We calculate the carrier density dependent ground state properties of graphene in the presence of random charged impurities in the substrate taking into account disorder and interaction effects non-perturbatively on an equal footing in a self-consistent theoretical formalism. We provide detailed quantitative results on the dependence of the disorder-induced spatially inhomogeneous two-dimensional carrier density distribution on the external gate bias, the impurity density, and the impurity location. We find that the interplay between disorder and interaction is strong, particularly at lower impurity densities. We show that for the currently available typical graphene samples, inhomogeneity dominates graphene physics at low ($\lesssim 10^{12} \text{ cm}^{-2}$) carrier density with the density fluctuations becoming larger than the average density.

PACS numbers:

The recent experimental realization [1] of single-layer graphene sheets has spurred an enormous amount of activity in studying the electronic properties of 2D chiral Dirac fermions in the context of solid state materials physics. While much of this interest is fundamental, a substantial part of it also derives from the technological prospect of graphene being used as a novel transistor material. To understand current experiments and be able to design future graphene-based electronic devices it is essential to know the properties, origin and effects of extrinsic disorder in graphene. The low energy electronic states of graphene are described by a massless Dirac equation. In clean isolated graphene (the so-called intrinsic graphene) the Fermi energy lies exactly at the Dirac point (i.e. the charge neutrality point) where the linear chiral electron and hole bands cross each other. Several works [2] calculated the graphene conductivity assuming the graphene Fermi energy to be exactly at the Dirac point throughout the graphene layer. These works found the Dirac point conductivity to be either 0, $\infty$ or, in the limit of vanishing disorder, equal to the universal value $\sigma_D \equiv 4e^2/\pi\hbar$. In current experiments however the measured conductivity at the Dirac point [3] is finite and much bigger (by a factor of 2-20) than the universal theoretical prediction $\sigma_D$ and varies strongly from sample to sample. The discrepancy can be resolved if we consider that disorder in addition to represent the main source of scattering has an other important effect: it locally shifts the Dirac point removing, at zero gate voltage, the Fermi energy from the charge neutrality point [3]. This leads immediately to a disorder-induced inhomogeneous density landscape with electron-hole puddles. Such puddles have been proposed theoretically [4, 5] and observed experimentally [6, 7]. Experiments, by themselves, are unable to directly identify the cause of the carrier density inhomogeneities. Two kinds of disorder have been proposed in graphene to have this effect: ripples [8] and random charge impurities [9]. Transport theories [3, 9, 10, 11] based on the presence of charge impurities have been successful in explaining the experimental results [3]. But whether the puddles arise from the random charged impurities or from some other mechanism [8] has remained an open question. We provide in this Letter the first realistic theoretical description of the electron-hole puddles in graphene assuming the random charged impurity disorder to be the underlying mechanism. Our theoretical results are in excellent qualitative agreement with the existing experimental data [3, 7]. A quantitative comparison between our results and future experiments with higher quantitative accuracy would enable a definitive understanding of the nature of the disorder in graphene.

At low energies the quasiparticles in graphene can be described by a massless Dirac-fermion, MDF, model with an ultraviolet cutoff wave vector $k_c$. We set $k_c = 1/a_0$, where $a_0$ is the graphene lattice constant, $a_0 = 0.246 \text{ nm}$, corresponding to an energy cut-off $E_c \approx 3 \text{ eV}$, and measure the energies from the Dirac point. To find the ground-state carrier density $n$ we use the Thomas-Fermi-Dirac (TF) theory. In contrast with the standard TF theory we retain the exchange potential non perturbatively through its local density approximation so that the energy functional $E[n]$ reads:

$$E[n] = \hbar v_F \left[ \frac{2\sqrt{\pi}}{3} \int d^2 r \sgn(n)|n|^{3/2} + \frac{r_s}{2} \int d^2 r \int d^2 r' \frac{n(r)n(r')}{|r-r'|} \right] + \frac{E_{ex}[n]}{\hbar v_F} + r_s \int d^2 r V_D(r)n(r) - \frac{\mu}{\hbar v_F} \int d^2 r n(r)$$

