LOGARITHMIC AFFINE STRUCTURES,
PARALLELIZABLE $d$-WEBS AND NORMAL FORMS

RUBEN LIZARBE AND FRANK LORAY

Abstract. We study the local analytic classification of affine structures with logarithmic pole on complex surfaces. With this result in hand, we can get the local classification of the logarithmic parallelizable $d$-webs, $d \geq 3$.

1. Introduction

An affine structure on a (smooth) complex surface $S$ is a maximal atlas of charts $(\phi_i : U_i \to \mathbb{C}^2)$ with transition charts $\phi_j \circ \phi_i^{-1}$ induced by global affine transformations

$$\text{Aff}(\mathbb{C}^2) = \{ F : \mathbb{C}^2 \to \mathbb{C}^2 ; \ Z \mapsto AZ + B, \ A \in \text{GL}_2(\mathbb{C}), \ B \in \mathbb{C}^2 \}$$

(see [6] and references therein). In other words, this is a $(G, X)$-structure in the sense of Ehresmann-Thurston, where $X = \mathbb{C}^2$ and $G = \text{Aff}(\mathbb{C}^2)$. The vector space of constant vector fields $\mathbb{C}(\partial_x, \partial_y)$ on $X = \mathbb{C}^2$ is invariant under the action of $\text{Aff}(\mathbb{C}^2)$ and is therefore well defined locally on $S$ when pulled-back by the special charts $\phi_i$’s. This defines a flat (or curvature free) and torsion free affine connection $T_S \times T_S \to T_S$ ; $(X, Y) \mapsto \nabla_X Y$ whose local horizontal sections correspond to these vector fields. Flatness provides the existence of a basis $(Y_1, Y_2)$ of local horizontal sections, i.e. $\nabla_X Y_i = 0$ for all $X$. Torsion freeness implies commutativity of the corresponding vector fields $[Y_1, Y_2] = 0$. See section 2 for more details. Klingler classified in [6] all affine structures on compact complex surfaces.

In general, none of the local commuting vector fields are globally defined, due to the monodromy of the connection, which is the linear part of the...

monodromy of the affine structure. However, the case of finite monodromy can be related to stronger structure. For instance, when the monodromy is trivial, then the commuting vector fields globalize to define a flat pencil of foliations in the sense of [7]. When the monodromy is finite, of order $d$ say, then we get parallelizable $d$-webs.

The goal of this work is to investigate a singular version of these structures. A **meromorphic affine structure** on $S$ is a meromorphic affine connection $\nabla$ on $S$ (i.e. with meromorphic Christoffel symbols in local trivializations) with identically vanishing torsion and curvature. We will say that the meromorphic affine structure is **logarithmic** (resp. **regular-singular**) if the corresponding affine connection, viewed as a linear meromorphic connection on the tangent bundle, is logarithmic (resp. regular-singular) in the sense of [3]. The polar set defines a divisor $D$ on $S$ and our aim in this paper is to provide a sharp description of the regular affine structure at the neighborhood of a generic point of (the support of) $D$. In order to list our models, it is convenient to describe the closed 1-forms $\omega_t$ corresponding to constant 1-forms $dx + tdy$ on $X = \mathbb{C}^2$ rather than vector fields or connection.

**Theorem A.** Let $S$ be a complex surface, and $\nabla$ be a logarithmic affine structure on $S$ with polar divisor $D$. Then, at a generic point $p$ of $D$, there are local coordinates $(S,p) \to (\mathbb{C}^2,0)$ such that the affine structure belongs to one of the following models (with pole $\{y = 0\}$):

1. $\omega_t = dx + ty^\nu dy$, $\nu \in \mathbb{C}^*$,
2. $\omega_t = dx + t\left(\frac{dw}{y} + \frac{dw}{y}\right)$, $n \in \mathbb{Z}_{>1}$,
3. $\omega_t = dx - y^n \ln(y)dy + ty^ndy$, $n \in \mathbb{Z}_{\geq 0}$,
4. $\omega_t = \frac{dw}{y^n} + (c-x)\frac{dw}{y^n} - \ln(y)dx + tdx$, $n \in \mathbb{Z}_{>1}$, $c = 0, 1$.

Here, generic point means any point outside a discrete subset that includes at least singular points of $D$. Outside the divisor $D$, we get a regular affine structure whose local charts are obtained by integrating $\phi = (\int \omega_0, \int \omega_\infty)$. The local affine charts degenerate along $D$, and may have monodromy around.

One of our motivations comes from the study of singular $d$-webs (see [1], [4], [16] or [18]). In the regular setting, a $d$-**web** $\mathcal{W} = \mathcal{F}_1 \boxtimes \cdots \boxtimes \mathcal{F}_d$ is locally given by $d$ foliations $\mathcal{F}_i$ in general position (i.e. pairwise transversal). We will say that $\mathcal{W}$ is **parallelizable**, if there exist local coordinates $(x, y)$ in which $\mathcal{F}_i : dx + t_i dy$ for $i = 1, \ldots, d$. When $d \geq 3$, then these normalizing coordinates are unique up to affine transformation and such a $d$-web therefore defines an affine structure. In the singular setting, a $d$-web is defined
by a multi-section of the projectivized tangent bundle \( \pi : \mathbb{P}(T_S) \to S \), i.e. a surface \( \Sigma_W \subset \mathbb{P}(T_S) \) without vertical component, that intersects a generic fiber at \( d \) distinct points. The discriminant \( \Delta_W \) in \( S \) is the locus of points \( p \in S \) where \( \pi^{-1}(p) \) intersect \( \Sigma_W \) at \( < k \) points: it is the singular locus of \( W \). The singular \( d \)-web is said parallelizable if the regular \( k \)-web induced on \( S \setminus \Delta_W \) is parallelizable. It turns out that, for \( d \geq 3 \), a singular parallelizable \( d \)-web defines a meromorphic affine structure with regular-singular poles along \( \Delta_W \) (and smooth outside). We say that \( W \) is logarithmic if the affine structure is so. In that direction, we can prove:

**Theorem B.** Let \( W \) be a singular parallelizable \( d \)-web on \( S \), \( d \geq 3 \), with logarithmic singular points. Then, at a generic point of the discriminant \( \Delta \), \( W \) is contained in one of the following pencils:

1. \( \{(dx)^q + ty^p(dy)^q = 0\}_t \), with \( (p, q) \) relatively prime positive integers,
2. \( \{y^p(dx)^q + t(dy)^q = 0\}_t \), with \( (p, q) \) relatively prime positive integers,
3. \( \{y^{n+1}dx + t(1 + y^n)dy = 0\}_t \), with \( n \) positive integer.

For instance, in the first case, for each \( t \) we get a \( q \)-web, except for \( t = 0 \) or \( \infty \) where we get a single foliation \( dx \) or \( dy \); then \( W \) is the superposition of several of these webs. In the last item, the monodromy is trivial and the web splits as a union of \( d \) foliations belonging to the pencil.

In the second section, we introduce the notions of affine connections, Riccati foliations and pencils of foliations and the corresponding notions of curvature and torsion. The regular setting is already described in [8], and we explain how to adapt to the singular setting. In particular, we establish one-to-one correspondence between meromorphic affine structures and singular parallelizable Riccati foliations. An important example of Riccati foliations is induced by a pencil of foliations on a surface that will allow us to understand other cases.

In the third section, we prove our first main result about local classification of affine structures with logarithmic pole.

In the fourth section we give a brief exposition of \( d \)-webs on surfaces, \( d \geq 3 \), with constant cross-ratio to later establish a relationship between Riccati foliations and webs. Then we deduce our second main result about the local normal forms of logarithmic hexagonal \( d \)-webs.

### 2. Affine structure, affine connection and Riccati foliations

An affine structure on a smooth complex surface \( S \) is a maximal atlas of charts \( (\phi_i : U_i \to \mathbb{C}^2) \) with transition charts \( \phi_j \circ \phi_i^{-1} \) induced by global affine
transformations

$$\text{Aff}(\mathbb{C}^2) = \{ F : \mathbb{C}^2 \to \mathbb{C}^2 ; \ Z \mapsto AZ + B, \ A \in \text{GL}_2(\mathbb{C}), \ B \in \mathbb{C}^2 \}.$$  

If $\phi : U \to \mathbb{C}^2$ is in the atlas, then any $F \circ \phi : U \to \mathbb{C}^2$ is also in the atlas, and any chart on $U$ belonging to the atlas takes this form. Any local chart can be continued analytically along any path. Indeed, given a path $\gamma : [0, 1] \to S$ starting from $p_0 = \gamma(0) \in U$, then we can cover $\gamma$ by open sets $U_0 = U, U_1, \ldots, U_n$ such that

- when $t \in [0, 1]$ increases from 0 to 1, then $\gamma(t)$ intersects successively the $U_i$'s with $i$ increasing from 0 to $n$,
- intersections $U_i \cap U_{i+1}$ are contractible,
- there is a well-defined chart $\phi_i : U_i \to \mathbb{C}$ in the affine atlas.

