ABSTRACT

The adhesive properties of Chinese hamster V79 cells were analyzed and characterized by various cell dissociation treatments. The comparisons of aggregatability among cells dissociated with EDTA, trypsin + Ca^{2+}, and trypsin + EDTA, revealed that these cells have two adhesion mechanisms, a Ca^{2+}-independent and a Ca^{2+}-dependent one. The former did not depend on temperature, whereas the latter occurred only at physiological temperatures. Both mechanisms were trypsin sensitive, but the Ca^{2+}-dependent one was protected by Ca^{2+} against trypsinization.

In morphological studies, the Ca^{2+}-independent adhesion appeared to be a simple agglutination or flocculation of cells, whereas the Ca^{2+}-dependent adhesion seemed to be more physiological, being accompanied by cell deformation resulting in the increase of contact area between adjacent cells.

Lactoperoxidase-catalyzed iodination of cell surface proteins revealed that several proteins are more intensely labeled in cells with Ca^{2+}-independent adhesiveness than in cells without that property. It was also found that a cell surface protein with a molecular weight of approximately 150,000 is present only in cells with Ca^{2+}-dependent adhesiveness. The iodination and trypsinization of this protein were protected by Ca^{2+}, suggesting its reactivity to Ca^{2+}. Possible mechanisms for each adhesion property are discussed, taking into account the correlation of these proteins with cell adhesiveness.

KEY WORDS cell adhesion, cell surface proteins, Ca^{2+}, Chinese hamster cells, lactoperoxidase-catalyzed iodination

Cellular adhesiveness is one of the fundamental properties of cells constituting tissues in multicellular organisms. Basic studies on cell adhesion will provide important information for understanding control mechanisms in cell behavior and morphogenesis. Although there have been many studies of the adhesive properties of cells, the reports from different laboratories are often conflicting.

For example, temperature independence of cell aggregation was found by several workers (3, 16), whereas other authors obtained the opposite results (7, 17, 18, 28, 31, 34). Divalent cation dependence of cell adhesion has often been reported (1, 2, 11, 29, 31, 34), whereas recent studies revealed that some cell types do not require divalent cations for aggregation under some conditions (4, 8, 32). Such apparently conflicting results could be due to a difference in adhesive properties among different cell types and/or to the existence of multiple cell adhesion mechanisms which could
be detected differentially depending on experimental conditions. In the present study, we have compared the adhesiveness of Chinese hamster V79 cells suspended from monolayer cultures by a variety of methods. Our results show that this single cell type can display different adhesion mechanisms depending on the method of preparation of the cell suspension. The molecules that are possibly related to each mechanism were explored, using lactoperoxidase-catalyzed iodination of cell surface proteins.

**MATERIALS AND METHODS**

**Cell**

The Chinese hamster V79 lung cell line (9, 27) was used in this study. Cells were grown on plastic tissue culture plates (Falcon Plastics, Div. of BioQuest, Oxnard, Calif.) in Eagle's Minimal Essential Medium (MEM) supplemented with 15% fetal calf serum, Grand Island Biological Co., Grand Island, N.Y.), 0.2% lactalbumin hydrolysate (GIBCO), and 58.5 mg/l L-glutamine.

