Abstract
We examine the long time behaviour of $A + B \rightarrow 0$ reaction diffusion systems with initially segregated species $A$ and $B$. All of our analysis is carried out for arbitrary (positive) values of the diffusion constants $D_A$, $D_B$, and initial concentrations $a_0$ and $b_0$ of $A$'s and $B$'s. We divide the domain of the partial differential equations describing the problem into several regions in which they can be reduced to simpler, solvable equations, and we merge the solutions. Thus we derive general formulae for the concentration profiles outside the reaction zone, the location of the reaction zone center, and the total reaction rate. An asymptotic condition for the reaction front to be stationary is also derived. The properties of the reaction layer are studied in the mean-field approximation, and we show that not only the scaling exponents, but also the scaling functions are independent of $D_A$, $D_B$, $a_0$ and $b_0$.

Key words: reaction kinetics; diffusion; segregation; partial differential equations.

1 Introduction

The study of the interfacial region formed in diffusion limited $A + B \rightarrow 0$ type reactions between domains of unlike species has attracted much current interest [1]-[18]. A natural way to examine this problem is to prepare a system with the components initially segregated along the plane $x = 0$, and then investigate the spatio-temporal evolution of their concentrations $\rho_A$ and $\rho_B$, and the reaction rate $R$. Such geometry, first studied by Gálfy and Rácz [2], was already investigated by means of various methods, including experiments [3, 4, 5], numerical simulations [6, 7, 8, 9], analytical computations [10, 11, 12], scaling [2, 9, 13, 14] and dimensional [13, 15] analysis.

A standard way to treat the initially separated problem analytically is to solve the following partial differential equations [2]

$$\begin{align*}
\frac{\partial \rho_A}{\partial t} &= D_A \frac{\partial^2 \rho_A}{\partial x^2} - R \\
\frac{\partial \rho_B}{\partial t} &= D_B \frac{\partial^2 \rho_B}{\partial x^2} - R
\end{align*}$$

(1)

with the initial state given by

$$\begin{align*}
\rho_A(x, t = 0) &= a_0 H(-x) \\
\rho_B(x, t = 0) &= b_0 H(x)
\end{align*}$$

(2)

where $\rho_A(x, t)$ and $\rho_B(x, t)$ are the local concentrations of A’s and B’s, $R$ is the reaction rate, $H(x)$ denotes the Heavyside step function, and $a_0, b_0, D_A$ and $D_B$ are some positive constants related to the initial concentrations of species A and B and their diffusion coefficients respectively. It is customary [2, 3, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17] to assume $D_A = D_B \equiv D$, which leads to the conclusion that $u(x, t) = \rho_A - \rho_B$ obeys the readily solvable diffusion equation $\partial_t u = D \partial^2_x u$ irrespective of $R$. Finally some form of $R$ must be assumed, and in most cases either the mean field approximation $R \propto \rho_A \rho_B$ [2, 16, 12, 16], or its generalization $R \propto \rho_A^m \rho_B^n$ [8, 9, 13, 14] was adopted.

With these assumptions, two fundamental concepts were developed, both referring to the long time limit. According to the first one [4], the long time behavior of the system inside the reaction layer can be described with a help of some scaling functions $S_A, S_B$ and $S_R$ through

$$\begin{align*}
\rho_A(x, t) &\propto t^{-\gamma} S_A \left( \frac{x - x_f(t)}{\ell^\alpha} \right), \\
\rho_B(x, t) &\propto t^{-\gamma} S_B \left( \frac{x - x_f(t)}{\ell^\alpha} \right)
\end{align*}$$

(3)

(4)
\[ R(x, t) \propto t^{-\beta} S_R \left( \frac{x - x_f(t)}{t^\alpha} \right), \quad (5) \]

where \( x_f(t) \) denotes the point at which the reaction rate \( R \) attains its maximal value, and exponents \( \alpha, \beta \) and \( \gamma \) are some positive constants given, for \( R \propto \rho_A^m \rho_B^n \), by \( \gamma = 1/(m + n + 1) \), \( \alpha = \frac{1}{2} - \gamma \) and \( \beta = 1 - \gamma \). The scaling ansatz is based on the assumption that the width \( w(t) \) of the reaction layer grows with time as \( t^\alpha \) with \( \alpha < 1/2 \), so that in addition to the diffusion length scale \( \lambda_D \sim \sqrt{D t} \), the problem possesses also another relevant length scale \( w \propto t^\alpha \).