Then we have $\phi_i = F_{i,i+1} \circ \phi_{i+1}$ on $U_i \cap U_{i+1}$ so that $F_{i,i+1} \circ \phi_{i+1}$ provides an analytic extension of $\phi_i$ on $U_{i+1}$. Starting from $\phi_0 = \phi$ on $U$, we can extend it successively as follows

$$\phi_0 = F_{0,1} \circ \phi_1 = F_{0,1} \circ F_{1,2} \circ \phi_2 = \cdots = F_{0,1} \circ F_{1,2} \circ \cdots \circ F_{n-1,n} \circ \phi_n =: \phi^\gamma.$$  

We can check that the analytic continuation $\phi^\gamma$ of $\phi$ along $\gamma$ depends only on the homotopy type of $\gamma$ with fixed boundary. When $\gamma$ is a loop (and $U_0 = U_n$, $\phi_0 = \phi_n = \phi$), then we get

$$\phi^\gamma = F_{0,1} \circ F_{1,2} \circ \cdots \circ F_{n-1,n} \circ \phi = F_\gamma \circ \phi$$

and this defines the monodromy representation

$$\pi_1(S, p_0) \to \text{Aff}(\mathbb{C}^2) ; \ \gamma \mapsto F_\gamma.$$  

One can locally pull-back constant vector fields $\mathbb{C}\langle \partial_x, \partial_y \rangle$ by affine charts and we get, locally on $S$, a two-dimensional vector space of commuting vector fields. Mind that none of these vector field is globally defined, due to the monodromy of the structure: the linear part of $F_\gamma$ acts on this vector space in the natural way. We can encode these collections of local vector fields into a flat structure on $T_S$, i.e. a affine connection (see section 2.1). By duality, we can also pull-back the constant differential 1-forms $\mathbb{C}\langle dx, dy \rangle$ and get, locally on $S$, a two-dimensional vector space of closed 1-forms; this can also be encoded into a flat linear connection on the cotangent bundle $\Omega^1_S$. We can recover the affine charts (and structure) from these latter data by locally straightening commuting vector fields to $(\partial_x, \partial_y)$, or closed 1-forms to
LOGARITHMIC AFFINE STRUCTURES, d-WEBs AND NORMAL FORMS

(dx, dy) (in fact, coordinates of \( \phi \) are given by integrating closed 1-forms).

A last object related to the affine structure is the pull-back of foliations by parallel lines which locally defines a 1-parameter family of foliations on \( S \), a so called Veronese web, that is encoded by a Riccati foliation on the projectivized tangent or cotangent bundle.

2.1. **Affine connections.** There are several notions of connections in the literature. From the point of view of algebraic geometers, an affine connection is a linear connection on the tangent bundle, i.e. a \( \mathbb{C} \)-linear map

\[
\nabla : T_S \to T_S \otimes \Omega^1_S
\]

satisfying the Leibniz rule \( \nabla(fY) = df \otimes Y + f \nabla Y \). The contraction with a vector field \( X \) provides a \( \mathbb{C} \)-linear map

\[
T_S \times T_S \to T_S : (X, Y) \mapsto \nabla_X Y := i_X(\nabla Y)
\]

which is \( \mathcal{O}_S \)-linear with respect to \( X \), and satisfies the Leibniz rule with respect to \( Y \). This is the point of view of differential geometers. Finally, the equation for horizontal sections \( \nabla Y = 0 \), viewed as a Pfaffian system on the total space \( V \) of \( T_S \), defines a distribution of 2-planes transversal to the fibration \( V \to S \). This gives a way to lift vector fields on \( S \) to vector fields on \( V \): this is a connection in the sense of Ehresmann.

In local coordinates \( (x, y) : U \to \mathbb{C}^2 \) on \( S \), one can trivialize the tangent bundle \( T_S|_U \) by choosing the basis \( (\partial_x, \partial_y) \). Then the linear connection writes

\[
\nabla = d + \theta, \quad \text{where} \quad \theta = \begin{pmatrix} \theta_{11} & \theta_{12} \\ \theta_{21} & \theta_{22} \end{pmatrix}
\]

with \( \theta_{ij} \) holomorphic 1-forms on \( U \) and Christoffel symbols are given by their coefficients \( \theta_{ij} = \Gamma^i_{1j}dx + \Gamma^i_{2j}dy \). The Ehresmann distribution is given by the corresponding system

\[
\nabla Z = 0 \iff \begin{cases}
    dz_1 + \theta_{11}z_1 + \theta_{12}z_2 = 0 \\
    dz_2 + \theta_{21}z_1 + \theta_{22}z_2 = 0
\end{cases}
\]

where \( Z = z_1 \partial_x + z_2 \partial_y \).

We define the curvature of an affine connection as

\[
R^\nabla_{X,Y}Z = \nabla_X \nabla_Y Z - \nabla_Y \nabla_X Z - \nabla_{[X,Y]}Z
\]

where \( [X,Y] \) denotes the Lie bracket between vector fields. We say that \( \nabla \) is flat if the curvature vanishes identically. Equivalently, the linear connection
satisfies $\nabla \cdot \nabla = 0$, which locally writes
\[
d\theta + \theta \wedge \theta = 0 \iff \begin{cases} 
  d(\theta_{11} + \theta_{22}) = 0 \\
  d\theta_{12} + (\theta_{11} - \theta_{22}) \wedge \theta_{12} = 0 \\
  d(\theta_{11} - \theta_{22}) + 2\theta_{12} \wedge \theta_{21} = 0 \\
  d\theta_{21} + \theta_{21} \wedge (\theta_{11} - \theta_{22}) = 0
\end{cases}
\]  
(6)

The flatness condition is equivalent to Frobenius integrability for the associate Ehresmann distribution, and therefore to the existence of a basis $(Y_1, Y_2)$ of local horizontal sections, i.e. $\nabla_X Y_i = 0$ for all $X$.

We define the **torsion** of an affine connection as
\[
T^\nabla(X, Y) = \nabla_X Y - \nabla_Y X - [X, Y].
\]  
(7)

We say that $\nabla$ is torsion-free if the torsion vanishes identically. In local coordinates, this is equivalent to
\[
\theta_{11}(\partial_y) = \theta_{12}(\partial_x) \quad \text{and} \quad \theta_{21}(\partial_y) = \theta_{22}(\partial_x).
\]  
(8)

A flat connection is torsion-free if, and only if, basis of horizontal sections define commuting vector fields $[Y_1, Y_2] = 0$. Indeed, we can always assume $Y_1 = f(x, y)\partial_x$ and $Y_2 = g(x, y)\partial_y$ in convenient coordinates so that the matrix connection writes $\theta = -\text{diag} \left( \frac{df}{f}, \frac{dg}{g} \right)$ and we have:

\[
\text{torsion-free} \iff \frac{\partial f}{\partial y} = \frac{\partial g}{\partial x} = 0 \iff [f(x, y)\partial_x, g(x, y)\partial_y] = 0.
\]

2.2. **Riccati foliation and Veronese web.** Here, we provide another point of view which is more convenient for our computations (see [8] for much more details). In fact, we need a little bit less to encode an affine structure. It is well-known that projective linear transformations $\text{PGL}(3, \mathbb{C})$ acting on $\mathbb{P}^2$, are locally characterized by the fact that they send lines to lines. In particular, the affine subgroup $\text{Aff}(\mathbb{C}^2)$ stabilizing the line at infinity is characterized by the fact that it preserves parallel lines. In other words, it preserves the $1$-parameter family of foliations $\mathcal{F}_t = \ker(dy - tdx)$ where $t \in \mathbb{P}^1$ (setting $\mathcal{F}_\infty = \ker(dx)$). When we pull-back on $S$ by affine charts, we get a Veronese web which is locally the data of a pencil of pairwise transversal foliations:

\[
\mathcal{F}_t = \ker(\omega_t), \quad \omega_t = \omega_0 - t\omega_\infty
\]  
(9)

(see [7] for instance). Globally on $S$, elements of this pencil are permuted by the monodromy of affine charts and we fail to have a global pencil: we only have a so-called **Veronese web**.
To properly define such a structure on $S$, we consider the projectivized tangent bundle $\mathbb{P}(T_S) \to S$ which is a $\mathbb{P}^1$-bundle over $S$ whose fiber at a point $p \in S$ is the set of directions through $p$. We will denote by $M$ the total space of $\mathbb{P}(T_S)$ and by $\pi : M \to S$ the natural projection. It is naturally equipped with a contact structure (see below) so that the natural lifts of curves are Legendrian. A foliation on $S$ corresponds naturally to a (smooth) section of this bundle and a Veronese web corresponds to a flat structure on the bundle, i.e. a 2-dimensional foliation that is transversal to the fibration: locally on $U \subset S$, $M|_U$ is foliated by sections, each of them producing an element of the pencil. Below, we detail in local coordinates.

