(Dated: March 22, 2022)

Light emission from carbon nanotubes is expected to be dominated by excitonic recombination. Here we calculate the properties of excitons in nanotubes embedded in a dielectric, for a wide range of tube radii and dielectric environments. We find that simple scaling relationships give a good description of the binding energy, exciton size, and oscillator strength.

PACS numbers: 78.67.Ch,71.10.Li,71.35.Cc

The optical properties of carbon nanotubes have received increasing experimental and theoretical attention. Optical absorption and emission spectra of carbon nanotubes have been studied by a number of groups [1, 2, 3, 4, 5, 6]; and electro-optical devices have already appeared [7, 8]. Initial attempts to explain the experimental observations naturally took independent-electron approximations [9, 10, 11, 12].

A number of theoretical approaches have been used to describe these excitons. One approach involves variational calculations [10, 11]. While valuable, these have been limited to an effective-mass approximation, and do not address issues of spectral weight. The most accurate description is provided by an \textit{ab initio} solution of the Bethe-Salpeter equation using GW-corrected quasiparticle energies [13]. However, it is not currently feasible to apply this computationally intensive approach to a wide range of nanotube sizes or environments.

Here we use an intermediate level of theory to provide a broad overview of the exciton properties. We calculate the excitonic properties of nanotubes embedded in a dielectric, for the range of tube radii and dielectric constants most relevant to potential applications. We find that the exciton size, binding energy, and oscillator strength all exhibit robust (though approximate) scaling relationships. The relationships obtained for the excitonic properties can be used to better understand and optimize the operation of nanotube opto-electronic devices.

The proper procedure for the calculation of excitons has been described in detail in Ref. [13]. It involves solving the Bethe-Salpeter equation,

\[ \Delta_k A_k^S + \sum_{k'} K_{k,k'} A_{k'}^S = \Omega S A_k^S \]

where the kernel \( K_{k,k'} \) describes the interaction between all possible electron-hole pairs of total momentum \( q_{\text{exc}} \), and \( \Delta_k \) is the quasiparticle energy for a non-interacting electron and hole with wavevector \( k \) and \( q_{\text{exc}} - k \). The exciton momentum \( q_{\text{exc}} \) is equal to that of the exciting photon, and is hereafter approximated by \( q_{\text{exc}} = 0 \). We approximate the quasiparticle energies by eigenvalues of the tight-binding Hamiltonian \([14, 15]\) \( (t = 3.0 \, \text{eV}) \), with any additional self-energy corrections restricted to the so-called “scissors operator”, in which the self-energy is approximated by a rigid shift of the conduction band relative to the valence band. Since the quasi-particle band-structures are not well known for nanotubes of varying diameters and embedding media, we report only properties that are not affected by the magnitude of this shift.

For the optically active singlet excitons, the interaction has two contributions, direct (\( K^d \)) and exchange (\( K^x \)):

\[ K_{k,k'} = K^d_{k,k'} + 2K^x_{k,k'} \]

where the direct (exchange) term is evaluated with the screened (bare) Coulomb interactions \([13]\). The unscreened Coulomb interaction between carbon p\text{z} orbitals is modelled by the Ohno potential, which realistically describes organic polymer systems:

\[ V(r_{ij}) = \frac{U}{\sqrt{(1 + U r_{ij})^2 + 1}} \]

where \( r_{ij} \) is the distance between sites \( i \) and \( j \), and \( U = 11.3 \, \text{eV} \) is the energy cost to place two electrons on a single site \( (r_{ij} = 0) \). Our results are not sensitive to the value of \( U \) when the size of the exciton is large.

An ideal calculation would include the nonlocal dielectric response of both the nanotube itself and the medium in which it is embedded. Here, for computational simplicity, we replace this complicated response function with a single dielectric constant \( \varepsilon \) \([16]\). This is most accurate for narrow tubes, and for embedding media with large dielectric constants. In this regime, the exciton length along the tube is large relative to the tube radius, and most of the dielectric screening occurs in the surrounding medium. The screening is then well described by the dielectric constant \( \varepsilon \) of the nanotube environment. For isolated nanotubes, or tubes in low-\( \varepsilon \) media, this treatment is not very accurate. Fortunately, it is most accurate in precisely the regime of greatest technological interest. Modulated electro-optical devices \([7, 8]\) are most practical for relatively narrow tubes embedded in SiO\text{}\(_2\) \( (\varepsilon \sim 4) \) or higher-\( \varepsilon \) materials.