According to the second theory, called the quasistationary approximation \([13, 16]\), the currents \( J_A(t) \) and \( J_B(t) \) of particles A and B arriving at the interface layer from the two densely occupied domains are changing so slowly, that the relatively narrow interface has enough time to equilibrate. To 'equilibrate' means here to reach a state completely determined by the current boundary conditions, i. e. by \( J_A \) and \( J_B \). Mathematically this is equivalent to the assumption that the state of the reaction zone is entirely given by equations obtained from (1) by replacing its left sides, or the time derivatives, with zero. This leads to much simpler equations

\[
\begin{align*}
D_A \frac{\partial^2 \rho_A}{\partial x^2} &= R \\
D_B \frac{\partial^2 \rho_B}{\partial x^2} &= R
\end{align*}
\]

which are to be solved with the boundary conditions \( \partial \rho_A / \partial x \to -J_A(t) \) and \( \rho_B \to 0 \) as \( x \to -\infty \), and \( \rho_A \to 0, \partial \rho_B / \partial x \to J_B(t) \) as \( x \to +\infty \). The most important feature of the quasistationary equations (3) is that they depend only on \( x \), with time \( t \) being a parameter entering their solutions \( \rho_A(x, t) \) and \( \rho_B(x, t) \) only through the time dependent boundary currents \( J_A \) and \( J_B \).

It was conjectured by Gálli and Rácz \([4]\) that the first of the above assumptions, \( D_A = D_B \), is irrelevant with regard to the long time behavior of the system, the ratio \( D_A / D_B \) affecting perhaps the form of the scaling functions \( S_A, S_B \) and \( S_R \), but not the values of exponents \( \alpha, \beta \) and \( \gamma \). This hypothesis was generally accepted after numerical \([3]\) and experimental \([4]\) verification. However, there is still no analytical theory referring to the general case \( D_A \neq D_B \). For two reasons this situation arouses some anxiety. First, it is practically impossible to find in Nature two species with exactly the same diffusion constants. Second, the above mentioned verification encompassed only the case where the ratio \( D_A / D_B \) was of order 1, whereas it is known \([3, 17]\), that if one of the diffusion constants is equal zero, the mean-field exponents assume values entirely different from those predicted by Gálli and Rácz, namely \( \alpha = 0, \beta = 1/2 \) and \( \gamma = 1/4 \). The aim of this paper is to present such general theory comprising the case of any positive diffusion constants \( D_A \) and \( D_B \).
Unfortunately, we know of only one successful attempt to derive the macroscopic form of $R$ from the microscopic properties of the system \[1\]. Dimensional analysis leads to another important conclusion that the mean field approximation should be valid only in spaces of dimension higher than $d_c = 2$ \[9, 13, 15\]. Therefore our basic equation (1) might seem useful only for these two sorts of systems for which the form of $R$ is known. In our approach, however, we will not need to impose any special restriction on the form of $R$. Instead, we will require that the solutions of (1) satisfy a few physically justifiable relations. Therefore our theory can be applied even to the systems for which the form of $R$ remains unknown, including experiments and microscopic models. In such cases verification of our postulates should be far easier than the task of finding the exact form of $R$, let alone solving (1) afterwards.

The paper is organized as follows. In the next section we will present the assumptions our theory has been founded on, as well as their short physical justification. The general theory is formulated in the third section. In the next section we will use it to derive and discuss the scaling ansatz in the mean field approximation. The final, fifth section is devoted to conclusions.

2 Assumptions

We will consider systems which can be described with the Gálfí and Rácz equations (1) and the boundary conditions (2). We will assume that $D_A, D_B, a_0$ and $b_0$ are some known positive constants. Our analysis will be based on a few physical assumptions.

i. At any time $t > 0$ there exists a unique point $x_f(t)$ at which the reaction term $R$ attains its maximal value, and a unique point $x_0(t)$ at which $D_A\rho_A(x_0, t) - D_B\rho_B(x_0, t) = 0$.

ii. The reaction is concentrated in a region $|x - x_f| \sim w(t) \sim t^\alpha$ with $0 < \alpha < 1/2$. Outside this region, for $x \ll x_f - w$, there is $\rho_A \gg \rho_B$, and for $x \gg x_f + w$ we have $\rho_A \ll \rho_B$.

iii. The evolution of $\rho_A$ in the region $x \ll x_f - w$ can be approximated by

$$\rho_A(x, t) = a_0 - C_A \left[ \text{erf} \left( \frac{x}{\sqrt{4D_A t}} \right) + 1 \right],$$

where $C_A$ is a constant, and $\text{erf}(x) \equiv 2^{-1/2} \int_0^x \exp(-\eta^2) \, d\eta$ is the error function \[19\].