Starting from the affine structure, and the associate flat affine connection $\nabla$ on $T_S$, we deduce the above flat structure by the action of $\nabla$ on directions (remind $\nabla$ is $\mathbb{C}$-linear). In local coordinates $(x, y) : U \to \mathbb{C}^2$, vectors $z_1 \partial_x + z_2 \partial_y$ in the fiber of $T_S$ are replaced by homogeneous coordinates $(z_1 : z_2) = (1 : z)$ with $z \in \mathbb{P}^1$ in $\mathbb{P}(T_S)$. Therefore, the $\mathbb{P}^1$-bundle writes

$$\pi : M|_U = \mathbb{P}^1 \times U \to U \quad \text{with} \quad ((1 : z), (x, y)) \mapsto (x, y),$$

and the contact structure writes $dy = zdx$. Then equations (4) induce a Riccati type Pfaffian equation

$$\omega = dz + \alpha z^2 + \beta z + \gamma = 0, \quad \alpha, \beta, \gamma \in \Omega^1(U)$$

where

$$\begin{cases} 
\alpha = -\theta_{12} \\
\beta = \theta_{22} - \theta_{11} \\
\gamma = \theta_{21}
\end{cases}$$

The Frobenius integrability condition of $\omega$ writes as follows

$$\omega \wedge d\omega = 0 \iff \begin{cases} 
 d\alpha + \alpha \wedge \beta = 0, \\
 d\beta + 2\alpha \wedge \gamma = 0, \\
 d\gamma + \beta \wedge \gamma = 0.
\end{cases}$$

and is directly implied by flatness condition (6). We therefore get a foliation $\mathcal{H}^\nabla$ defining a flat structure on $\mathbb{P}(T_S)$. Each leaf of $\mathcal{H}^\nabla$ defines a local section $(1 : z) = (f(x, y) : g(x, y))$ and therefore a foliation, generated by $f(x, y)\partial_x + g(x, y)\partial_y$. More precisely, there exists a first integral for $\mathcal{H}^\nabla$ of the form

$$F(x, y, z) = \frac{f_0(x, y) + zg_0(x, y)}{f_\infty(x, y) + zg_\infty(x, y)}, \quad \delta := \det \begin{pmatrix} f_0 & g_0 \\ f_\infty & g_\infty \end{pmatrix} \neq 0$$

(14)
i.e. one retrieve the Riccati equation (11) from the Pfaffian equation \( dF = 0 \) yielding

\[
\begin{align*}
\alpha &= \frac{g_\delta d\infty - g_\infty d\delta}{g_\delta} \\
\beta &= \frac{f_\delta d\infty - f_\infty d\delta + g_\delta d\infty - f_\infty d\delta}{g_\delta} \\
\gamma &= \frac{f_\delta d\infty - f_\infty d\delta}{g_\delta}
\end{align*}
\] (15)

We note that \( F \) can be deduced from a basis of \( \nabla \)-horizontal sections

\[
M = \begin{pmatrix} f_0 & f_\infty \\ g_0 & g_\infty \end{pmatrix}, \quad dM + \theta M = 0.
\]

The leaves of the foliation \( \mathcal{H}^\nabla \) are defined by fibers \( F(x, y, z) = t, \ t \in \mathbb{P}^1 \), and, taking into account the contact structure \( dy - zdx = 0 \), we retrieve the local pencil of foliations defining the Veronese web structure:

\[
F(x, y, z) = t
\]

\[
\begin{pmatrix} f_0(x, y)dx + g_0(x, y)dy \\ \omega_0 \end{pmatrix} - t \begin{pmatrix} f_\infty(x, y)dx + g_\infty(x, y)dy \\ \omega_\infty \end{pmatrix} = 0.
\] (16)

More generally, a flat structure on \( \mathbb{P}(TS) \to S \) is a Riccati foliation \( \mathcal{H} \), locally defined in trivialization chart by a Riccati equation (11) satisfying flatness condition (13). This is the way to define a Veronese web on \( S \).

To define an affine structure, it remains to characterize those Veronese webs that are locally parallelisable, i.e. equivalent to the pencil of constant foliations up to change of coordinates (flat pencils in [7]). In other words, it remains to translate the torsion free condition on the Riccati equation. For this, we note that we can lift a Riccati equation (11) to a unique torsion free connection (3) by setting (12) and

\[
\kappa = \theta_{11} + \theta_{22}, \quad \text{with} \quad \kappa = (2\gamma_2 - \beta_1)dx + (\beta_2 - 2\alpha_1)dy
\] (17)

under notation

\[
\begin{pmatrix} \alpha \\ \beta \\ \gamma \end{pmatrix} = \begin{pmatrix} \alpha_1 \\ \beta_1 \\ \gamma_1 \end{pmatrix} dx + \begin{pmatrix} \alpha_2 \\ \beta_2 \\ \gamma_2 \end{pmatrix} dy,
\] (18)

Then, the resulting connection is flat if, and only if \( d\kappa = 0 \). From [8, Proposition 3.2], the 2-form \( d\kappa \) does not depend on the choice of local coordinates \( (x, y) \) and defines a global 2-form on \( S \) we call torsion and denote \( K(\mathcal{H}) \in \Gamma(S, \Omega^2_S) \) this global 2-form. We will say that the Veronese web (or Riccati foliation) is torsion-free if \( d\kappa = 0 \).
Following [7], a pencil of foliations $F_t$ is defined by a family of Pfaffian equations
\[(\omega_0 - t\omega_\infty = 0)_t \quad \text{with} \quad \omega_0 \wedge \omega_\infty \neq 0 \quad (19)\]
where the vector space $\mathbb{C}(\omega_0, \omega_\infty)$ is well-defined up to multiplication by a function. In particular, one can assume $\omega_0$ or $\omega_\infty$ to be a closed 1-form, but not both of them in general. Then are equivalent:

- the pencil $F_t$ is flat in the sense of [7],
- one can define $F_t$ by (19) with $d\omega_0 = d\omega_\infty = 0$,
- $F_t$ is locally equivalent to the linear pencil $dy - tdx = 0$,
- the corresponding Riccati foliation on $\mathbb{P}(T_S)$ is torsion-free: $d\kappa = 0$.

### 2.3. Meromorphic affine structures and singular Riccati foliations.

Let $S$ be a smooth complex surface, $M = \mathbb{P}(T_S)$ be the projectivization of the tangent bundle of $S$, and $\pi : M \to S$ the natural projection. A singular Riccati foliation $\mathcal{H}$ on $M$ is a singular holomorphic foliation of codimension 1 on $M$, transverse to the generic fiber of $\pi$.

The (effective) polar divisor $D$ of the Riccati foliation is defined as the direct image under $\pi$ of the tangency divisor between $\mathcal{H}$ and the vertical foliation defined by the fibers of $\pi$.

Consider a trivialization of $M$ over an open set $U$ like in (10) with coordinates $(x, y) : U \to \mathbb{C}^2$ and contact structure given by $dy = zdx$. Then the foliation $\mathcal{H}$ is given by a non zero meromorphic 1-form $\omega$ of the type:
\[\omega = dz + \alpha z^2 + \beta z + \gamma, \quad \alpha, \beta, \gamma \in \Gamma(U, \Omega^1(D)) \quad (20)\]
where $\alpha$, $\beta$ and $\gamma$ are meromorphic 1-forms on $U$, and satisfying moreover Frobenius integrability condition (13). The poles of $\alpha$, $\beta$ and $\gamma$ define the polar divisor $D$ of $\mathcal{H}$.

The torsion of a singular Riccati foliation $\mathcal{H}$ on $M = \mathbb{P}(T_S)$ is a meromorphic 2-form $K(\mathcal{H}) \in \Gamma(S, \Omega^2_S(2D))$ which is locally defined by $d\kappa$ where $\kappa$ is given by (17). We then say that $\mathcal{H}$ is torsion-free when $K(\mathcal{H})$ is identically vanishing. A meromorphic affine structure is the data of a torsion-free singular Riccati foliation on $\mathbb{P}(T_S)$. From section 2.2, we see that we get an affine structure in the usual sense on the complement $S \setminus D$ of the polar locus. But the affine charts degenerate along $D$.

We will say that the affine structure is logarithmic (resp. regular-singular) if it is locally induced by a logarithmic (resp. regular-singular) connexion
\[\nabla_i : T_S|_{U_i} \to T_S|_{U_i} \otimes \Omega^1_{U_i}(D)\]
in the sense of Deligne [3] (see also [15]). These properties can be checked at a generic point of all irreducible components of $D$ and translate as follows on the Riccati foliation.

**Proposition 2.1.** Let $\mathcal{H}$ be a torsion-free singular Riccati foliation on $\mathbb{P}(T_S)$. Then are equivalent:

- the affine structure is logarithmic,
- $\nabla_{\mathcal{H}}$ is logarithmic (see definition below),
- $\omega$ and $d\omega$ have at most simple poles, where $\omega$ is the Riccati 1-form defining $\mathcal{H}$ in local charts.

Are also equivalent:

- the affine structure is regular-singular,
- there is a bimeromorphic bundle transformation $\psi : \mathbb{P}(T_S) \to P$ such that $\psi_* \mathcal{H}$ is a logarithmic Riccati foliation on $P$.
- in local trivializations of $\mathbb{P}(T_S)$, solutions of the Riccati equation $\omega$ have polynomial growth when approaching $D$.

There is a unique flat and torsion-free meromorphic connection

$$\nabla_{\mathcal{H}} : T_S \to T_S \otimes \Omega^1_S(D)$$

lifting the flat structure $\mathcal{H}$ on $T_S$: it is defined in charts by identities (12) and (17). We do not know whether $\mathcal{H}$ regular-singular $\Rightarrow \nabla_{\mathcal{H}}$ is regular-singular.

**Proof.** Due to (12) and (17), we see that coefficients of $\omega$ have simple poles if, and only if, coefficients of the matrix connection (3) has simple poles. Moreover, the same formula together with $d\kappa = 0$ shows that the same equivalence holds true for differential of coefficients, i.e. $d\theta$ has simple poles if, and only if, $d\omega$ has simple poles.

