j) = 1 and by defining y = 1 we again satisfy the new formula. Now, given a satisfying assignment to the new formula, we either have that z(x_i) = 1 or z(x_j) = 1 in which case the original formula is clearly satisfiable, or we have that z(y) = 0 in which case z(x_k) = 1 (otherwise, the clause (x_i \lor y) is not satisfied) and again, the original formula is satisfied. Since we use different variables y for different clauses, we can assign the required value to each one of these variables, and that concludes our proof.

Next, we give a reduction from (2\textsuperscript{+}, 2\textsuperscript{-}, 4\textsuperscript{-})-SAT to the problem of deciding whether a fact \varphi' \in T_D is relevant to q\textsubscript{\text{q3S T-R}}. Given a formula \varphi \in (2\textsuperscript{+}, 2\textsuperscript{-}, 4\textsuperscript{-}), we build the input database D to our problem as follows: for every variable x_i in \varphi we add an endogenous fact R(i), and an exogenous fact T(i) to D. For every clause (x_i \lor x_j) in \varphi, we add an exogenous fact S(i,j,a,a) where a is a fresh constant. For every clause (\neg x_i \lor x_j) we add an exogenous fact S(b,i,j,k) where b is a new constant. For every (x_i \lor x_j \lor \neg x_k \lor x_i) in \varphi we add an exogenous fact S(i,j,\neg k,l). In addition, we add the exogenous facts S(d, d, c, c), R(a), R(c), T(a) where c and d are fresh constants, and an endogenous fact T(c) which we denote as f.

We now show that Shapley(D,q,f) \neq 0 if and only if \varphi is satisfiable. In fact, we show that Shapley(D,q,f) > 0 if and only if \varphi is satisfiable, since T appears only as a positive atom in q and f can only be positively relevant to q. Observe that D_a \models q since every (exogenous) fact S(i,j,a,a), along with the exogenous facts R(a), T(a) satisfies q. We assume here that every \varphi contains at least one clause of the form (x_i \lor x_j) (otherwise, there is no fact S(i,j,a,a) in D). We can assume that since the satisfiability problem is trivial for (2\textsuperscript{+}, 2\textsuperscript{-}, 4\textsuperscript{-}) formulas that do not contain at least one clause of the form (x_i \lor x_j) (as all such formulas are satisfied by the assignment z where z(x) = 0 for every variable x). Hence, the (2\textsuperscript{+}, 2\textsuperscript{-}, 4\textsuperscript{-})-SAT problem remains hard under this assumption.

Assume that \varphi is satisfiable by an assignment z, and consider the set E = \{R(i) \mid z(x_i) = 1\}. We claim that (D_a \cup E) \not\models q. For every exogenous fact S(i,j,a,a), at least one of facts R(i) or R(j) is in E, since the clause (x_i \lor x_j) is satisfied; hence, S(i,j,a,a), T(a) and R(a) cannot jointly satisfy q. Moreover, for every S(b,h,i,j), at most one of the facts R(i) and R(j) are in E, since the clause (\neg x_i \lor \neg x_j) is satisfied as well. Finally, for every S(i,j,k,l), it holds that if both R(k) and R(l) are in E, then at least one of R(i) and R(j) is in E as well, since the clause (x_i \lor x_j \lor \neg x_k \lor \neg x_l) is satisfied. On the other hand, it holds that (D_a \cup E \cup f) \not\models q, since the facts S(d,d,c,c), R(c) and T(c) are in (D_a \cup E \cup f) while the fact (d) is not. Therefore, we conclude that f is relevant to q\textsubscript{\text{q3S T-R}}.

Now, assume that \varphi is not satisfiable. Let E ⊆ (D_a \setminus \{f\}). Recall that the only endogenous facts in D_a \setminus \{f\} are the facts R(i) for i ∈ {1, …, n}. We now define the assignment z such that z(x_i) = 1 if and only if R(i) ∈ E. Since z is not a satisfying assignment, at least one clause c in \varphi is not satisfied. If c is of the form (x_i \lor x_j), then none of R(i) or R(j) is in E, in which case the exogenous facts S(i,j,a,a), R(a) and T(a) satisfy q. If c is of the form (\neg x_i \lor x_j), then both R(i) and R(j) are in E, and they satisfy q jointly with the facts S(b,h,i,j) and T(a) (as the fact R(k) is not in D). Otherwise, c is of the form (x_i \lor x_j \lor \neg x_k \lor \neg x_l), in which case none of R(i) or R(j) is in E, while both R(k), R(l) are in E; hence, the facts S(i,j,k,l), T(k), R(k) and R(l) jointly satisfy q. In all of these cases, we conclude that (D_a \cup E) \models q; thus, adding f in a permutation after the facts of E would not affect the query result, and f is not relevant to q\textsubscript{\text{q3S T-R}}. This concludes our proof of Proposition 5.5.