Similarly, for $x \gg x_f + w$, the evolution of $\rho_B$ can be estimated by

$$\rho_B(x, t) = b_0 + C_B \left[ \text{erf} \left( \frac{x}{\sqrt{4D_B t}} \right) - 1 \right],$$
where $C_B$ denotes another constant. Both $C_A$ and $C_B$ depend on the initial parameters $a_0, b_0, D_A$ and $D_B$.

iv. The quasistatic approximation is valid in the region $-(D_A t)^{1/2} \ll x \ll (D_B t)^{1/2}$.

The first assumption introduces two functions $x_f(t)$ and $x_0(t)$, restricting the considerations to the cases where they are uniquely defined. Function $x_f$ identifies directly the location of the reaction layer at time $t$, and $x_0$ is an auxiliary, mathematical object helpful in examining the behavior of $x_f$. That $x_0$ exists for any $t > 0$ stems from the initial conditions (2). As for the second postulate, it was satisfied by all the $A + B \rightarrow 0$ interfacial systems examined so far. The third assumption comes from the observation that, due to postulate ii), in the region $x \ll x_f - w$ the concentration of particles $A$ is expected to be much bigger than that of $B$’s, the latter having to cross the whole reaction layer to get there. Therefore, the evolution of A’s is practically unaffected by B’s, and so it should be governed by the standard diffusion equation $\partial_t \rho_A = D_A \partial_x^2 \rho_A$. The particular, based on the error function form (7) of its solution was predicted and experimentally confirmed by Koo and Kopelman [3]. Notice also that for any time $t$ such form of $\rho_A$ guarantees that the relation $\lim_{x \rightarrow -\infty} \rho_A = a_0$ implied by the initial conditions (2) is also fulfilled. A similar argument leads to (8). As for the last postulate, the quasistationary approximation is based on the following observation [13]. The diffusion current of particles arriving at the reaction layer is $J \propto t^{1/2}$, so the characteristic time scale on which this current changes is $\tau_J \sim (\frac{d \log J}{dt})^{-1} \propto t$, whereas the equilibration time of the reaction front is $\tau_F \sim w^2 \propto t^{2\alpha}$; therefore $\alpha < 1/2$ implies that as time goes to infinity, the ratio $\tau_F/\tau_J$ goes to 0, validating the quasistatic approximation.

As we mentioned above, we will not impose any explicit restrictions on the form of the macroscopic reaction rate $R$ requiring only that it be consistent with the above postulates. However, to investigate the behavior of the $A + B \rightarrow 0$ system inside the reaction zone we will need more detailed information about $R$. Therefore in Section 4 we will concentrate on the mean-field approximation $R \propto \rho_A \rho_B$.

3 Analysis

The following observation constitutes the basis of the analysis of our model. For sufficiently long time $t$, at any point $x$ we can employ either assumption iii) or iv) or both of them − see Fig. 1. Therefore we can divide the $x$ axis into several regions, and in each of them the initial problem of solving (1) can be reduced to a much simpler one. Then, the overlapping of the domains of applicability of iii) and iv) will enable us to merge the solutions.
Figure 1: Schematic diagram of the regions of applicability of postulates iii) and iv). Asymptotically \( w(t) \propto t^\alpha \ll t^{1/2} \).

Consider first the region \(-\sqrt{D_A}t \ll x \ll \sqrt{D_B}t\). By assumption iv) the system is governed here by quasistationary equations (6). They imply that \( \Psi(x,t) \equiv D_B \rho_B - D_A \rho_A \) satisfies \( \partial^2 \Psi/\partial x^2 = 0 \). Therefore \( \Psi \) is linear in \( x \). Let \( J(t) \) denote its slope. By definition of \( x_0 \) we have \( \Psi(x_0,t) = 0 \). Thus we arrive at the conclusion that at sufficiently long time \( t \), for \(-\sqrt{D_A}t \ll x \ll \sqrt{D_B}t\), there is

\[
D_B \rho_B - D_A \rho_A \approx J(t)(x - x_0(t)) ,
\]

and so \( J_A(t) = J_B(t) = J(t) \). The notation \( f(t) \approx g(t) \) means \( \lim_{t \to \infty} f(t)/g(t) = 1 \).