For the second part, we know (see [3], or [15]) that $\nabla_{\mathcal{H}}$ is regular-singular singular points of linear connections are characterized by solutions having polynomial growth along the divisor $D$ (which needs not be reduced in that case), and so must be those solutions of $\mathcal{H}$. This growth property is invariant under bimeromorphic bundle transformation. We can therefore assume that $\mathcal{H}$ is in normal form like in [12, Theorem 1], minimizing the pole order. Then, it has simple poles otherwise it would have irregular singular points with exponential growth, and poles can only be logarithmic since they cannot be erased by bimeromorphic bundle transformation. Of course, logarithmic implies polynomial growth for Riccati equation (same computation as for linear connection). Conversely, if solutions of $\mathcal{H}$ have polynomial growth
then so are the solutions of the unique trace-free connection $\nabla^0$ lifting $\mathcal{H}$ in a local trivialization of $\mathbb{P}(T_S)$ (by setting $\theta_1 + \theta_2 = 0$ instead of (17)). \hfill \Box

As a particular case of affine structures, we have those defined by a global pencil of foliations. In the singular case, a singular pencil of foliation is defined by a pencil $\omega_t = \omega_0 - tw_\infty$ of global meromorphic 1-forms, such that $\omega_0 \wedge \omega_\infty \neq 0$. In that direction, we have

**Proposition 2.2.** The following data are equivalent:

- a flat singular pencil on $S$,
- a torsion-free Riccati foliation on $\mathbb{P}(T_S)$ with regular singularities and trivial monodromy.

*Proof.* A singular pencil, with singular locus $D$ given by poles and zeroes of $\omega_0 \wedge \omega_\infty$, clearly implies the existence of a Riccati foliation on $\mathbb{P}(T_U)$ where $U = S \setminus D$. By construction, the Riccati foliation admits a meromorphic first integral given by (14) and therefore extends with regular-singular points. Conversely, a Riccati foliation with trivial monodromy defines a pencil of foliations outside the polar locus; if it is regular-singular, then these foliations (horizontal sections) extend meromorphically on $S$, to form a global pencil. \hfill \Box

We will study Riccati foliations at the neighborhood of a point $p \in D$ such that $D$ is smooth at $p$ and logarithmic (or regular-singular). We will use the following classical result (see [2, Proposition 1.1.16] or [15, Theorem 1.6]):

**Proposition 2.3.** Let $D = \{y = 0\}$ be a smooth divisor of $(\mathbb{C}^2, 0)$ and $\mathcal{H}$ be a Riccati foliation on $\mathbb{P}^1 \times (\mathbb{C}^2, 0) \rightarrow (\mathbb{C}^2, 0)$, having polar divisor $D$. If $\mathcal{H}$ is logarithmic (resp. regular-singular) along $D$, then, up to biholomorphic (resp. bimeromorphic) bundle transformation, we can assume that the foliation $\mathcal{H}$ is given by one of the following equations:

1. $dz = \lambda \frac{du}{y}$, $\lambda \in \mathbb{C}$, or
2. $dz = (nz + y^n) \frac{du}{y}$, $n \in \mathbb{Z}_{\geq 0}$.

3. **Local classification of torsion-free Riccati foliations with logarithmic pole**

Let us start with Lemmata about classification of local multivalued functions and 1-forms in dimension one. The first one is very classical.
Lemma 3.1. Let \( f \) be a (possibly multivalued) function on \((\mathbb{C}, 0)\) of the form \( f(x) = x^\nu h(x) \) where \( \nu \in \mathbb{C}^* \) and \( h(x) \) holomorphic and non vanishing at \( 0 \). Then \( f \) is conjugated to \( x^\nu \), i.e. \( f(x) = \varphi^* x^\nu := (\varphi(x))^\nu \) for some local diffeomorphism \( \varphi \).

Proof. If we write \( \varphi(x) = xu(x) \) with \( u(x) \) holomorphic and non vanishing on \((\mathbb{C}, 0)\), then conjugacy \( f = \varphi^* x^\nu \) is reduces to \( h = u^\nu \). Since \( h \) is non vanishing, there is a local holomorphic determination of \( \log(h) \), and a solution is given by \( u(x) = \exp(\nu^{-1} \log(h(x))) \). \( \square \)

For multivalued 1-forms, we have:

Lemma 3.2. Let \( \omega = x^\nu u(x) \, dx \) be a multivalued 1-form on \((\mathbb{C}, 0)\) where \( \nu \in \mathbb{C} \) and \( u(x) \) holomorphic and non vanishing at \( 0 \).

- If \( \nu \notin \mathbb{Z}_{<0} \), then \( \omega \) is conjugated to \( x^\nu \, dx \), i.e. \( \omega = \varphi^* (x^\nu \, dx) \) for some local diffeomorphism \( \varphi(x) \).
- If \( \nu \in \mathbb{Z}_{<0} \), then \( \omega \) is meromorphic. Denote by \( n = -\nu \in \mathbb{Z}_{>0} \) its pole order, and by \( \lambda \in \mathbb{C} \) its residue at \( 0 \). Then
  1. If \( n = 1 \), then \( \omega \) is conjugated to \( \lambda \, dx \).
  2. If \( n > 1 \), then \( \omega \) is conjugated to \( \frac{dx}{x^n} + \lambda \frac{dx}{x} \).

Proof. Assume first \( \nu \notin \mathbb{Z}_{<0} \). Then \( \nu + 1 \neq 0 \), and we can rescale \( x \) by an homothecy to set \( u(0) = 1 \). Write \( \varphi(x) = x \exp(g(x)) \) and substitute in \( \omega = \varphi^* (x^\nu \, dx) \). Then we find:

\[
u(x) = e^{(\nu+1)g(x)}(1 + xg'(x)),
\]

which means that \( y = g(x) \) is solution of the differential equation

\[
x \frac{dy}{dx} = e^{-(\nu+1)y} u(x) - 1.
\]

The right-hand-side expands as:

\[
x \frac{dy}{dx} = u_1 x - (\nu + 1)y + \text{h.o.t.}
\]

By Briot-Bouquet, there exists a holomorphic solution \( y = g(x) \) with initial condition \( g(0) = 0 \) provided that \( \nu + 1 \notin \mathbb{Z}_{\leq 0} \), which proves the first part of the statement.

Assume now that \( \omega \) is meromorphic (but non holomorphic). If \( n = 1 \), then write \( \omega = \lambda \frac{dx}{x} (1 + h(x)) \) with \( h(x) \) holomorphic and vanishing at \( 0 \). Then write \( \varphi(x) = xu(x) \) with \( u(x) \) holomorphic and non vanishing at \( 0 \). Then \( \omega = \varphi^* (\lambda \frac{dx}{x}) \) is equivalent to \( \frac{du}{u} = h \frac{dx}{x} \) which can be solved by setting \( u(x) := \exp \int h(x) \frac{dx}{x} \).
If \( n > 1 \), then taking appart the residual part, we can write
\[
\omega = -d\left(\frac{h(x)}{(n-1)x^{n-1}}\right) + \lambda \frac{dx}{x}
\]
with \( h(x) \) holomorphic and non vanishing. Moreover, up to homothecy, we can assume \( h(0) = 1 \). Then write \( \varphi(x) = xu(x) \), and conjugacy equation yields
\[
-d\left(\frac{h(x)}{(n-1)x^{n-1}}\right) = \frac{d\varphi}{\varphi^n} + \lambda \frac{du}{u}
\]
(we have simplified residues). After integration, we get the functional equation:
\[
h = \frac{1}{u^{n-1}} - (n-1)\lambda x^{n-1} \log(u).
\]
Considering the main determination of \( \log(u) \), the right-hand-side is holomorphic and vanishes at \((x,u) = (0,1)\), and has non zero derivative along \( \partial u \), so that Implicit Function Theorem provides a holomorphic solution \( u(x) \) with \( u(0) = 1 \). \(
\)
Let us now consider a logarithmic affine structure on a surface \( S \), and let \( D \) be the (reduced) polar divisor. The affine structure is defined by a torsion-free Riccati foliation on \( \mathbb{P}(T_S) \), and at the neighborhood of any point \( p \in S \setminus D \), by a flat pencil of foliations defined by
\[
\omega_t = \omega_0 + t\omega_\infty \quad \text{where} \quad d\omega_0 = d\omega_\infty = 0, \quad \text{and} \quad \omega_0 \wedge \omega_\infty \neq 0.
\]
Moreover, the vector space \( V := \mathbb{C}\langle \omega_0, \omega_\infty \rangle \) does not depend on any choice and the analytic continuation of \( \omega_0, \omega_\infty \) around branches of the divisor \( D \) gives rise to a representation
\[
\pi_1(S \setminus D, p) \to \text{GL}(V),
\]
the linear monodromy of the affine structure. In particular, the 1-forms \( \omega_0, \omega_\infty \) do not extend, even meromorphically, along \( D \), but define multivalued 1-forms around. Consider an irreducible component \( D_0 \) of \( D \). Then, the conjugacy class of the local monodromy around \( D_0 \) is well-defined, and might not fix any non zero 1-form. However, in the logarithmic case, some foliations of the pencil must extend as explained below:

**Proposition 3.3.** Let \( \mathcal{H} \) be a torsion-free Riccati foliation on \( \mathbb{P}(T_S) \) and \( p \in D \) be a point on the smooth part of (the support of) \( D \). Assume that the structure is regular-singular at \( p \). Then the projective monodromy has at least one fixed point, and each fixed point gives rise to a non trivial 1-form
\( \omega \in V \) with multiplicative monodromy around \( D \), and the corresponding foliation \( F_\omega \) extends as a (possibly singular) holomorphic foliation on \((S,p)\).

Moreover, if \( F_\omega \) is transversal to \( D \) at \( p \), then \( \omega \) extends as a closed holomorphic (and non vanishing) 1-form at the neighborhood of \( p \).