(1)

where $v_F = 10^6 \text{ m/s}$ is the Fermi velocity, $r_s \equiv e^2/(\hbar^2 v_F)$ is the coupling constant with $\epsilon$ the effective background dielectric constant, $E_{ex}[n]$ is the exchange energy, $V_D$ is the disorder potential and $\mu$ is the chemical potential. The first two terms in (1) are the kinetic energy and the Hartree part of the Coulomb interaction, respectively. For graphene on SiO$_2$ substrate $\epsilon = 2.5$ and then $r_s =$
0.8. By differentiating $E[n]$ with respect to $n$ we find:

$$\frac{\delta E}{\delta n} = \hbar v_F \left[ \text{sgn}(n) \sqrt{\pi |n|} + \frac{r_s}{2} \int \frac{n(r') d^2 r'}{r - r'} + r_s V_D \right] + \Sigma(n) - \mu$$

(2)

where $\Sigma(n)$ is the Hartree-Fock self-energy evaluated at the Fermi wavevector $k_F = \text{sgn}(n) \sqrt{\pi |n|}$:

$$\Sigma(n) = \sqrt{\pi |n|} \text{sgn}(n) n_s \left[ \frac{1}{4} \ln \frac{4k_F}{\sqrt{\pi |n|}} - \frac{2C + 1}{2\pi} + \frac{1}{8} \right]$$

(3)

where $C \approx 0.916$.

We assume $V_D$ to be the 2D Coulomb potential in the graphene plane generated by a random 2D distribution, $C(r)$, of impurity charges placed at a distance $d$ from the graphene layer. Denoting by angular brackets the average over disorder realizations we assume:

$$\langle C(r) \rangle = 0; \quad \langle C(r_1) C(r_2) \rangle = n_{imp} \delta(r_2 - r_1)$$

(4)

where $n_{imp}$ is the 2D impurity density. A non zero value of $\langle C(r) \rangle$ can be taken into account by a shift of $\mu$, i.e. of the gate voltage. $n_{imp}$ and $d$ should be taken as effective parameters characterizing the impurity distribution in a minimal two parameter model. In current graphene samples obtained through mechanical exfoliation possible sources of charge impurities are most likely ions in the substrate that drift close to the surface, charges trapped between the graphene layer and the substrate and free charges that stick to the top surface of the graphene layer. This picture is consistent with the vast literature on disorder in Si MOSFET and has recently been indirectly confirmed by experiments on suspended graphene. The values of $n_{imp}$ extracted from transport measurements, and used in this work, are indeed of the same order of magnitude, $[10^{11} - 10^{12}] \text{ cm}^{-2}$, as the ones used to describe quantitatively disorder effects of MOSFET devices on SiO$_2$. Combining Eq. (2) - (3) we find the ground state carrier density by solving the equation $\delta E/\delta n = 0$ using the steepest descent method. Our calculations are done for a finite square lattice of size $L \times L$. All the results presented in this Letter are obtained for $L = 200$ nm and are found to be independent of system size for $L \gtrsim 100$ nm. For the discretization in real space we use a $1$ nm step.

For a given disorder realization, for $\mu = 0$, a typical result, including exchange, for $n(r)$ is shown in Fig. 1 (a). For $n > 0$ ($n < 0$) we have particles (holes). The result without exchange is characterized by larger density fluctuations. This is clear from Fig. 1 (b) which shows that the density distribution is more strongly peaked around $n = 0$ when exchange is taken into account. The result of Fig. 1 (b) is counter-intuitive because exchange suppresses density inhomogeneity instead of enhancing it as in parabolic-band inhomogeneous electron liquids. A complementary DFT-LDA calculation, using single disorder realizations with few impurities, has also found similar results. Contrary to our work in the correlation contributions have been taken into account. Given the numerical complexity of the DFT-LDA approach in only small samples were considered and disorder averaged results, that would permit a close quantitative comparison, were not presented. The results for single disorder realizations are qualitatively similar to ours, showing that correlation terms have only a minor quantitative effect. The reason is that in graphene to very good approximation the correlation term scales with $n$ in the same way as exchange but with opposite sign and therefore its effect is to simply reduce the exchange strength.