**Preparation of Single Cells**

Cell monolayers that had just attained a confluent state were used for preparing single cells. Such cultures were usually obtained by inoculating 1.2-1.4 x 10^6 cells/cm² culture dish area, and by incubating for 2 days at 37°C. Overcrowded cultures were avoided because they failed to give well-dispersed single cells. Three different methods were used to dissociate the cell monolayers: the resulting cell suspensions are designated E-, TC-, or TE-cells, depending on the method of dissociation. (a) E-cells: A cell monolayer on a 14-cm diameter culture dish was rinsed three times with Puck's Ca²⁺- and Mg²⁺-free saline (CMF, reference 25), and incubated with 10 ml of 1 mM EDTA in 10 mM HEPES-buffered saline (HCMF; 8.0 g of NaCl, 0.4 g of KCl, 0.09 g of Na₂HPO₄·7H₂O, 1.0 g of glucose, 2.38 g of HEPES (N-2-hydroxyethyl-piperazine-N'-2-ethanesulfonic acid), and 4.8 ml of 1 N NaOH in 1,000 ml of H₂O, pH 7.4) for 15 min at 37°C. (b) TC-cells: A cell monolayer on the same-size plate was rinsed three times with 1 mM CaCl₂ in CMF and incubated with 10 ml of 0.01% crystalline trypsin (type I, Sigma Chemical Co., St. Louis, Mo.) in HCMF containing 0.1 mM CaCl₂ for 15 min at 37°C. (c) TE-cells: EDTA in method 1 was replaced by 0.01% crystalline trypsin in HCMF containing 1 mM EDTA. All these incubations were done on a gyratory shaker (model G-76, New Brunswick Scientific Co., Inc., New Brunswick, N.J.) at 100 rpm. Cells detached from the plate were centrifuged and resuspended in 5 ml of CMF. This CMF was supplemented with 0.01% soybean trypsin inhibitor (type I-S, Sigma Chemical) in cases where cells had been trypsinized. Cells were washed two more times with CMF and finally suspended in the medium to be used for the experiment. The above-described methods were modified, when necessary, as described in the text.

**Measurement of Cell Aggregation**

Plastic wells (2.8 cm x 1.5 cm) were used for the assay of cell aggregation as previously described (31, 32). 1 x 10^6 cells suspended in 3 ml of HCMF were put into each well, which had been previously coated with bovine serum albumin (BSA; Armour Fraction V, Armour Pharmaceutical Co., Chicago, Ill.) to prevent attachment of cells to the plastic (29). After addition of a reagent the effect of which was to be tested, cells were incubated at 37°C on a gyratory shaker at 80 rpm. The aggregation was stopped with a gentle swirling of the dish and subsequent addition of 2 ml of 5% glutaraldehyde in HCMF. It was previously determined that this fixation procedure does not cause any artificial aggregation or dissociation of preformed aggregates (31). To measure cell aggregation, the total particle number in cell suspension was counted with a Coulter counter (model ZB, Coulter Electronics Inc., Hialeah, Fla.) with 100-µm aperture. The extent of aggregation was represented by the ratio of the total particle number at time t of incubation (Nt) to the initial particle number (No), the latter being identical to the total number of cells added to the medium. The validity of this method has been previously established (6, 33).

**Iodination of Cells**

Dissociated cells were suspended in cold HCMF with 10 mM glucose at a cell concentration of 3 x 10^6 cells/ml. ^125I-Na (5 mCi/0.1 ml, carrier free, New England Nuclear, Boston, Mass.) was added to a final concentration of 200 or 400 µCi/ml, followed by lactoperoxidase (B grade, Calbiochem, San Diego, Calif.) and glucose oxidase (type V, Sigma Chemical) to final concentrations of 20 µg/ml and 0.2 U/ml, respectively. The lactoperoxidase was previously dialyzed against HCMF to remove contaminating Ca²⁺. The reaction mixture was incubated at 5°C for 7 min with occasional swirling, and the cells were sedimented and washed four to five times with Hanks' saline solution. Cell viability and aggregatability were not affected by iodination.