Consider now the region \(-\sqrt{D_A}t \ll x \ll x_f - w\), so that \( \epsilon \equiv x_f - x \) fulfills \( t^\alpha \ll \epsilon \ll t^{1/2} \). Applying assumption ii) to (9) we can approximate the form of \( \rho_A \) by

\[
\rho_A(x,t) \approx -D_A^{-1} J(t)(x - x_0(t)) .
\]

On the other hand, however, by assumption iii), \( \rho_A \) can be here as well expressed by equation (7). So we have

\[
a_0 - C_A \left[ \text{erf} \left( \frac{x_f(t) - \epsilon}{\sqrt{4D_A}t} \right) + 1 \right] \approx -D_A^{-1} J(t)(x_f(t) - x_0(t) - \epsilon) \]

and

\[
\frac{\partial}{\partial x} \left( a_0 - C_A \left[ \text{erf} \left( \frac{x}{\sqrt{4D_A}t} \right) + 1 \right] \right) \bigg|_{x_f-\epsilon} \approx -D_A^{-1} J(t) .
\]

By assumption ii), for any \( x \) located outside the reaction layer, the ratio \( \rho_A/\rho_B \) will either converge to zero, or diverge to infinity as \( t \to \infty \). However, by definition of \( x_0 \), this ratio assumes the constant value \( D_B/D_A \) at \( x = x_0 \). So \( x_0 \) must lie inside the reaction layer. As its width grows as \( t^{\alpha} \), we conclude that there must exist a number \( \theta \) such that \( |x_f(t) - x_0(t)| \leq \theta t^\alpha \). We can see now that in the long time limit \( |x_f - x_0| \) becomes negligibly small compared to \( \epsilon \) which, in turn, gets negligibly small.
compared to $t^{1/2}$. Therefore we can drop $\epsilon$ on the left hand side of (11) and (12), and $x_f - x_0$ on the r. h. s. of (11). After these transformations the asymptotic value of the l. h. s. of (11) turns out independent of $\epsilon$, whereas the r. h. s. of (11) becomes proportional to $\epsilon J(t)$. As $\epsilon$ can vary between $t^\alpha$ and $t^{1/2}$, we conclude that $J(t)\epsilon(t)$ goes either to 0, or to $\infty$. The latter case is impossible because (11) approximates the value of $\rho_A$ which must be finite. In the long time limit we therefore have

$$J(t)\epsilon(t) \to 0 ,$$  
(13)

$$a_0 - C_A \left[ \text{erf} \left( \frac{x_f(t)}{\sqrt{4DAt}} \right) + 1 \right] \to 0 ,$$  
(14)

and

$$J(t)\sqrt{t} \to C_A \sqrt{D_A/\pi} \exp \left( -\frac{x_f^2(t)}{4DAt} \right) .$$  
(15)

Similar arguments applied to the region $x_f + w \ll x \ll \sqrt{D_Bt}$ lead to

$$b_0 + C_B \left[ \text{erf} \left( \frac{x_f(t)}{\sqrt{4DBt}} \right) - 1 \right] \to 0 ,$$  
(16)

and

$$J(t)\sqrt{t} \to C_B \sqrt{D_B/\pi} \exp \left( -\frac{x_f^2(t)}{4DBt} \right) .$$  
(17)

It follows from (14) and (16) that in the long time limit

$$x_f(t)/\sqrt{t} \to C_f ,$$  
(18)

where $C_f$ is a constant given either by

$$C_f = 2\sqrt{D_A} \text{erf}^{-1} \left[ (a_0 - C_A)/C_A \right]$$  
(19)

or

$$C_f = 2\sqrt{D_B} \text{erf}^{-1} \left[ (C_B - b_0)/C_B \right] .$$  
(20)

Now (15), (17) and (18) imply that as time goes to infinity we have

$$J(t)\sqrt{t} \to C_J ,$$  
(21)

where $C_J$ is another constant given either by

$$C_J = C_A \sqrt{D_A/\pi} \exp \left( -\frac{C_f^2}{4D_A} \right)$$  
(22)
or

\[ C_J = C_B \sqrt{D_B/\pi} \exp\left(-\frac{C_J^2}{4D_B}\right). \]  

(23)

Notice that (24) is consistent with (13).