The results of Fig. 1 are visually very similar to the ones observed in experiments, but a quantitative comparison can only be achieved by calculating the disorder-averaged statistical properties. For a given quantity $X$ we therefore calculate its disorder averaged value, $\langle X \rangle$, and spatial correlation function $\langle (\delta X(r))^2 \rangle = \langle (X(r) - \langle X \rangle)(X(0) - \langle X \rangle) \rangle$. From these results we extract the rms of the fluctuations, $X_{rms} = \sqrt{\langle (\delta X(0))^2 \rangle}$, and their typical correlation length $\xi_X \equiv \text{FWHM}$ of $\langle (\delta X(r))^2 \rangle$. At the neutrality point $\xi \equiv \xi_\text{n}$ can be loosely taken as a measure of the electron-hole puddle size. In Fig. 2 we present the disordered averaged results at the Dirac point as a function of $n_{imp}$. We see that exchange suppresses the amplitude of the density fluctuations and increases their correlation length and that its effect becomes increasingly important as the impurity density decreases; for the lowest $n_{imp}$ the value of $n_{rms}$ including exchange is 3 times smaller than the value obtained without exchange, Fig. 2 (a). In addition we see that the scaling of $n_{rms}$ with $n_{imp}$ is very different with and without exchange. From Fig. 2 (b) we see that as $n_{imp}$ decreases $\xi$ increases very slowly, especially for low values of $d$, a result that underlines the importance of nonlinear screening terms. Adapted to a 2D distribution of charges the approach used in Ref. 16 for the scaling of $\xi$ on $n_{imp}$ gives $\xi \approx 1/(r_s \sqrt{n_{imp}})$. For $r_s = 0.8$ and $n_{imp} = 2 \times 10^9 \text{ cm}^{-2}$ we would then expect $\xi \approx 350$ nm, a value an order of magnitude larger than the value shown.
in Fig. 2(b). The reason for this discrepancy is that for small values of \( n_{imp} \) the carrier distribution is not characterized by smooth long-range fluctuations but rather by wide regions of very small carrier density (\( \approx 0 \)) interspersed with small electron-hole puddles with the typical size \( \xi \) shown in Fig. 2(b). This picture is confirmed in Fig. 2(c) where the disorder averaged area fraction, \( A_0 \), over which \( |n(r) - \langle n \rangle| < n_{rms}/10 \) is plotted as a function of \( n_{imp} \). We see that as \( n_{imp} \) decreases \( A_0 \) increases reaching more than 1/3 at the lowest impurity densities. The fraction of area over which \( |n(r) - \langle n \rangle| \) is less than 1/5 of \( n_{rms} \) surpasses 50% for \( n_{imp} \lesssim 10^{10} \text{cm}^{-2} \). Thus, much of the 2D landscape in this situation has very low (\( \ll n_{imp} \)) carrier density with a few random electron-hole puddles. In Fig. 2(d) the dependence of the excess charge \( \delta Q \equiv n_{rms} \pi \xi^2 \) on \( n_{imp} \) is shown. At high impurity densities (\( \gtrsim 10^{12} \text{cm}^{-2} \)) and values of \( d \gtrsim 1 \text{nm} \), \( \delta Q \) can be approximately identified with the average number of carriers per puddle, however the above discussion and the results for \( A_0 \) allow us to recognize that \( \delta Q \) for small \( n_{imp} \), is not the typical number of carriers per puddle. We see that for small \( n_{imp} \) (and/or \( d \)), because of the large fraction of area over which \( |n(r) - \langle n \rangle| \ll n_{rms} \), \( n_{rms} \) is much smaller than the typical carrier density in a electron-hole puddle of size \( \xi \). At low \( n_{imp} \) \( \delta Q \) grossly underestimates the number of carriers in a typical puddle of size \( \xi \). We find that at low \( n_{imp} \), \( n \) in these electron-hole puddles is a factor of 10 or more higher than \( n_{rms} \). This can already be seen for relatively high values of \( n_{imp} \) and \( d \); from Fig. 3(a) we see that \( |n| \) inside the electron-hole puddles takes values as high as \( 8 \times 10^{12} \text{cm}^{-2} \). The corresponding value of \( n_{rms} \) is only \( 8 \times 10^{11} \text{cm}^{-2} \), Fig. 3(a). Even in the limiting case of an isolated impurity with \( d = 0 \) the density profile obtained using the TF approach \( [17] \) is very similar to the one obtained starting from the Dirac equation and treating the interaction via RG \( [18] \). The additional \( \delta(r) \) for \( n(r) \) found in \( [18] \) and \( [19] \) in real graphene, in which the MDF model applies only at low energies, is regularized by \( \max(d, a_0) \), \( [20] \).

Our results are therefore quantitatively accurate.