Proof. The monodromy of the affine structure is the projectivization of the linear monodromy of acting on \( V \) as above. The projective monodromy around \( D \) at \( p \) is a Moebius transformation which has one or two fixed points, or is the identity. Each fixed point corresponds to a foliation \( F \) of the pencil which is uniform around \( D \). It also correspond to a local section of \( \mathbb{P}(T_S) \) outside of \( D \) that is invariant by the Riccati foliation (i.e. a leaf). By Fuchs Theory (see also [3]), because the Riccati equation is regular-singular, this section extends meromorphically along \( D \), therefore defining a singular foliation extending \( F \) along \( D \).

Finally, if \( F \) is transversal to \( D \), we can write locally \( F = \ker(dy) \) and \( D = [x = 0] \) in local coordinates \((x,y)\) at \( p \). Therefore, we can write \( \omega = f(x,y)dy \) for a multivalued function \( f \). But \( \omega \) is closed, so \( f(x,y) = f(y) \) with \( f \) holomorphic near \( y = 0 \); we promptly deduce that \( \omega \) extends at the origin. The function \( f \) does not vanish at 0, otherwise it would not define a regular pencil along \( y = 0 \), contradicting that the structure is regular outside \( x = 0 \). \qed

We are now going to solve the local classification problem at a generic point of a branch \( D_0 \) of \( D \) where the local projective monodromy has two fixed points.

**Theorem 3.4.** Consider a logarithmic affine structure on \( S \) with polar divisor \( D \) and let \( D_0 \) be a branch of \( D \) with semi-simple local monodromy. Then, at a generic point of \( D_0 \), the affine structure is described by one of the model below:

1. \( \omega_t = dx + ty^\nu dy, \nu \in \mathbb{C}^* \),
2. or \( \omega_t = dx + t(\frac{dy}{y^n} + \frac{dy}{y}) \), \( n \in \mathbb{Z}_{>1} \).

In the statement, by generic point, we mean outside of a discrete set of points along \( D \).

Proof. By assumption, the projective monodromy around \( D_0 \) has at least 2 fixed points. Applying Proposition 3.3 to these two fixed points, we get that the affine structure is defined around any point \( p \in D_0 \) which is smooth for \( D \) by the pencil \( \omega_t = \omega_0 + t\omega_\infty \) where \( \omega_0, \omega_\infty \) are multivalued closed 1-forms.
with multiplicative monodromy $\omega_i \mapsto c_i \omega_i$ around $D_0$, $c_i \in \mathbb{C}^*$, $i = 0, \infty$. Moreover, the corresponding foliations $\mathcal{F}_0, \mathcal{F}_\infty$ extend as (possibly singular) holomorphic foliations along at $(S,p)$. Moreover, the linear monodromy around $D_0$ is given in the basis $(\omega_0, \omega_\infty)$ by

$$
\begin{pmatrix}
c_0 & 0 \\
0 & c_\infty
\end{pmatrix};
$$

if $c_0 \neq c_\infty$ then no other foliation $\mathcal{F}_t : \{\omega_t = 0\}$ of the pencil is preserved by the monodromy. At a generic point $p \in D_0$, these two foliations are smooth (non singular) and each of them is either transversal to $D$, or $D$ is a local leaf of the foliation. In other words, we exclude special points where foliations are singular, or have isolated tangencies with $D$, or extra tangency between them. Then, we have 4 possibilities for $(\mathcal{F}_0, \mathcal{F}_\infty)$ up to permutation:

- $\mathcal{F}_0$ and $\mathcal{F}_\infty$ are transversal, and both transversal to $D_0$.
- $\mathcal{F}_0$ and $\mathcal{F}_\infty$ are transversal, and $D_0$ is a leaf of $\mathcal{F}_0$.
- $D_0$ is a common leaf of $\mathcal{F}_0$ and $\mathcal{F}_\infty$, and these foliations are transversal outside of $D_0$.
- $\mathcal{F}_0$ and $\mathcal{F}_\infty$ are tangent along $D_0$, but are transversal to $D_0$, and are transversal outside of $D_0$.

The proof ends by studying each of these 4 cases separately.

**Lemma 3.5.** If $\mathcal{F}_0$ and $\mathcal{F}_\infty$ are transversal, then the polar divisor $D$ of the structure must be invariant by either $\mathcal{F}_0$, or $\mathcal{F}_\infty$.

**Proof.** Assume by contradiction that $D$ is not invariant by either $\mathcal{F}_0$ or $\mathcal{F}_\infty$. At a generic point of $D$, the divisor is transversal to $\mathcal{F}_0$ and $\mathcal{F}_\infty$. We apply the last part of Proposition 3.3 and get that $\mathcal{F}_0$ and $\mathcal{F}_\infty$ are defined by holomorphic closed 1-forms $\omega_0, \omega_\infty$ at $p$, which write $\omega_0 = dx$ and $\omega_\infty = dy$ in convenient local coordinates at $p$. But clearly, the pencil is regular at $p$, contradiction. □

**Lemma 3.6.** If $\mathcal{F}_0$ and $\mathcal{F}_\infty$ are transversal and $D$ is invariant by $\mathcal{F}_\infty$, then there exist local coordinates in which the structure is generated by

1. $\omega_t = dx + t \nu dy$, $\nu \in \mathbb{C}^*$,
2. or $\omega_t = dx + t (\frac{dy}{y^n} + \frac{dy}{y})$, $n \in \mathbb{Z}_{>1}$.

**Proof.** We can choose local coordinates such that $\mathcal{F}_0 = \ker(dx)$ and $\mathcal{F}_\infty = \ker(dy)$. Moreover, by Proposition 3.3, we can write $\omega_0 = f(x)dx$ with $f$ holomorphic and non vanishing; after coordinate change $x := \varphi(x) = \int f(x)dx$, we can assume $\omega_0 = dx$ and $\omega_\infty = g(x,y)dy$ for a multivalued function $g$. Since $\omega_\infty$ is closed, we get $g(x,y) = g(y)$, still multivalued. The
corresponding Riccati equation in the local trivialization of \( \mathbb{P}(T_S) \) is deduced as follows:

\[
\omega_t = dx + tg(y)dy \quad \Rightarrow \quad \frac{1}{t} = g(y)\frac{dy}{dx} =: g(y)z
\]

which, after derivation gives

\[
0 = zdg + gdz \quad \Rightarrow \quad \omega = dz + \frac{dg}{g}z = 0.
\]

In case \( \omega \) has a multiple pole, then we easily deduce that we have an irregular singular point. So, in the regular-singular case, we must have a simple pole and we again easily check that it is logarithmic. Applying Lemma 3.2, we deduce that, after \( y \)-coordinate change, we get one of the model of the statement. Indeed, in case \( \nu \in \mathbb{Z}_{<0} \) in Lemma 3.2, we can replace \( \omega_\infty \) by a multiple to normalize the residue \( \lambda = 1 \).

Lemma 3.7. If \( F_0 \) and \( F_\infty \) are tangents along \( D \), and transversal to \( D \), then there exist local coordinates in which the structure is generated by

\[
\omega_t = dx + td(y^n), \quad n \in \mathbb{Z}_{\geq 2}.
\]

In the regular singular case, we also get the following local models

\[
\omega_t = f(x)dx + td(x + y^n), \quad n \in \mathbb{Z}_{\geq 2}, \quad f \in \mathcal{O}^*.
\]

Proof. We first apply [9, Lemme 5.3] to deduce that there is a change of coordinates such that \( F_0 = \{dx = 0\} \), and \( F_\infty = \{d(x + y^n) = 0\} \), \( n \geq 2 \), so that \( D = \{y = 0\} \), \( \omega_0 = f(x,y)dx \) and \( \omega_\infty = g(x,y)d(x+y^n) \). Since \( \omega_0 \) and \( \omega_\infty \) are closed, and \( \omega_0 \) extends holomorphically at \( p \) (Proposition 3.3), we have \( f(x,y) = f(x) \) and \( g(x,y) = g(x+y^n) \) with \( f,g \in \mathcal{O}^* \). In fact, we can normalize the restriction \( \omega_\infty\vert_D = g(x)dx \) to \( dx \) by a change of \( x \)-coordinate and then reapply [9, Lemme 5.3] to get the normal form

\[
\omega_0 = f(x)dx \quad \text{and} \quad \omega_\infty = d(x+y^n).
\]

This pencil induces the Riccati equation

\[
\omega = dz - \frac{1}{ny^{n-1}}\frac{df}{f} + \left( (n-1)\frac{dy}{y} - \frac{df}{f} \right)z.
\]

One can check that, after meromorphic gauge transformation \( \tilde{z} = zy^{n-1} \), the Riccati foliation becomes holomorphic: the above local model is always regular-singular. However, after derivation, we get that \( d\omega \) has a pole of order \( n \geq 2 \) unless \( f'(x) = 0 \), so \( f \) is a constant: we obtain the pencil of the statement (with a different basis). \( \square \)
Lemma 3.8. If $D$ is invariant by $F_0$ and $F_{\infty}$, then $F_0$ and $F_{\infty}$ are generic elements of the pencils described in Lemma 3.6 (with $\nu \in \mathbb{Z}_{<0}$ in the first case).

We start recalling a local technical Lemma for foliations tangent along a common leaf ([11, Lemma 5], [17, Proposition 1], [14, Lemma 4.7, 4.9]):

Proposition 3.9. Let $F$ and $G$ be two smooth foliations at $(\mathbb{C}^2,0)$ that have $y = 0$ as a common leaf, and transversal outside. Then, up to change of coordinates, we can assume $F$ and $G$ are defined by the respective first integrals

$$f(x,y) = y \quad \text{and} \quad g(x,y) = y + xy^{k+1}, \quad k \in \mathbb{Z}_{\geq 0},$$

where $k+1$ is the order of tangency, defined by the vanishing order of $df \wedge dg$ along $y = 0$.