To calculate the optical properties, we evaluate the
imaginary part of the dielectric function for light polarized along the nanotube axis:

$$\varepsilon_2(\omega) = \frac{8\pi^2e^2}{V_0m^*} \sum_{S} \sum_{k} A_k^S \frac{P_{ce}(k)}{\Delta_k^S}^2 \delta(\hbar\omega - \Omega_S)$$  \hspace{1cm} (4)

where $P$ is the dipole matrix element, $\Omega$ is the optical response of the tube, $\varepsilon_2(\omega)$ obeys a sum rule, where $\int \varepsilon_2d\omega \propto \sum_k P_{ce}(k)/\Delta_k^S$ is a constant independent of the strength of the screened interaction $\varepsilon^2/\varepsilon$.

We solve the BSE equation by direct diagonalization, choosing a $k$ sample sufficient to converge the low-energy optical spectra (and a fortiori the binding energies). We calculate the binding energy, size, and spectral function for singlet excitons. The binding energy of the first optically active exciton vs. $\varepsilon$ is shown on Fig. 1a for four zig-zag tubes with diameters $d = 1.0 - 2.5$ nm. (There is another singlet state 3-5 meV lower in energy, but it is optically silent by symmetry.)

The dependence of binding energy $E_{b1}$ on $\varepsilon$ in Fig. 1a can be fitted well with a power law, with the exponent being almost independent of the tube diameter. This suggests a more general power law scaling, which we can motivate in an effective mass approximation as follows. Given a variation wavefunction described by a single parameter $L$ that scales the size along the tube axis, the exciton binding energy is:

$$E_L \propto \frac{\hbar^2}{2mL^2} - \frac{e^2}{\varepsilon R} f\left(\frac{L}{R}\right) = \frac{\hbar^2}{mR^2}\frac{1}{\varepsilon R} \left(\frac{L}{R}\right)^2$$  \hspace{1cm} (5)

Here the first term is the kinetic energy, and $m$ is the effective mass. The second term is the potential energy, which depends on the exciton size via the dimensionless function $f(L/R)$. Then the exciton binding energy is:

$$E_b = \min_L (E_L) = \frac{\hbar^2}{mR^2} = \frac{\hbar^2}{mR^2} \left(\frac{L}{R}\right)^2 \frac{1}{\varepsilon R}$$  \hspace{1cm} (6)

$$E_b \approx A_1 R^{-2} m_0^{-1} \varepsilon^{-\alpha}$$  \hspace{1cm} (7)

where we approximate the function $h$ by a power law over the range of interest, with empirical parameters $\alpha$ and $A_1$. The effective mass $m$ depends on the tube indices (i.e. on radius and chirality).

In 3D semiconductors, the potential energy is $\propto 1/L$, and the energy is minimized when the exciton size $L_S \propto \varepsilon/m$, so the binding energy scales as $E_b \propto m/\varepsilon^2$. This corresponds to true scaling, with a power law $\alpha = 2$ in Eq. (7). In the case of nanotubes, the power-law scaling is only an approximation. Nevertheless, for the most important range of tube sizes and dielectric constants, the behavior is rather well described by a power-law scaling in $R$ and $\varepsilon$ with a single value of $\alpha$. Indeed, all the binding energies for the first and second excitons in semiconducting tubes, with all possible chiralities, ($d = 1.0 - 1.5$ nm) collapse onto a single curve shown in Fig. 1b. Similar energy scaling was reported by Pedersen in a variational effective-mass model. In the range $\varepsilon \gtrsim 4$, where our approach is most reliable, we obtain the best fit with $\alpha = 1.40$.

The second exciton that is optically active derives primarily from the second band of the nanotube. It falls within the continuum of the first band, and so becomes a resonance with a finite lifetime. By artificially turning off the interband coupling, we determine that this coupling has very little effect on the exciton energy.

Considerable attention has been focused on the ratio $E_{b2}/E_{b1}$ between the binding energies of the first and second excitons. ($E_{b2}$ is defined relative to the second-band quasiparticle gap. Note that the exciton formation energies involve also the quasiparticle bandgaps.) The scaling relation of Eq. (7) predicts $E_{b2}/E_{b1} = (m_2/m_1)^{\alpha-1}$, where $m_2$ and $m_1$ are the effective masses of the first and second bands. In the case of zig-zag tubes:

$$m_1 = \frac{\hbar^2\Delta_1}{3a^2\Delta^2} \left(1 + \frac{\Delta_1}{2}\right)^{-1}$$

$$m_2 = \frac{\hbar^2\Delta_2}{3a^2\Delta^2} \left(1 - \frac{\Delta_2}{2}\right)^{-1}$$  \hspace{1cm} (8)

Here $\Delta_1$ and $\Delta_2$ are the tight-binding bandgaps; $a$ is the graphene lattice constant; and for tube indices $(n,0)$, $\sigma=1$ if $\text{mod}(n,3)=1$ and $\sigma=-1$ if $\text{mod}(n,3)=2$.