**Sodium Dodecyl Sulfate-Polyacrylamide Gel Electrophoresis**

Sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis was done by the method of Laemmli (15) with modifications. The separation gel solution consisted of 7.5% acrylamide, 0.375 M Tris-HCl (pH 8.8), 0.2% N,N'-methylene-bis-acrylamide, and 0.1% SDS. The gel was polymerized in a slab (1 mm x 17 cm) by the addition of 0.05% N,N',N'-tetramethylethylenediamine (TEMED) and 0.05% ammonium persulfate (final concentrations). The stacking gel, which contains 3.2% acrylamide, 0.125 M Tris-HCl (pH 6.8), 0.36% N,N'-methylene-bis-acrylamide, and...
0.1% SDS, was polymerized with 0.1% TEMED and 0.16% riboflavin. The electrode buffer contained 6 g of Tris, 28.8 g of glycine and 1 g of SDS in 1,000 ml. Cells were dissolved in 0.125 M Tris-HCl (pH 6.8), 2% SDS, 10% glycerol, 2 mM phenylmethylsulfonylfluoride, and 0.001% bromphenol blue (sample buffer). After addition of 5-10% 2-mercaptoethanol, the samples were incubated in boiling water for 2 min. Electrophoresis was carried out at 11 mA until the bromphenol blue marker reached a distance of 13 cm from the top of the separation gel. The gels were stained with 0.25% Coomassie Blue in 25% 2-propanol and 10% acetic acid. After destaining with 5% ethanol and 10% acetic acid, gels were dried under vacuum and autoradiographed with X-ray film (RP/R54 Eastman Kodak Co., Rochester, N.Y.).

Other Reagents
Other reagents used were obtained from the following sources: cycloheximide, dithiothreitol, β-galactosidase, catalase, and ovalbumin from Sigma Chemical, colcemid from GIBCO, tetracaine from Schwarz/Mann Div., Becton, Dickson & Co. (Orangeburg, N.Y.), cytochalasin B from Imperial Chemical Industries Ltd. (Cheshire, England), and neuraminidase from Calbiochem. A23187 was a gift from Eli Lilly and Co. (Indianapolis, Indiana). Myosin was extracted from mouse leg by the method of Perry (21).

RESULTS

Aggregation of Cells after Different Treatments for Dissociation

The reaggregative properties of cells dissociated with 1 mM EDTA, 0.01% trypsin + 0.1 mM CaCl₂, or 0.01% trypsin + 1 mM EDTA were compared. Cells dissociated with 1 mM EDTA (E-cells) aggregated rapidly (Fig. 1a). This aggregation was enhanced by the addition of 1 mM Ca²⁺, but occurred even in the absence of divalent cations. Cells dissociated with 0.01% trypsin + 0.1 mM Ca²⁺ (TC-cells) did not aggregate in the absence of divalent cations, but rapidly aggregated in the presence of Ca²⁺ (Fig. 1b). Cells dissociated with 0.01% trypsin + 1 mM EDTA completely lost their aggregability and exhibited no Ca²⁺ effect (Fig. 1c).

The effect of various concentrations (0.01–10 mM) of Ca²⁺ and Mg²⁺ on the aggregation of these three types of cells was studied. For E- and TC-cells, Ca²⁺ was maximally effective at 1 mM. TE-cells did not aggregate at any concentration of Ca²⁺. Mg²⁺ enhanced the aggregation of all three cell types, but to a much lesser degree than did Ca²⁺ for E- or TC-cells, suggesting different specificities for the two ions.

E-cells were treated with 0.01% trypsin (with or without Ca²⁺) to determine whether such cells had an identical aggregation pathway to TC-cells. E-cells treated with trypsin + Ca²⁺ retained their ability to aggregate in the presence of Ca²⁺, but lost the ability to aggregate in the absence of Ca²⁺ (Table I). This property is exactly the same as that of TC-cells. E-cells treated with trypsin without Ca²⁺ completely lost their aggregability, exactly like TE-cells. These results show that E-cells possess the same Ca²⁺-dependent adhesive property found in TC-cells.

The effect of temperature on the aggregation of E- and TC-cells was studied (Fig. 2). E-cells

| With 1 mM Ca²⁺ | 0.39 0.99           |
| Without Ca²⁺  | 0.97 0.96            |

* E-cells (1 x 10⁷ cells) washed once with HCMF or 1 mM Ca²⁺ in HCMF were incubated in 2 ml of 0.01% trypsin in the absence or presence of 1 mM Ca²⁺, respectively, at 37°C for 10 min.
† Aggregation was assayed at 30 min of incubation.