Moreover, this normalisation is not unique: if a diffeomorphism $\Phi(x,y)$ of $(\mathbb{C}^2,0)$ commutes with the normal form, then we obtain new first integrals that factor through the initial ones as follows:

$$f \circ \Phi = \varphi \circ f \quad \text{and} \quad g \circ \Phi = \psi \circ g$$

for one-dimensional diffeomorphisms $\varphi$ and $\psi$. Then this provides a one-to-one correspondance between

- symmetries $\Phi$ of the normal form,
- pairs $(\varphi, \psi)$ of diffeomorphisms coinciding up to order $k+1$, i.e. satisfying $\varphi(y) - \psi(y) = o(y^{k+1})$.

Proof. The first part of the statement is proved in each of the quoted references. The second part is not stated like this, and we give the proof. We just have to explain how to reconstruct $\Phi$ from the pair $(\varphi, \psi)$. Clearly, by action on $f$, we see that $\Phi = (\phi(x,y), \varphi(y))$. Then, action on $g$ gives

$$\psi(y + xy^{k+1}) = \varphi(y) + \phi(x,y)(\varphi(y))^{k+1}$$

which already gives the condition $\psi(y) = \varphi(y) \mod y^{k+2}$. But this rewrites

$$\phi(x,y) = \frac{\psi(y + xy^{k+1}) - \varphi(y)}{y^{k+1}} = \frac{\psi(y) - \varphi(y)}{y^{k+1}} + \psi'(0)x + o(x)$$

which shows that $\phi(x,y)$ is uniquely determined, holomorphic, of the form $\phi(x,y) = \psi'(0)x + cy + \text{h.o.t.}$.

$\Box$
Proof of Lemma 3.8. Following Proposition 3.9, there is a change of coordinates such that

\[ F_0 = \ker(dy), \quad \text{and} \quad F_\infty = \ker(d(y + xy^{n+1})), \quad n \in \mathbb{Z}_{\geq 0}, \]

so that \( D = \{y = 0\} \). The pencil writes

\[ \omega_0 = g(x, y)dy \quad \text{and} \quad \omega_\infty = f(x, y)d(y + xy^{n+1}) \]

and by closedness of the 1-forms, we can furthermore assume

\[ f(x, y) = f_0(y + xy^{n+1}), \quad \text{and} \quad g(x, y) = g_0(y) \]

for possibly multivalued holomorphic functions \( f_0, g_0 \) on the punctured neighborhood of \( 0 \in \mathbb{C} \). Hence, this pencil induces a Riccati foliation given by

\[ \omega = dz - \left( \frac{df}{f} - \frac{dg}{g} + (n + 1)\frac{dy}{y} \right) z \]

(21)

By considering the term in \( z \), we see that \( \frac{df}{f} - \frac{dg}{g} \) must be a meromorphic 1-form. After gauge transformation \( \tilde{z} = \frac{z}{y^n+1} \), we get

\[ dz - \left( \frac{df}{f} - \frac{dg}{g} \right) z \]

\[ - \left( (1 + (n + 1)xy^n) \left( \frac{df}{f} - \frac{dg}{g} \right) + n(n + 1)xy^{n-1}dy + (n + 1)y^n dx \right) z^2. \]

This latter equation has an irregular singular point whenever \( \frac{df}{f} - \frac{dg}{g} \) has a multiple pole; we deduce that \( \frac{df}{f} - \frac{dg}{g} \) must have at most simple pole, and in that case, the Riccati foliation is regular-singular.

Assume now that the structure is logarithmic. Considering the coefficient of \( z^2 \) in (21), and its restriction to \( x = 0 \), we see that

- \( \frac{df}{f} \) must be logarithmic (coefficient of \( dx \))
- \( \frac{df}{f} - \frac{dg}{g} \) must be holomorphic, vanishing at order \( n \) along \( y = 0 \) (coefficient of \( dy \))

Applying Lemma 3.2 to \( f_0(y)dy \), we have two cases:

\[ f_0(y)dy = \varphi^* y^\nu dy, \quad \nu \in \mathbb{C}^*, \quad \text{or} \quad \varphi^* \frac{dy}{y^{k+1}} + \frac{dy}{y} \]

for some local diffeomorphism \( \varphi(y) \).

First case: \( f_0(y)dy = \varphi^* y^\nu dy \). Once more we apply Proposition 3.9 and we get that there exists a change of coordinates on \( (\mathbb{C}^2, 0) \) such that \( f(x, y) = (y + xy^{n+1})^\nu \). Therefore, we have \( \frac{dg}{g} = \nu \frac{dy}{y} + h(y)dy \) with \( h(y) \) holomorphic,
vanishing at order $n$ at $y = 0$. Substituting in (21), and assuming first $n > 0$, we see that the non logarithmic terms are:

$$(\nu + n + 1)\left(\frac{dx}{y} + nx\frac{dy}{y^2}\right)$$

and we deduce that $\nu = -n - 1$. In the case $n = 0$, the non logarithmic term is:

$$(\nu + 1)\frac{dx}{y}$$

and we find $\nu = -1$ as before.

Second case: a similar study shows that, when $f_0(y)dy = \varphi^*\frac{dy}{y} + \frac{dy}{y}$, again, $k = n$, and we can finally assume $f_0(y) = \frac{1}{y^{n+1}} + \frac{1}{y}$ or $\frac{1}{y^{n+1}}$. Taking into account the vanishing order of $\frac{df}{f} - \frac{dg}{g}$, we deduce that $g_0(y) - f_0(y)$ is holomorphic, and $g_0(y)$ is conjugated to $f_0$ by a diffeomorphism tangent to the identity up to order $n + 1$. Therefore, Proposition 3.9, we can assume moreover that $g_0(y) = f_0(y)$. We then arrive to the normal form

$$\omega_t = \frac{dy}{y^{n+1}} + \epsilon \frac{dy}{y} + t\left(\frac{1}{(y + xy^{n+1})^{n+1}} + \frac{\epsilon}{y + xy^{n+1}}\right)d(y + xy^{n+1}),$$

with $\epsilon = 0$ or 1. Setting $t = -1$, we get that

$$\omega_{-1} = a(x, y)dx + b(x, y)dy \quad \text{with} \quad a(0) = -1, \; \text{and} \; b(0) = 0.$$

Finally, replacing $\omega_0$ and $\omega_{-1}$ by $\omega_0$ and $\omega_{-1}$, we get back to the case $F_0$ and $F_{-1}$ transversal in Lemma 3.6. \hfill $\square$

Here the proof of the theorem ends. \hfill $\square$

Now, we are going to solve the local classification problem in the remaining cases.

**Theorem 3.10.** Consider a logarithmic affine structure on $S$ with polar divisor $D$ and let $D_0$ be a branch of $D$ with parabolic local monodromy. Then, at a generic point of $D_0$, the affine structure is described by one of the model below:

1. $\omega_t = dx - y^n \ln y dy + ty^n dy, \; n \in \mathbb{Z}_{\geq 0},$
2. $\omega_t = -\ln y dx + \frac{dy}{y^n} + (c - x)\frac{dx}{y} + tdx, \; n \in \mathbb{Z}_{> 0},$

where $c = 0$ or 1.

**Proof.** The proof is quite similar to Theorem 3.4. Using the same argument we conclude that the structure is defined by multivalued closed 1-forms $\omega_t = \omega_0 + t\omega_{-1}$. 
Since the monodromy of the Riccati foliation \( \mathcal{H} \) has an only fixed point, this means that the corresponding pencil of foliations \( \mathcal{F}_t = \ker(\omega_t) \) has an only one element that extends through the polar divisor, that we can assume to be \( \mathcal{F}_\infty \). At a generic point of \( D_0 \), \( \mathcal{F}_\infty \) is smooth, either tangent to \( D_0 \) (i.e. \( D_0 \) is a leaf), or transversal to \( D_0 \). We discuss these two cases separately.

**Lemma 3.11.** If \( D_0 \) is invariant by \( \mathcal{F}_\infty \), then there exist local coordinates such that the pencil is generated by

\[
\omega_t = dx - y^n \ln y dy + ty^n dy, \quad \text{where} \quad n \in \mathbb{Z}_{\geq 0}.
\]

**Proof.** We choose coordinates such that \( D_0 = \{ y = 0 \} \) and \( \mathcal{F}_\infty = \ker(dy) \). Therefore, we can write \( \omega_\infty = f(y)dy \) and \( \omega_0 = gdx + hdy \) for multivalued functions \( f, g, h \) (by closedness, \( f \) only depends on \( y \)). So, this pencil induces a Riccati foliation \( \mathcal{H} \) given by

\[
\omega = dz + \left( \frac{df}{f} - \frac{dg}{g} \right) z + \left( \frac{h df}{g f} - \frac{dh}{g} \right) z^2.
\]

Taking \( \tilde{z} = \frac{1}{z} \) we have

\[
\tilde{\omega} = d\tilde{z} + \left( \frac{dg}{g} - \frac{df}{f} \right) \tilde{z} + \left( \frac{dh}{g} - \frac{h df}{g f} \right).
\]  

(22)