So far we have introduced four constants \( C_A, C_B, C_f \) and \( C_J \). The first two of them, \( C_A \) and \( C_B \), control the asymptotic profile of the majority species outside the reaction layer. The third constant, \( C_f \), governs the location of the reaction layer center. Finally, through the formula \( J(t) \approx \int R(x,t)dx \approx C_J/t^{1/2} \), parameter \( C_J \) is related to the magnitude of the current \( J(t) \) of particles entering the reaction layer, or, equivalently, the total reaction rate at time \( t \). Due to the form of the initial state (2) we expect \( \partial_x \rho_A \leq 0 \) and \( \partial_x \rho_B \geq 0 \), which implies \( C_A > 0, C_B > 0 \) and \( C_J > 0 \).

Equations (19), (20), (22) and (23) can be reduced to

\[ \Phi\left(\frac{-C_f}{2\sqrt{D_A}}\right) = \frac{a_0\sqrt{D_A}}{b_0\sqrt{D_B}} \Phi\left(\frac{C_f}{2\sqrt{D_B}}\right), \]  

(24)

where

\[ \Phi(x) \equiv [1 - \text{erf}(x)] \exp(x^2). \]  

(25)

An important feature of \( \Phi(x) \) is that it diminishes monotonically from \( \infty \) to 0 as \( x \) grows from \( -\infty \) to \( \infty \). This property guarantees that equation (24) always has a unique solution \( C_f = C_f(a_0/b_0, D_A, D_B) \) which, moreover, can be readily found numerically. The only problem that can appear while solving (24) numerically is that when \( x \) is positive, \( \Phi(x) \) is a product of a very small and a very big numbers. For this reason, if \( x \) is greater than 5, we suggest to use the asymptotic form \( \Phi(x) \approx 1/(\sqrt{\pi x}) \) which comes from the asymptotic properties of the error function \( \text{erf} \).

With \( C_f \) computed from (24), the values of \( C_A, C_B \) and \( C_J \) can now be calculated from (19), (20) and (22). The opposite statement is also true: if we know (e.g. from an experiment) the values of \( C_A, C_B, C_f \) and \( C_J \), our equations determine uniquely the values of \( a_0, b_0, D_A \) and \( D_B \).

The immediate consequence of (24) is that the sign of \( C_f \) is determined by the sign of \( a_0\sqrt{D_A}/(b_0\sqrt{D_B}) - 1 \). In particular we conclude that

\[ C_f = 0 \iff a_0\sqrt{D_A} = b_0\sqrt{D_B}. \]  

(26)

This formula is important for planning experiments, as it clarifies the way the initial concentrations of the species should be chosen in order to have the reaction layer move asymptotically as slowly as possible. Condition (26) is consistent with that of Jiang and Ebner’s [3] who, by numerical examination of the mean field approximation \( R \propto \rho_A\rho_B \), found a stronger relation \( x_f = 0 \iff a_0\sqrt{D_A} = b_0\sqrt{D_B} \). Our general
formula, derived for any reaction term $R$, implies only that with this particular choice of the initial parameters the function $x_f$ cannot be changing as fast as $t^{1/2}$. An example of a system where $C_f = 0$ and $x_f(t) \propto t^\alpha$ was investigated in [14].

Equation (24) enables us also to observe a striking similarity between the long and short time behavior of $x_f$. According to [10], in the short time limit the reaction term does not affect the solutions of (1), and so $\rho_A$ and $\rho_B$ assume the same forms as in the readily solvable case $R = 0$. The point $x_f$ can be then found as the point at which $\partial R / \partial x = 0$. For $R \propto \rho_A^m \rho_B^n$ such procedure yields $\lim_{t \to 0} x_f / \sqrt{t} = C_0$, where $C_0$ can be found from the relation very similar to that of (24).

$$\Phi \left( \frac{C_0}{2\sqrt{D_A}} \right) = \frac{m\sqrt{D_B}}{n\sqrt{D_A}} \Phi \left( \frac{-C_0}{2\sqrt{D_B}} \right).$$  \hspace{1cm} (27)

### 4 The reaction layer

In the previous section we carried out our analysis without imposing any restrictions on the form of the macroscopic reaction term $R$. As we now proceed to examine the asymptotic properties of the reaction layer, we will obviously need more specific information about $R$. Therefore we will concentrate on the mean field approximation $R = k\rho_A \rho_B$, $k = \text{const.}$, still allowing $a_0$, $b_0$, $D_A$ and $D_B$ to take any positive values.