FIGURE 2

Effect of temperature on cell aggregation.
(a) E-cells in the presence (O-O) and absence (●-●) of 1 mM Ca²⁺ at 2°C, and in the absence of Ca²⁺ at 37°C (X-X-X). (b) TC-cells in the presence (O-O) and absence (●-●) of 1 mM Ca²⁺ at 2°C.

Aggregated at a low temperature (2°C); however, Ca²⁺ did not promote this aggregation. Interestingly, the rate of aggregation of E-cells at the low temperature was almost the same as that at 37°C in Ca²⁺-free medium (Fig. 2a). The aggregation of TC-cells was totally inhibited at low temperature (Fig. 2b).

Ca²⁺-Protective Effect on Cell Adhesiveness against Trypsinization

The effect of various cations as substitutes for Ca²⁺ to obtain the same aggregative properties of TC-cells was examined. In these experiments, the cell monolayer was rinsed with CMF supplemented with the ion to be tested and was subsequently trypsinized (15 min at 37°C) in the presence of that ion. Cell aggregation was then assayed in the presence of 1 mM Ca²⁺ after 30 min of incubation. Mg²⁺ (1-10 mM) and Mn²⁺ (0.1 mM) could not substitute for Ca²⁺. Aggregative properties of cells trypsinized in the presence of these ions were identical to those of TE-cells.

To determine whether or not the adhesion sites on the cell surface are directly protected by Ca²⁺ from trypsin digestion, the aggregation of cells in the presence of trypsin was examined. TC-cells were suspended in HCMF at room temperature in the dishes to be used for the aggregation experiment. 1 mM Ca²⁺ was then added to the cell suspension, followed by trypsin (0.01% final concentration) 1 or 5 min later. The cells were brought to 37°C on a gyratory shaker to examine their aggregatability. The results, shown in Table II, revealed that aggregation was totally unaffected by the presence of trypsin if Ca²⁺ was added 5 min before addition of the enzyme. Addition of trypsin as early as 1 min after Ca²⁺ resulted in small numbers of aggregating cells. As expected, when trypsin was added to the cells before the addition of Ca²⁺, no cell aggregation occurred. These experiments show that Ca²⁺ directly protects the adhesive property of cells against trypsinization.

Effect of Preincubation of TC-cells in Ca²⁺

The question of whether TC-cells acquire adhesive capacity irreversibly during incubation with Ca²⁺ was tested. TC-cells were incubated with 1 mM Ca²⁺ at 37°C for 60 min on a gyratory shaker at high speed (180 rpm) preventing their aggregation. The cells were collected, rinsed with

| No trypsin$        | 0.32                 |

* Trypsin (0.01%) and Ca²⁺ (1 mM) were added from 10- and 100-fold concentrated stock solutions, respectively.
† Aggregation was assayed at 30 min after the final addition of trypsin or Ca²⁺.
§ Control contains 1 mM Ca²⁺.
CMF, and reincubated with or without 1 mM Ca\(^{2+}\) to assay their aggregability. The result showed that cells preincubated with Ca\(^{2+}\) still require Ca\(^{2+}\) for aggregation in the medium. TC-cells, therefore, need the continuous presence of Ca\(^{2+}\) to display their adherent property.

**Recovery of Ca\(^{2+}\)-Dependent Adhesiveness in TE-Cells**

The Ca\(^{2+}\)-dependent adhesiveness which is absent in TE-cells should be recovered metabolically after protein synthesis if the responsible sites were digested by trypsin. This was confirmed as follows. TE-cells were plated with normal cell culture medium containing serum (see Materials and Methods) onto Falcon plastic tissue culture dishes (Falcon Plastics). After appropriate incubation periods, they were harvested by the method for making TC-cells, and their aggregatability was assayed. Control plates contained 100 \(\mu\)g/ml cycloheximide to inhibit protein synthesis. Cycloheximide tended to inhibit cell attachment to the plate and also cell spreading on it; only cells attached on the plate were used for this experiment. Fig. 3 shows that cells start to recover their Ca\(^{2+}\)-dependent adhesiveness between about 1 and 2.5 h of incubation and acquire considerable adhesive ability by 6 h. Cycloheximide completely inhibited this recovery.