Since \( \mathcal{H} \) is assumed to have a logarithmic pole, with parabolic monodromy, by Proposition 2.3, there exists an isomorphism \( z \mapsto \varphi(x, y, z) \) of \( \mathbb{P}^1 \)-bundle such that \( \varphi_* \mathcal{H} \) is induced by \( \tilde{\omega} = d\tilde{z} - n\tilde{z}\frac{dy}{y} - y^{n-1}dy, \quad n \in \mathbb{Z}_{\geq 0} \). The Riccati foliation has a single invariant section which is given by \( \{ \tilde{z} = \infty \} \) and \( \{ \tilde{z} = 0 \} \) respectively, and we deduce that the bundle isomorphism takes the form

\[
\tilde{z} = a \tilde{z} + b, \quad \text{where} \quad a \in \mathcal{O}_0^* \quad \text{and} \quad b \in \mathcal{O}_0.
\]

So \( \mathcal{H} \) is induced by

\[
\tilde{\omega} = d\tilde{z} + \left( \frac{da}{a} - \frac{dy}{y} \right) \tilde{z} + \left( \frac{db}{a} - \frac{nb dy}{ay} - \frac{y^{n-1}dy}{a} \right), \quad n \in \mathbb{Z}_{\geq 0}.
\]  

(23)

Comparing equations (22) and (23) and then solving we have \( g = cf^a y^{-n} \) and \( h = cf(y^{-n}b - \ln y) + e \), where \( c \in \mathbb{C}^* \) and \( e \in \mathbb{C} \). We can suppose \( c = 1 \) and \( e = 0 \) by rescaling the \( t \) parameter of the pencil, so \( \omega_t = f y^{-n} dx + f(y^{-n}b - \ln y) dy + tf dy \). Closedness condition for \( \omega_0 \) gives:

\[
\frac{f'(y)}{f(y)} = \frac{n}{y} + \frac{b_x - a_y}{a}_{\text{holomorphic}}
\]  

(24)
Hence, applying Lemma 3.2 with \( \nu = n \geq 0 \), we get a change of \( y \)-coordinate which normalizes \( \omega_{\infty} = y^n dy \). Replacing \( f(y) = y^n \) in (24), we get \( a_y = b_x \) and therefore

\[
\omega_t = \frac{adx + bdy}{\text{closed}} - y^n \ln y dy + ty^n dy.
\]

Since \( a \in \mathcal{O}_0^* \), the 1-form \( adx + bdy \) can be normalized to \( dx \) by a change of \( x \)-coordinate, which does not affect the other terms of \( \omega_t \) and we get the form of the statement. \( \square \)

**Lemma 3.12.** If \( D \) is transversal to \( \mathcal{F}_{\infty} \), then there exist local coordinates such that the pencil is generated by

\[
\omega_t = (1 - x) \frac{dy}{y} - \ln y dx + tdx
\]

or

\[
\omega_t = \frac{dy}{y^n} + (c - x) \frac{dy}{y} - \ln y dx + tdx, \quad n \in \mathbb{Z}_{>1}
\]

where \( c = 0 \) or 1.

**Proof.** We choose coordinates such that \( D_0 = \{ y = 0 \} \) and \( \mathcal{F}_{\infty} = \ker(dx) \). Since \( \mathcal{F}_{\infty} \) is transversal to \( D_0 \), then \( \omega_{\infty} \) extends through \( D_0 \), and since it is closed, it can be normalized to \( \omega_{\infty} = dx \). We note that \( \omega_{\infty} \) cannot vanish otherwise there is an extra polar component for the Riccati equation. We can write \( \omega_0 = gdx + hdy \) for multivalued functions \( g, h \). So, the induced Riccati foliation \( \mathcal{H} \) is given by

\[
\omega = dz + \frac{dh}{h} z + \frac{dg}{h}.
\]

Likely as in the previous proof, the fact that the monodromy is parabolic, \( z = \infty \) is invariant and the Riccati equation is logarithmic imply that we can write

\[
\omega = dz + \left( \frac{da}{a} - n \frac{dy}{y} \right) z + \left( \frac{db}{a} - \frac{nbdy}{ay} - \frac{y^{n-1}dy}{a} \right), \quad n \in \mathbb{Z}_{\geq0}
\]

where \( a \in \mathcal{O}_0^* \) and \( b \in \mathcal{O}_0 \). Comparing equations (25) and (26) and then solving we have \( h = cay^{-n} \) and \( g = cby^{-n} - c \ln y + e \), where \( c \in \mathbb{C} \) and \( e \in \mathbb{C} \). In fact, one can check that \( c \neq 0 \), otherwise the Riccati equation has a pole along \( x = 0 \). We can therefore suppose \( c = 1 \) and \( e = 0 \) by rescaling the \( t \) parameter of the pencil, so that

\[
\omega_t = a \frac{dy}{y^n} + \left( \frac{b}{y^n} - \ln y \right) dx + tdx.
\]
Closedness condition for $\omega_0$ gives

$$nb + y^n = y(b_y - a_x), \quad n \in \mathbb{Z}_{\geq 0}.$$  \hspace{1cm} (27)

One easily check that $n = 0$ yields a contradiction. Now we are going to divide into two cases for the values of $n$.

First case $n = 1$. By Lemma 3.2 with parameter, there is a change of $y$-coordinate that normalizes $a(x, y)\frac{dy}{y}$ to $a(x, 0)\frac{dy}{y}$, i.e. we can now assume that $a = a(x)$. Replacing it in (27) and writing $b = y\tilde{b}$ we have $y\tilde{b}_y = a'(x) + 1$. We deduce that $a'(x) + 1 = \tilde{b}_y = 0$, and therefore $\tilde{b} = \tilde{b}(x)$ and $a(x) = c - x, c \in \mathbb{C}$. However, $c = 0$ is impossible, since this would create a pole along $x = 0$ for the Riccati equation. Applying the diffeomorphism $x \to cx$ and dividing $\omega_t$ by $c$, we can assume $c = 1$ and hence

$$\omega_t = (1 - x)\frac{dy}{y} + (\tilde{b}(x) - \ln y)dx + tdx.$$

Finally taking the change of coordinates $(x, y) \to (x, y \exp(\frac{h}{2y}))$, where $h'(x) = \tilde{b}(x)$, we can set $\tilde{b} = 0$, and we get the first normal form of the statement.

Second case $n > 1$. By Lemma 3.2 with parameter, there is a change of $y$-coordinate that normalizes $a(x, y)\frac{dy}{y^n}$ to $a(x, 0)\frac{dy}{y}$, $\epsilon \in \mathcal{O}_0$. Closedness condition (27) shows that $b = y^n\tilde{b}$, and replacing it in (27), we have $1 + \epsilon'(x) = y^n\tilde{b}_y$. Hence $1 + \epsilon'(x) = \tilde{b}_y = 0$, and we get by integration $\tilde{b} = \tilde{b}(x)$ and $\epsilon = c - x$, for some $c \in \mathbb{C}$. In the case $c \neq 0$, taking the diffeomorphism $x \to cx$ and rescaling $\omega_t$, we can assume that $c = 1$. Therefore, we have

$$\omega_t = \frac{dy}{y^n} + (c - x)\frac{dy}{y} + (\tilde{b}(x) - \ln y)dx + tdx,$$

where $c = 0$ or 1. Finally, we show that we can set $\tilde{b}(x) = 0$ by a last change of $y$-coordinate. For this, we consider the change of coordinate $\psi(x, y) = (x, \varphi(x, y))$, where $\varphi = yu, u \in \mathcal{O}_0^*$. Here we choose $\varphi$ with the property that

$$\frac{\partial \varphi}{\partial y} \frac{dy}{\varphi^n} + (c - x)\frac{\partial \varphi}{\partial y} \frac{dy}{y^n} = \frac{dy}{y^n} + (c - x)\frac{dy}{y},$$

this is equivalent to

$$\frac{1}{(1 - n)y^{n-1}u^{n-1}} + (c - x)\ln u = \frac{1}{(1 - n)y^{n-1}} - h(x).$$
For \( h'(x) = \tilde{b}(x) \) the implicit function theorem guarantees the existence of a nonzero holomorphic solution \( u(x, y) \). We can check that
\[
\psi^* \left( \frac{dy}{y^n} + (c - x) \frac{dy}{y} \right) = \frac{dy}{y^n} + (c - x) \frac{dy}{y} + \ln u dx - h'(x) dx,
\]
Thus we have the desired conjugation. \( \square \)

So, the proof of the theorem ends. \( \square \)

Finally through Theorems 3.4 and 3.10 we get normal forms for Riccati foliations with logarithmic pole.

**Corollary 3.13.** Let \( \mathcal{H} \) be a torsion-free Riccati foliation with logarithmic pole over \( \mathbb{P}^1 \times (\mathbb{C}^2, 0) \to (\mathbb{C}^2, 0) \), of polar divisor \( D \). If the origin is a generic point of \( D \), then after a change of coordinates on \( (\mathbb{C}^2, 0) \) we have the foliation \( \mathcal{H} \) is given by one of the following equations with their respective monodromies listed below:

| Type | Equation | Monodromy |
|------|----------|-----------|
| Pencil | \( dx + t y^n dy \) | \( z \mapsto e^{2\pi i \nu} z \) |
| Riccati | \( dx + t \left( \frac{dy}{y^n} + \frac{dy}{y} \right) \) | Identity |
| | \( dx - y^n \ln(y) dy + ty^n dy \) | \( z \mapsto z + 1 \) |
| | \( \frac{du}{yn+1} + (c - x) \frac{dy}{y} - \ln(y) dx + tdx \) | \( z \mapsto z + 1 \) |

4. **Logarithmic parallelizable webs**

A regular \( d \)-web on \( (\mathbb{C}^2, 0) \) is the superposition \( \mathcal{W} = \mathcal{F}_1 \boxtimes \mathcal{F}_2 \boxtimes \cdots \boxtimes \mathcal{F}_d \) of \( d \) regular foliations \( \mathcal{F}_i \) that are moreover pairwise transversal:
\[
\mathcal{F}_i = \ker(\omega_i), \quad \omega_i = a_i(x, y) dx + b_i(x, y) dy
\]
for \( i = 1, \cdots, d \), with
\[
\omega_i \wedge \omega_j = \det \begin{pmatrix} a_i & b_i \\ a_j & b_j \end{pmatrix} dx \wedge dy \neq 0.
\]
The \( d \)-web \( \mathcal{W} \) is said parallelizable if, after a convenient change of coordinates, it is defined by linear foliations of parallel lines, i.e. with \( a_i, b_i \) constant functions.