By assumption iv) we expect that in the region $-(D_A t)^{1/2} \ll x \ll (D_B t)^{1/2}$ we can apply the quasistatic approximation equations (3). Let $\rho_A(x,t)$ and $\rho_B(x,t)$ denote their solutions for some values of $D_A$, $D_B$, $x_0(t)$ and $J(t)$. By the following linear transformation we introduce two new functions of a single variable $\tilde{\rho}_A(x)$ and $\tilde{\rho}_B(x)$

$$\begin{align*}
\rho_A(x,t) &= \eta_A(t) \tilde{\rho}_A[(x - x_0(t))/w(t)] \\
\rho_B(x,t) &= \eta_B(t) \tilde{\rho}_B[(x - x_0(t))/w(t)]
\end{align*}$$  \hspace{1cm} (28)

where

$$w(t) \equiv \sqrt[3]{\frac{D_A D_B}{k J(t)}} = \sqrt[3]{\frac{D_A D_B}{k C_J}} t^{1/6},$$  \hspace{1cm} (29)

$$\eta_A(t) \equiv J(t) w(t) / D_A = \left( \frac{D_B}{k} \right)^{1/3} \left( \frac{C_J}{D_A} \right)^{2/3} t^{-1/3},$$  \hspace{1cm} (30)

$$\eta_B(t) \equiv J(t) w(t) / D_B = \left( \frac{D_A}{k} \right)^{1/3} \left( \frac{C_J}{D_B} \right)^{2/3} t^{-1/3}.$$  \hspace{1cm} (31)

Denoting $\tilde{R}(x) \equiv \tilde{\rho}_A(x) \tilde{\rho}_B(x)$ we have also

$$R(x,t) \equiv k\rho_A \rho_B = C_J^{4/3} (D_A D_B)^{-1/3} k^{1/3} t^{-2/3} \tilde{R}[(x - x_0)/w(t)].$$  \hspace{1cm} (32)
The essential property of $\tilde{\rho}_A(x)$ and $\tilde{\rho}_B(x)$ is that they constitute the particular solution to equations (6) with $D_A = D_B = J = k = 1$ and $x_0 = 0$. Therefore, by symmetry, $\tilde{R}(x)$ assumes its maximal value for $x = 0$, and so equation (32) implies that $R$ attains the maximal value at $x = x_0$. Therefore not only are the above formulae consistent with Gálfí and Rácz’s scaling ansatz, but through $C_J(a_0, b_0, D_A, D_B)$ they also exactly relate the quantities of physical importance (e.g. $w(t)$) to the parameters of the system ($D_A, D_B, a_0, b_0$ and $k$).

Because (28) can be applied to systems with any positive values of ‘external’ parameters $a_0, b_0, D_A, D_B$ and $k$, we arrive at the conclusion that the long time evolution of initially segregated $A + B \rightarrow 0$ systems is even more universal that it was predicted by Gálfí and Rácz; namely, not only the scaling exponents, but also the form of the scaling functions does not depend on the external parameters. Therefore, to find the scaling properties of the reaction layer it is sufficient to concentrate on the simplest, symmetric case $D_A = D_B$ and $a_0 = b_0$.

Notice that we have achieved these results by means of a simple, linear transformation (28). In this way we took advantage of the very feature of equations (1) and (6) that prevents them from being solved analytically – nonlinearity.

The above analysis is straightforward and can be easily generalized for many other reaction terms $R$. In particular, for $R = k\rho_A^m\rho_B^n$, with $k = \text{const}$ and $m, n$ being any (positive) real numbers, the following relation should be used instead of (29)

\[ w^{m+n+1} \equiv D_A^m D_B^n k^{-1} J^{1-m-n}. \]

This formula, together with (21), (30) and (31), generalizes the scaling theory of Cornell et al. [9] for the case of any positive $a_0, b_0, D_A, D_B, m$ and $n$.