**Effect of Other Reagents on Aggregation of TC-Cells**

As summarized in Table III, colcemid, tetracaine, neuraminidase, or the Ca\(^{2+}\)-ionophore A23187 had no effect on TC-cell aggregation. Cytochalasin B and cycloheximide inhibited aggregation only slightly. TC-cells preincubated with 10 mM dithiothreitol in HCMF at 37\(^{\circ}\)C for 30 min lost their aggregability without a significant reduction in cell viability. This result suggests that sulfhydryl groups may be important in the function of adhesion sites.

**Morphological Studies of Cell Aggregation**

Cell aggregates formed after a 60-min incubation at 37\(^{\circ}\)C were subjected to further morphological studies. E-cells in the presence of Ca\(^{2+}\) tightly adhered to one another with large contact areas (Fig. 4a), suggesting that the deformation of cells occurred to increase the contact area between the apposed cells after the aggregation. TC-cells in the presence of Ca\(^{2+}\) also adhered to one another over large contact areas (Fig. 4c). A peculiar feature of TC-cell aggregates was that those cells were associated with one another often as rodlike one-dimensional chains of cells, which branched in several directions.

| **Tetracaine**                        |                      |
| 1 mM tetracaine                       | 0.19                 |
| **Colcemid**                          |                      |
| 10 \(\mu\)g/ml colcemid              | 0.22                 |
| 10 \(\mu\)g/ml cytochalasin B        | 0.38                 |
| 100 \(\mu\)g/ml cycloheximide        | 0.32                 |
| **Dithiothreitol**                    |                      |
| 10 mM dithiothreitol                  | 0.94                 |

*Aggregation was assayed at 30 min of incubation in the presence of the indicated concentrations of Ca\(^{2+}\) in A and B, and in the presence of 1 mM Ca\(^{2+}\) in C, D, and E. ‡ Cells pretreated with the enzyme in HCMF for 15 min at 37\(^{\circ}\)C were rinsed with CMF and allowed to aggregate. The value in parentheses shows the aggregability in Ca\(^{2+}\)-free medium. § Cells were preincubated with each reagent in HCMF for 30 min at room temperature. Then Ca\(^{2+}\) was added, and the preparation was brought to 37\(^{\circ}\)C. || Cells were preincubated with dithiothreitol in HCMF at 37\(^{\circ}\)C for 30 min, washed, and allowed to aggregate.

A23187 had no effect on TC-cell aggregation. Cytochalasin B and cycloheximide inhibited aggregation only slightly. TC-cells preincubated with 10 mM dithiothreitol in HCMF at 37\(^{\circ}\)C for 30 min lost their aggregability without a significant reduction in cell viability. This result suggests that sulfhydryl groups may be important in the function of adhesion sites.
Aggregates of E-cells in Ca$^{2+}$-free medium showed a different morphology. Individual cells within an aggregate remained round like unaggregated cells (Fig. 4b). Mg$^{2+}$ had no effect on the morphology of E-cell aggregates (Fig. 4d).

**Correlations of Cell Adhesiveness to Cell Surface Proteins**

To further characterize the cell surface components associated with the cell adhesion properties observed above, the lactoperoxidase-catalyzed iodination of intact cells (12, 22, 23) was examined, and the iodinatable protein species were compared among E-, TC-, and TE-cells by SDS-polyacrylamide gel electrophoresis. Those cells freshly prepared were iodinated in HCMF at 5°C. Fig. 5 (a, b, and c) shows autoradiographs of the SDS gel electrophoresis patterns obtained from the whole cell proteins extracted from iodinated E-, TC-, and TE-cells. A number of radioactive bands appeared in all three types of cells. Several bands, particularly two components whose molecular weight (mol wt) is approximately 60,000, were, however, apparently more intensely labeled in E-cells than in trypsinized cells. When the radioactive bands of TC- (Fig. 5b) and TE-cells (Fig. 5c) were compared, one clear difference was observed. A radioactive protein with a molecular weight of approximately...
150,000 (abbreviated 150K protein) appeared predominantly in TC-cells. No other differences were observed between TC- and TE-cells, even when 15% polyacrylamide gels were used to separate lower molecular weight proteins. Interestingly, the iodination of the 150K protein was remarkably suppressed when the iodination medium contained 1 mM Ca²⁺ (Fig. 5d), whereas 1 mM Mg²⁺ had no effect on the iodination pattern. Iodination of other components was not affected by Ca²⁺. No differences in the iodination pattern for TC- and TE-cells were observed after preincubation of the cells in the presence of 1 mM Ca²⁺ (30 min at 37°C), except for the 150K protein.