We now prove the correctness of IsPosRelevant and IsNegRelevant for deciding whether a fact is positively or negatively relevant to q. We start with IsPosRelevant and prove the following.

**Lemma D.2.** Let q be a polarity-consistent CQ\textsuperscript{+}. Then, the algorithm IsPosRelevant(D,q,f) returns true, given D and f, if and only if f is positively relevant to q.

**Proof.** Assume that f is positively relevant to q. Thus, there exists E ⊆ D_a such that (D_a \cup E) \not\models q while (D_a \cup E \cup \{f\}) \models q. Hence, there is a homomorphism h from the variables of q to the constants of D such that every positive atom and none of the negative atoms of q is mapped to a fact of D_a \cup E \cup \{f\}. We claim that the algorithm will return true in the iteration of the for loop when h is selected. By the definition of h we have that P ∈ (E \cup \{f\}), while for every f' \in N it holds that f' \not\in (E \cup \{f\}). Moreover, since (D_a \cup E) \not\models q, the homomorphism h maps a positive atom of q to f; hence f' \in P. Since q is polarity consistent, by adding a set of facts corresponding to negative atoms of q we cannot change the query result from false to true. Therefore, the fact that (D_a \cup E) \not\models q implies that (D_a \cup E \cup \{\neg q_{\textit{D}_a} \}) \not\models q. Since no fact of N appears in E, the set D_a \cup (P \setminus \{f\}) \cup (\neg q_{\textit{D}_a} \setminus N) can be obtained from D_a \cup E \cup (\neg q_{\textit{D}_a} \setminus N) by removing a set of facts corresponding to positive atoms of q, and, again, since q is polarity consistent, we conclude that (D_a \cup (P \setminus \{f\}) \cup (\neg q_{\textit{D}_a} \setminus N)) \not\models q.
Next, assume that the algorithm returns true. Thus, there exists a mapping \( h \) from the variables of \( q \) to the constants of \( D \) such that \((D_x \cup P \cup \{f\}) \setminus (\neg q(D_n) \cup \neg \{f\}) \neq q\). Let \( E = (P \setminus \{f\}) \cup (\neg q(D_n) \cup \{f\})\). We will now show that \((D_x \cup E \cup \{f\}) \models q\) and since \((D_x \cup E \cup \{f\}) \models q\), this will conclude our proof. By the definition of \( N \) and since \( h \) does not map any negative atom of \( q \) to a fact in \( D_x \), we have that \( h \) does not map any negative atom of \( q \) to a fact in \( D_x \cup E \cup \{f\} \). Moreover, since \( h \) maps every positive atom of \( q \) to a fact in \( D_x \cup P \cup (\neg q(D_n) \setminus N) \), we have that \((D_x \cup P \cup (\neg q(D_n) \setminus N) \cup \{f\}) \neq q\). Let \( E = (P \cup (\neg q(D_n) \setminus N)) \). We will now show that \((D_x \cup E) \models q\) and since \((D_x \cup E \cup \{f\}) \models q\), this will conclude our proof. By the definition of \( N \) and since \( h \) does not map any negative atom of \( q \) to a fact in \( D_x \), we have that \( h \) does not map any negative atom of \( q \) to a fact in \( D_x \cup E \cup \{f\} \). Moreover, since \( h \) maps every positive atom of \( q \) to a fact in \( D_x \), we have that every positive atom of \( q \) is mapped by \( h \) to a fact in \( D_x \cup P \). Therefore, we conclude that \( h \) is a homomorphism mapping every positive atom and none of the negative atoms of \( q \) to facts of \( D_x \cup P \cup (\neg q(D_n) \setminus N) \) and we have that \((D_x \cup E) \models q\). □

Finally, we prove that the relevance problem is hard for the UCQ \( \queriesAT\). Recall that \( \queriesAT\) is \( \exists q_1 \forall q_2 \forall q_3 \forall q_4 \) where:

\[
q_1(x) \models C(x_1, x_2, x_3, v_1, v_2, v_3), T(x_1, v_1), T(x_2, v_2), T(x_3, v_3)
\]

\[
q_2(x) \models V(x), \neg T(x, x), \neg T(x, \emptyset)
\]

\[
q_3(x) \models T(x, 1), T(x, 0)
\]

\[
q_4(x) \models R(\emptyset)
\]

**Proposition 5.8.** Given a database \( D \) and the fact \( f = R(\emptyset) \), deciding whether \( f \) is relevant to \( \queriesAT\) is \( \mathsf{NP}\)-complete.