From the theoretical analysis \( [5, 9, 10, 11] \) and experimental transport results \( [3] \) one obtains for typical graphene samples on SiO\(_2\), \( d = 1 \text{nm} \) and \( n \approx 3 \times 10^{11} \text{cm}^{-2} \). For these values, from Fig. 2(a) and (b) we see that \( n_{rms} \approx 3 \times 10^{11} \text{cm}^{-2} \) and \( \xi = 9 \text{nm} \). The value of \( n_{rms} \) is in very good agreement with the recent STM \( [7] \) and SET \( [8] \) results. The value of \( \xi \) is also in very good agreement with the STM results and consistent with the results of Ref. \( [9] \) that, given the lower SET spatial resolution (\( \gtrsim 150 \text{nm} \)), could only provide for \( \xi \) an upper bound of 30 nm.

At a finite gate voltage, \( V_g \), the average carrier density \( \langle n \rangle = C_g V_g/e \) is induced, where \( C_g \) is the gate capacitance. In our calculations we indirectly fix \( \langle n \rangle \) by varying the chemical potential \( \mu \). The relation between \( \mu \) and \( \langle n \rangle \) is shown in Fig. 3(a). Contrary to ordinary parabolic band fermionic systems the relation between \( \mu \) and \( \langle n \rangle \) strongly depends on disorder even when exchange is neglected. This is also shown in Fig. 3(b) in which \( \mu \) is plotted as a function of \( n_{imp} \) for a fixed value of \( \langle n \rangle \). The dependence of \( \mu(\langle n \rangle) \) on \( n_{imp} \) even without exchange is due to the fact that in graphene the kinetic energy does not scale linearly with \( n \). From Fig. 3(a) we see that only for \( n_{imp} \lesssim 10^{10} \text{cm}^{-2} \) \( \mu(\langle n \rangle) \) follows the equation valid for clean graphene. We also notice that \( \mu(\langle n \rangle) \) is strongly affected by exchange. The results of Fig. 3 demonstrate the interplay of disorder and interaction in graphene and show how the dependence of \( \mu \) on \( \langle n \rangle \), and in particular the average compressibility \( 1/(n^2 \partial \mu/\partial n) \), can be used to probe the strength of disorder and many-body effects. In Fig. 3(a) the disorder averaged density distribution obtained including exchange is plotted for different values of \( \langle n \rangle \), i.e. of \( V_g \). For \( V_g = 0 \) the distribution has a strong peak (\( \approx 20 \) times the maximum of the y-scale of Fig. 4(a)) at \( n = 0 \). As \( V_g \) increases the \( n \) peak survives and a broad peak at finite \( n \) develops. For large enough \( V_g \) the \( n = 0 \) peak disappears and the density distribution is characterized only by the broad peak centered at \( n = \langle n \rangle \). The results without exchange are qualitatively similar. The double peak structure for finite \( V_g \) provides direct evidence for the existence of puddles over a finite voltage range. High values of \( V_g \) remove one
mentally. That in current samples $n = 5 \times 10^{11} \text{ cm}^{-2}$, as high as for clean graphene with (without) exchange. The inset of Fig. 4 (b) shows $\mu(n)$ for $n$ as a function of $n_{\text{imp}}$ for $d = 1 \text{ nm}$. We can see that in current samples $n_{\text{rms}} > \langle n \rangle$ for carrier densities as high as $\langle n \rangle \approx 10^{12} \text{ cm}^{-2}$. The particular dependence of the carrier density distribution and $n_{\text{rms}}$ on $V_g$ are unique to inhomogeneities created by charged impurities and is a prediction that should be easy to verify experimentally.

We conclude by summarizing our key qualitative findings: (1) both disorder and many-body effects become quantitatively very important on the chemical potential close to the Dirac point; (2) many body effects are more important at lower values of $n_{\text{imp}}$; (3) for low $n_{\text{imp}}$ the ground state near the Dirac point is characterized by small puddles and large regions of almost zero ($|n| \ll n_{\text{imp}}$) carrier density; (4) in current samples $n_{\text{rms}} \gtrsim \langle n \rangle$ for carrier densities as high as $\langle n \rangle \approx 10^{12} \text{ cm}^{-2}$; (5) the number of carriers per puddle is $\sim 1-5$ at low carrier densities; (6) our theory agrees well with the existing data but more experiments will be required to test our quantitative predictions.

We thank S. Adam, M. Fuhrer, E. H. Hwang, and especially A. H. MacDonald for discussions. The numerical calculations have been performed on the University of Maryland High Performance Computing Cluster (HPCC). This work is supported by NSF-NRI-SWAN and US-ONR.