It is common to treat the gap values in the infinite-radius limit, $\Delta_\infty = 2\Delta_1 = 2a/\sqrt{3}R$. This is rather accurate (within 5%) for tubes with $d = 1.0 - 2.5$. On the other hand, for the same range of diameters, the effective
mass ratio $m_2/m_1$ varies from 3.4 to 1.3, approaching the infinite-radius limit $m_2/m_1 \to 2$ much more slowly than the gap ratio. Thus caution must be used in discussing available experimental data in terms of the $R \to \infty$ limit \cite{11}. In particular, for the (8,0) tube $m_2/m_1 = 0.96$, and according to Eq. (7) the binding energies of the first two excitons should be very similar. Indeed, the accurate first-principles calculations by Spataru et. al. \cite{12} find the binding energies of the first and second excitons ($A'_1$ and $C'_1$ in \cite{12}) to be 0.99 and 1.00 eV. Using $\epsilon = 1.93$ to best reproduce this, our calculations give $E_{b1} = 0.99$ eV and $E_{b2} = 1.05$ eV. In contrast, the (10,0) tube has $m_2/m_1 = 4.14$, and for the same $\epsilon = 1.93$ we find $E_{b2}/E_{b1} = 1.41$. [The simple $m^{-1}$ scaling is not accurate for such small $\epsilon$.] It is important to note that the effective mass dependence similar to Eq. (5) holds also for chiralities other from zig-zag tubes. Thus we expect exciton properties in tubes of index $(m,n)$ to depend primarily on whether $\text{mod}(n-m,3)=1$ or 2, independent of the chiral angle.

To quantify the exciton size, we use the root-mean-square (RMS) distance between electron and hole, $L_s$. The size $L_1$ of the first exciton is shown in Fig. 2a as a function of $\epsilon$, for four different tube diameters. The size is approximately linear in $\epsilon$. From Eq. (5), $L_s/R$ is expected to be a function of $mR/\epsilon$. Combining this with the observed linear dependence on $\epsilon$, we anticipate that the exciton size will obey the scaling relationship:

$$\frac{L_1}{R} = A_L + B_L \frac{\epsilon}{Rm_1}$$

(9)

This is confirmed in Fig. 2a, which shows a linear dependence of $L_1/R$ on $\epsilon/m_1 R$ in all semiconducting tubes with $d = 1.0 - 2.5$ nm, for all chiralities.

The exciton size directly affects observable quantities such as the exciton oscillator strength and the radiative lifetime. The exciton oscillator strength is proportional to the probability to find an electron and a hole at the same position \cite{19}. In 3D semiconductors this is inversely proportional to the exciton volume $1/L^3$. In the case of nanotubes the electron and hole wavefunctions are confined in two dimensions and therefore the oscillator strength should be inversely proportional to the exciton size $L_1$.

Typical optical absorption spectra are shown on Fig. 2b-c, calculated for a (19,0) tube in different dielectric media. As $\epsilon$ increases, the spectral function converges to the non-interacting limit. For $\epsilon = 10$, the spectral weight transfer to the first and second excitons, as a fraction of the total spectral weights for first and second bands in the non-interacting limit, are 71% and 55% respectively. The second exciton resonance is more bound than the first, by 63 meV vs. 43 meV. The higher spectral weight transfer to the first exciton is due not to stronger binding, but rather to the smaller band gap $\Delta_1$.

![Figure 2](https://example.com/figure2.png)

**FIG. 2:** (a) First exciton RMS e-h separation $L_1$ in four zig-zag tubes (13,0), (19,0), (25,0), and (31,0). The solid lines are the best linear fits. The slope $k$ scales approximately as $m^{-1}$: the product $km_1$ (in a.u.) equals 0.167, 0.160, 0.157, and 0.155 for tubes with diameter 1.0, 1.5, 2.0, and 2.5 nm, respectively. (b) The linear scaling of $L_1/R$ with $\epsilon/mR$ in semiconducting tubes of all possible chirality with $d = 1.0 - 2.5$ nm, and $\epsilon = 2 - 15$. The solid line is the best fit to Eq. (9) to the results in the range $\epsilon \geq 4$, giving $A_L = 2.13$ and $B_L = 0.174$ (for $m$ and $R$ in a.u.). The RMS discrepancy between the fit and the full calculations is 2% for the subset of data having $\epsilon \geq 4$ or $\epsilon/mR^2 \geq 9.5$.