5 Conclusions

We have investigated the long time behavior of the concentrations $\rho_A$ and $\rho_B$ of phases A and B in the Gálfí and Rácz’s problem. Our analysis is the first analytical attempt to consider it in the general case of arbitrary positive initial concentrations $a_0$ and $b_0$, and diffusion constants $D_A$ and $D_B$ of A’s and B’s.

Our approach is very general, as it does not impose any restrictions on the form of the macroscopic reaction rate $R$. Instead, it is based on the assumption that in the long time limit $\rho_A$ and $\rho_B$ satisfy a few physically justifiable relations. Therefore our theory can be applied to various systems, including those for which the form of the
macroscopic reaction rate $R$ remains unknown. Another peculiar feature of our theory is that, unlike most of previous studies, it does not concentrate on the investigation of the reaction layer only, but takes into account the properties of the whole, infinite system.

In this way we managed to derive general formulae for the concentration profiles of the majority species outside the reaction layer, the location of the layer, and the total reaction rate. It is interesting to notice that these quantities turned out independent of $R$. We also derived analytically Jiang and Ebner’s condition for the reaction front to be asymptotically stationary. This relation also turned out independent of $R$. These results correspond to the recent findings based on dimensional analysis [9, 13, 15], according to which the scaling properties of the reaction layer are independent of the form of $R$.

Next we derived the general scaling ansatz for the mean field approximation. We gave the formulae which exactly relate some quantities of physical importance, (e.g. the width $w$ of the reaction layer) to the external parameters of the system $a_0$, $b_0$, $D_A$, $D_B$ and $k$. It turned out that not only the scaling exponents, but also the forms of the scaling functions are independent of the values of these parameters. This justifies the customary approach of examining the properties of the reaction layer only in the simplest, symmetric case $a_0 = b_0$ and $D_A = D_B$.

Our work suggests also that the behavior of the reaction-diffusion system can be understood as a subtle interplay between two scaling regimes. The first one is valid far from the reaction zone, where the densities of particles A and B assume the scaling forms typical of purely diffusive systems: $\rho_A(x, t) \approx \Psi_A(x/t^{1/2})$ and $\rho_B(x, t) \approx \Psi_B(x/t^{1/2})$. These scaling laws determine also the location of the point $x_f(t)$ of the maximal reaction, and the magnitude of the current $J(t)$ of the particles entering the reaction zone. However, at $x_f$ the spatial derivatives of $\Psi_A$ and $\Psi_B$ suffer discontinuity. Therefore in the vicinity of $x_f$ a new form of scaling develops, and $\rho_A$ and $\rho_B$ assume the form $\rho_A(x, t) = S_A(x/t^\alpha)$ and $\rho_B(x, t) = S_B(x/t^\alpha)$ with $\alpha < 1/2$.

Although we confined our considerations only to the long time limit, it would be interesting to combine our results with those of Taitelbaum et al [10] for the short and intermediate times. We believe that the striking similarity between equations (24) and (27) is not accidental and should lead to a general theory comprising the short, intermediate and long time limit. The first attempt in this direction has already been made [18].

Notice also that the quasistationary approximation leads to new definitions of 'short', 'intermediate' and 'long' time regimes. Namely, we can define them as the time intervals in which the reaction term, in the vicinity of $x_f$, is vanishingly small compared to the time derivative ('short time'); or the interval in which they are of similar magnitude ('intermediate time'); or the interval in which it is the time
derivative that can be neglected ('long time').

Another interesting problem concerns the limit $D_A \to 0$ with other external parameters fixed. In this limit the scaling exponents (in the mean-field approximation) are expected to change from $\alpha = 1/6$, $\beta = 2/3$ to $\alpha = 0$, $\beta = 1/2$. The paper in which this problem is examined within the framework of the presented here theory is under preparation. We will mention here only that as $D_A$ goes to 0, the time at which the system reaches the long time regime goes to infinity, so the case $D_A = 0$ can be considered as the case where the system always remains in the 'intermediate' time regime.

Acknowledgments I am grateful to prof. L. A. Turski for pointing my attention to the case of unequal diffusion constants, and dr. H. Taitelbaum for many inspiring discussions and hospitality at the Bar-Ilan University. This work was supported by the Polish KBN Grant nr 2 P 302 181 07.