A correlation of the recovery of Ca²⁺-dependent adhesiveness in TE-cells with the appearance of the 150K protein species was suggested by the following iodination experiments. "Recovered" TE-cells were obtained as described in the previous section, and subjected to 125I-labeling. As shown in Fig. 6, the 150K protein appeared in TE-cells after their recovery (6 h) in normal culture medium, but did not appear in the presence of cycloheximide. Even though the 150K protein band shown here was not so intensely radiolabeled as that found on freshly prepared TC-cells, it is noteworthy that the recovery of Ca²⁺-dependent adhesiveness in TE-cells was also not complete.

**DISCUSSION**

The present studies suggest that V79 cells have at least two mechanisms for cell-to-cell adhesions: a Ca²⁺-independent and a Ca²⁺-dependent one. Ca²⁺-independent adhesion does not depend on temperature and is not accompanied by morphological change of cells after aggregation. In contrast, Ca²⁺-dependent adhesion requires physiological temperatures, and cells actively spread over one another after aggregation. Both mechanisms are trypsin-sensitive, but Ca²⁺-dependent adhesiveness was protected by Ca²⁺ against trypsinization. Ca²⁺-dependent adhesiveness was not made Ca²⁺-independent by preincubation of cells with Ca²⁺. These observations demonstrate that...
Recent studies have shown that some cell types do not necessarily require divalent cations for mutual adhesion under some conditions (4, 8, 32), suggesting the wider generality of the Ca\(^{2+}\)-independent mechanism shown here. Our findings are also consistent with the results of Curtis and Greaves (3) that EDTA-dissociated cells (chick embryonic) are able to aggregate at low temperature. The temperature independence of the Ca\(^{2+}\)-independent adhesion suggests that this adhesion does not involve any active cellular process but some direct chemical or physico-chemical interactions among cell surface components. Results of microscopic observations are consistent with this idea, because cells exhibited almost no morphological changes in aggregation, as seen in the agglutination or flocculation of nonliving particles.

Inasmuch as Ca\(^{2+}\)-independent adhesiveness of E-cells was abolished by the trypsin treatment, some proteins should be involved in the adhesion process. Iodination of intact cells demonstrated that several proteins are more intensely labeled in E-cells than in TC-cells, suggesting that one of those could be an important component for the adhesion. We have recently studied the adhesion of artificially generated phospholipid membrane vesicles to EDTA-dissociated cells (20). It was shown that the adhesion of such lipid vesicles is mediated by the 60,000 mol wt cell surface proteins, which are found predominantly in E-cells (Fig. 5a). Adhesion of the lipid vesicles to the cell surface does not require divalent cations and takes place at low temperature. These phenomena suggest that the 60,000 mol wt proteins may play some role in Ca\(^{2+}\)-independent adhesion, perhaps involving lipid-protein interaction between two cell surfaces (20).