The probability argument \cite{19} along with Eq. (1) suggest the following scaling relation for the exciton oscillator strength:

$$\frac{I_1}{I_0} = \frac{A_1}{\Delta^2 L_1 R} \left(1 - \frac{B_1 R}{L_1}\right)$$

(10)

where $I_0$ is the spectral weight of the first band for non-interacting particles. The second term is a higher order correction due to the band mixing and the non-constant band-to-band optical density. Figure 4a confirms this scaling. While $L_1$ is not directly observable, the figure is virtually unchanged if we use the actual calculated $L_1$ values instead of the scaling expression Eq. (9) for $L_1$. Thus $I_1/I_0$ obeys rather well an explicit scaling relationship with $\epsilon/Rm$.

The radiative lifetime of the excitons in carbon nanotubes is a key factor for possible applications in photonics and optoelectronics. The radiative lifetime of an exciton is inversely proportional to its oscillator strength. \cite{20}. In the regime of large binding ($\epsilon \lesssim 3$), $I_1 \approx I_0$. Then the oscillator strength per atom is almost independent of tube diameter and chirality, and is equal to $f_0 \approx (0.014 eV^{-1}) E_{exc}$. We emphasize however that the radiative lifetime and luminescence efficiency of nanotubes involve other factors as well. In principle, a single exciton coherently captures spectral weight from a macroscopic region \cite{21}; so the lifetime of an exciton actually depends on the coherence.
The best fit to Eq. (10) (RMS difference 3.5%) is obtained for helpful angle. This depends strongly on whether mod(n-m,3)=1 or 2, but is otherwise insensitive to the chiral angle.

FIG. 3: Absorption spectra $\varepsilon_2$ in (19,0) tube in dielectric environment (a) $\varepsilon = \infty$ (equivalent to no e-h interaction), (b) $\varepsilon = 10$, (c) $\varepsilon = 4$. ($E_s$ is the unknown self-energy shift.) Note expanded scales for dotted lines in continuum region in (b) and (c). The fractional spectral weight transfer to the first exciton is $I_1/I_0 = 0.71$, and 0.95 respectively. Spectra are broadened with a Gaussian width of 0.0125 eV. (d) The scaling of spectral weight transfer to the first exciton, $I_1$, according to Eq. (10), in all semiconducting tubes with $d=1.0-2.5$ nm and $\varepsilon = 2-15$ and all possible chiralities. The best fit to Eq. (10) (RMS difference 3.5%) is obtained with $A_1=1.22$ eV$^2$nm$^2$ and $B_1=1.61$.

length in the nanotube, which in turn depends on environment and temperature. (If the coherence length is sufficiently large, other length scales such as tube length or photon wavelength can become important.) Another important factor is that electrons and holes are relatively unlikely to form optically active excitons, because there are far more excitons that are optically inactive. Most importantly, only a tiny fraction of excitons have a total momentum compatible with photon emission, so phonon scattering plays an important role.

In conclusion, we have calculated optical spectra of carbon nanotubes including the electron-hole Coulomb interaction by solving the Bethe-Salpeter equation in a tight-binding wave function basis set. We find scaling relations with respect to the tube radius and dielectric constant $\varepsilon$, for the binding energy Eq. (11), exciton size Eq. (12), and oscillator strength Eq. (13). Thus the absorption and emission properties depend on the dielectric medium in which the nanotube is placed. We find a strong dependence on tube index (chirality), but only via the effective mass. This depends strongly on whether mod(n-m,3)=1 or 2, but is otherwise insensitive to the chiral angle.

[15] This approach neglects s-p hybridization, which becomes increasingly important for narrower tubes. Fortunately, the associated error is small for the entire range of tubes and excitation energies considered here [except perhaps for the (8,0) and (10,0) tubes which are mentioned in the text but not including in the scaling analysis]; see X. Blase, L. X. Benedict, E. L. Shirley, and S. G. Louie, Phys. Rev. Lett. 72, 1878 (1994).
[16] If the exciton binding energy is much smaller than the optical phonon energy in the dielectric medium, then the static dielectric constant $\varepsilon_0$ should be used in the scaling relations obtained here; but if much larger, then the screening $\varepsilon_\infty$ (i.e. for frequencies well above the phonon frequency) is used. A general treatment would require explicit inclusion of exciton-phonon coupling.