It is well-known that regular 1webs (foliations), and 2webs are parallelizable, but a general \( d \)-web is not for \( d \geq 3 \). The condition for a 3-web to be parallelizable is that it is hexagonal (see [18]). We will provide an explicit criterium in term of torsion later; for what follows, it is enough to define hexagonal=parallelizable for a 3-web. A necessary condition for a \( d \)-web \( \mathcal{W} \)
to be linearizable is to require that all extracted 3-webs are hexagonal; in that case, we will say that the $d$-web $W$ is \textbf{hexagonal}. However, this is not enough, as can be shown by considering $d$ pencils of lines through a general collection of $d$ points. A new constraint arising from $d \geq 4$ is as follows.

Assume by a change of local coordinates that $b_i \neq 0$ and denote the slope $e_i(x,y) := -\frac{a_i(x,y)}{b_i(x,y)}$. Then the \textbf{cross-ratio}:

$$\left(\mathcal{F}_1, \mathcal{F}_2; \mathcal{F}_3, \mathcal{F}_4\right) := \frac{(e_1 - e_3)(e_2 - e_4)}{(e_2 - e_3)(e_1 - e_4)}$$

is a holomorphic function on $(\mathbb{C}^2, 0)$ intrinsically defined by $W$. If a 4-web is parallelizable, then its cross-ratio must be constant. When we turn to a $d$-web $W$, $d \geq 4$, a necessary condition to be parallelizable is that any extracted 4-web has constant cross-ratio; in that case, we will say that the $d$-web $W$ \textbf{has constant cross-ratio}. By convention, a 3-web has constant cross-ratio. There is a natural link with the notion of pencil of foliations.

**Proposition 4.1.** Let $W$ be a regular $d$-web, $d > 3$. Then $W$ is contained in a pencil of foliations $\{\mathcal{F}_t\}_{t \in \mathbb{P}^1}$ if, and only if, $W$ has constant cross-ratio. In that case, are equivalent:

1. $W$ is parallelizable,
2. $W$ is hexagonal,
3. the pencil $\{\mathcal{F}_t\}_{t \in \mathbb{P}^1}$ is torsion free, i.e. $d\kappa = 0$.

Remind (Section 2.2) that a pencil of foliations corresponds to a Riccati foliation $\mathcal{H}$ on $\mathbb{P}(T_S)$ via formula (14-15-16) and the torsion $d\kappa$ is defined by (17). In fact, the torsion $d\kappa$ coincides (up to a non zero constant) to the Blaschke curvature of any extracted 3-web of the pencil.

**Proof.** The first part is a consequence of a well-known property for Riccati foliations. In fact, given a regular 3-web $W = \mathcal{F}_0 \boxtimes \mathcal{F}_1 \boxtimes \mathcal{F}_\infty$ on $(\mathbb{C}^2, 0)$, then there is a unique pencil $\{\mathcal{F}_t\}_{t \in \mathbb{P}^1}$ that contains $\mathcal{F}_0, \mathcal{F}_1$ and $\mathcal{F}_\infty$ as elements. Precisely, $\mathcal{F}_t$ is defined as the unique foliation such that

$$\left(\mathcal{F}_t, \mathcal{F}_0; \mathcal{F}_1, \mathcal{F}_\infty\right) = t$$

and we see that any extracted $d$-web must has constant cross-ratio.

For the second part, if $\mathcal{F}_0 \boxtimes \mathcal{F}_1 \boxtimes \mathcal{F}_\infty$ is parallelizable, say, then in convenient coordinates we can assume that it is $\ker(dx) \boxtimes \ker(dx - dy) \boxtimes \ker(dy)$ and the pencil (defined by constant cross-ratio) is therefore parallel. Finally, recall that the pencil is parallelizable if, and only if, the torsion is zero, i.e. $d\kappa = 0$. \qed
Globally, a regular $d$-web which has (locally) constant cross-ratio is better related to a Veronese web (or a Riccati foliation on $\mathbb{P}(T_S)$ with possibly non trivial monodromy).

A singular $d$-web $W$ on a surface $S$ is given by an open covering $\mathcal{U} = \{U_i\}$ of $S$ and $d$-symmetric 1-forms $\omega_i \in \text{Sym}^d \Omega^1_S(U_i)$ such that for each non-empty intersection $U_i \cap U_j$ of elements of $\mathcal{U}$ there exists a non-vanishing function $g_{ij} \in \mathcal{O}_S(U_i \cap U_j)$ such that $\omega_i = g_{ij} \omega_j$. The singular locus $\Delta$ is defined in charts by the discriminant of $\omega_i$ which is assumed to be non identically vanishing: $\Delta$ is empty, or an hypersurface, and the $d$-web is regular on $S \setminus \Delta$. We will say that $W$ is hexagonal, or has constant cross-ratio, or is parallelizable if the property holds on $S \setminus \Delta$.

**Theorem 4.2.** Let $W$ be a singular $d$-web on $S$, $d \geq 3$, with discriminant $\Delta$ and assume $W$ has constant cross-ratio. Then, the Riccati foliation $H$ defined by $W|_{S \setminus \Delta}$ on $\mathbb{P}(T_{S \setminus \Delta})$ (see Proposition 4.1) extends as a singular Riccati foliation on $\mathbb{P}(T_S)$ with regular-singularities along $\Delta$; moreover, it has finite monodromy.

If $W$ is hexagonal, then $H$ is torsion-free and defines an affine structure on $S$ with regular-singularities along $\Delta$.

**Proof.** By definition of singular $d$-web, the local foliations defined by $W$ at a generic point lift as a global multisection $\Sigma_W$ of $\mathbb{P}(T_S)$, possibly ramifying over $\Delta$. In local charts, sections of $\text{Sym}^d \Omega^1_S$ take the form

$$
\omega = a_0(x,y)(dx)^d + a_1(x,y)(dx)^{d-1}(dy) + \cdots + a_d(x,y)(dy)^d
$$

and the multisection $\Sigma_W$ is defined by

$$
\Sigma_W = \{a_0(x,y) + a_1(x,y)z + \cdots + a_d(x,y)z^d = 0\}, \quad z = \frac{dy}{dx}.
$$

The Riccati foliation $H$ defined by $W$ outside of $\Delta$ is determined as follows: the multisection $\Sigma_W$ is a union of leaves for $H$ and, since $d \geq 3$, this is enough to define $H$. All other leaves are algebraic (defined by constant cross-ratio, see proof of Proposition 4.1) and this implies that $H$ extends as a singular Riccati foliation over $\Delta$. The monodromy of $H$ induces a permutation of the local branches of $\Sigma_W$, and we get a morphism

$$
\text{Mon}(H) \rightarrow \text{Sym}(d)
$$

and it is injective since $d \geq 3$; therefore, $H$ has finite monodromy. We claim that the extension is regular-singular along $\Delta$. Indeed, after ramified covering $\pi : \tilde{S} \rightarrow S$, ramifying over $\Delta$, we can assume that the monodromy
of $\tilde{\mathcal{H}} = \pi^*\mathcal{H}$ is trivial, and we get a global pencil (leaves define global meromorphic sections). But this implies that we can trivialize the foliation by a global meromorphic gauge transformation. Therefore $\tilde{\mathcal{H}}$ is regular-singular. But this implies that $\mathcal{H}$ is regular-singular, for instance using characterization in term of polynomial growth (see [3]).

The last assertion is just a consequence of the definitions (Section 2.3). □

Let $\mathcal{W}$ be a singular parallelizable $d$-web on $S$. Then $\mathcal{W}$ is said logarithmic if the associate affine structure is logarithmic.

**Theorem 4.3.** Let $\mathcal{W}$ be a singular parallelizable $d$-web on $S$, $d \geq 3$, with logarithmic singular points. Then, at a generic point of the discriminant $\Delta$, $\mathcal{W}$ is contained in one of the following pencils:

1. $\{(dx)^q + ty^p(dy)^q = 0\}_t$, with $(p, q)$ relatively prime positive integers,
2. $\{y^p(dx)^q + t(dy)^q = 0\}_t$, with $(p, q)$ relatively prime positive integers,
3. $\{y^{n+1}dx + t(1 + y^n)dy = 0\}_t$, with $n$ positive integer.

**Proof.** By Theorem 4.2, $\mathcal{W}$ defines a logarithmic affine structure on $S$ with poles along the discriminant $\Delta$, with finite monodromy. Therefore, the monodromy cannot be parabolic, and we apply the local models of Theorem 3.4, with $\nu \in \mathbb{Q}^*$. Then the normal form $dx + ty^\nu dy$ splits into $\nu = \frac{p}{q}$ or $-\frac{p}{q}$, where $(p, q)$ relatively prime positive integers.

We did not succeed to find a regular-singular version of Lemma 3.8 and this is what is missing to provide normal forms for general torsion-free $d$-webs.