**Proof.** We construct a reduction from the satisfiability problem for 3CNF formulas. The input to the satisfiability problem is a formula \( \varphi = (c_1 \land \cdots \land c_n) \) over the variables \( x_1, \ldots, x_n \), where each \( c_i \) is a clause of the form \( (l_1 \lor l_2 \lor l_3) \), and each \( l_i \) is either a positive literal \( x_i \) or a negative literal \( \neg x_i \) for some \( k \in \{1, \ldots, n\} \). Given such an input, we build an input database \( D \) to our problem as follows. For every variable \( x_i \), we add an exogenous fact \( V(i) \), and two endogenous facts \( T(i, 1) \) and \( T(i, 0) \). In addition, for every clause \( (l_1 \lor l_2 \lor l_3) \) where \( l_i = x_k \) or \( l_i = \neg x_k \) for each \( t \in \{i, j, k\} \), we add an exogenous fact \( C(i, j, k, v_1, v_2, v_3) \), such that \( v_1 = 1 \) if \( l_i = x_k \) and \( v_2 = 0 \) if \( l_i = \neg x_k \). Finally, we add the endogenous fact \( R(\emptyset) \) to which we denote as \( f \). We claim that \( f \) is relevant to \( \varphi \) if and only if \( \varphi \) is satisfiable.

Observe that \( E \models q \) for every \( E \subseteq D \) such that \( E \models f \), since \( f \) satisfies the query \( q_4 \) by itself. Hence, \( f \) is relevant (and, more precisely, positively relevant) if and only if there exist \( E \subseteq D \) such that \( (D_x \cup E) \models q \). Now, assume that \( q \) is satisfiable by the assignment \( z \). We will show that \( f \) is relevant to \( q \). Consider the subset \( E \subseteq D \) that contains every fact \( T(i, v_i) \) such that \( z(x_i) = v_i \). Since \( z \) is a truth assignment, it assigns a single value to each variable; hence, it is straightforward that \((D_x \cup E) \models q_2 \) and \((D_x \cup E) \models q_3 \). Regarding the query \( q_1 \), since \( z \) is a satisfying assignment, for every clause in \( \varphi \) there is at least one literal \( l_i \) such that \( z(x_i) = 0 \) if \( l_i = \neg x_i \) and \( z(x_i) = 1 \) if \( l_i = x_i \). Therefore, the fact \( T(x_i, z(x_i)) \) does not appear in \( E \), and we have that \((D_x \cup E) \models q \). We conclude that \((D_x \cup E) \models q \) while \((D_x \cup E \cup \{f\}) \models q \) and that concludes our proof of the first direction.

As for the other direction, given a subset \( E \subseteq D \) such that \((D_x \cup E) \models q \) while \((D_x \cup E \cup \{f\}) \models q \), we define an assignment \( z \) such that \( z(x_i) = 1 \) if \( T(i, 1) \in E \) and \( z(x_i) = 0 \) if \( T(i, 0) \in E \). Since \((D_x \cup E) \models q \), it cannot be the case that \( E \) contains both facts \( T(i, 1) \) and \( T(i, 0) \) (or, otherwise, \((D_x \cup E) \models q_3 \)) and it cannot be the case that none of \( T(i, 1) \) and \( T(i, 0) \) belongs to \( E \) for some \( x_i \) (as otherwise, \((D_x \cup E) \models q_4 \)). Hence, \( z \) is a truth assignment. It is
only left to show that $z$ is a satisfying assignment. Assume, by way of contradiction, the clause $(l_i, l_j, l_k)$ is not satisfied. In this case, $z(x_t) = 0$ if $l_t = x_t$ and $z(x_t) = 1$ if $l_t = \neg x_t$ for each $t \in \{i, j, k\}$. Since $E$ contains a fact $T(t, z(x_t))$ for every variable $x_t$, this will imply that the facts $T(i, z(x_i)), T(j, z(x_j))$ and $T(k, z(x_k))$ satisfy $q_1$ jointly with the exogenous fact $(i, j, k, z(x_i), z(x_j), z(x_k))$, which is a contradiction to the fact that $(D_\chi \cup E) \nvDash q$.

Since the satisfiability problem is NP-complete for 3CNF formulas, we conclude that the relevance problem for the given UCQ is NP-complete as well. □