Ca\(^{2+}\)-dependent adhesion, which occurs only at a physiological temperature, might be related to other cellular processes such as enzymatic reactions, changes in fluidity of the plasma membrane, cellular motility, or contractile activity. Morphological studies show that E-cells or TC-cells increase contact areas by spreading over onto adjacent cells during aggregation in the presence of Ca\(^{2+}\), but not in the absence of Ca\(^{2+}\). This phenomenon suggests the possibility that the primary role of Ca\(^{2+}\) is to enhance the activity of pseudopodia or other cell motility machineries and to indirectly promote cell-cell adhesions by increasing the ability of cells to actively hold neighboring cells. This possibility, however, is unlikely for the following reasons. We observed that TC- and TE-cells exhibited a similar spreading activity with pseudopodia on a Falcon plastic culture dish (unpublished data), suggesting that the motility of those two cell types is similar. Furthermore, the drugs cytochalasin B, colcemid, and tetracaine, which are known to affect cellular motility, hardly inhibited the TC-cell aggregation. It thus seems that the motility of cells is not importantly relevant to the role of Ca\(^{2+}\) in rendering cells adhesive. Probably, the observed increase of contact area among adhered cells in TC- and E-cell aggregates in Ca\(^{2+}\) rather represents their high adhesiveness to one another, inasmuch as cells have the property of spontaneously spreading over the very adhesive substrate, as seen in cells plated on clean glass or plastic.

Studies of the mobility of membrane antigens or lectin receptors have revealed that these cell surface components can freely move laterally in the plasma membrane, the movement being temperature-dependent (5). It is reasonable to assume that the temperature dependence of Ca\(^{2+}\)-
dependent adhesion is associated with the mobility of adhesion sites in plasma membranes. Presumably, the components necessary for adhesion on one cell surface must move laterally to be coupled with complementary components on the surfaces of adjacent cells as discussed by several authors (8, 19, 28). In particular, if the adhesion requires a special arrangement of those components, such as cluster or patch formation, physiological temperatures would be absolutely necessary for that process, as shown in the case of lectin receptors or membrane antigens (5, 19). The fact that drugs known to interfere with the movement of such membrane components (cytochalasin B, colcemid, and tetracaine) hardly affected the Ca$^{2+}$-dependent adhesion does not seem to contradict the idea mentioned above, because these drugs do not necessarily inhibit the movement of membrane components (19). Therefore, it can be proposed that Ca$^{2+}$ is required for maintaining a particular arrangement of junctional components or for activating these components to make them functional. The one-dimensional arrangement of cells in TC-cell aggregates can be elucidated by assuming that the adhesion sites are sparsely located on the cell surface, being regulated by the lateral movement of the components in the plasma membrane. The dis-ordering of a unique arrangement of membrane particles in the tight junction by the removal of Ca$^{2+}$ from the medium has been recently reported (10).

Iodination of intact cells revealed that cells with the Ca$^{2+}$-dependent adhesiveness possess one radiolabeled component (150K protein), which was not found in nonadhesive TE-cells. Because it has been known that in the lactoperoxidase-catalyzed iodination system only proteins located on the cell surface are labeled under proper conditions (13, 14, 30), this 150K protein is probably a cell surface component. This idea is consistent with the fact that the 150K protein can be removed from cells by trypsin. The origin of this protein appeared to be cell derived. When TE-cells were cultured in media containing serum with or without cycloheximide, the 150K protein was recovered only in the absence of this drug. If the 150K protein is serum or some other exogenous component adsorbed on the cell surface, both cells should have equally contained this protein, but this was not found. However, we cannot rule out one possibility that the 150K protein is an exogenous material and that the protein synthesis inhibitor might have prevented the recovery of some cellular components which were required for the adsorption of this protein to the cell surface.

An interesting property of the 150K protein is its ability to react to Ca$^{2+}$; this protein was protected by Ca$^{2+}$ against iodination as well as against trypsinization. This suggests that the 150K protein undergoes conformational or positional changes in the plasma membrane by reacting to Ca$^{2+}$, which lead to the modification of its susceptibility to both lactoperoxidase and trypsin. Thus, it can be assumed that this protein is involved in the Ca$^{2+}$-dependent adhesion mechanism through such a property to react to Ca$^{2+}$.

This idea is supported by the observation that the 150K protein is the only component that distinguishes between TC- and TE-cells, as far as studied by the present technique, and is also consistent with the proposed role of Ca$^{2+}$ in the adhesion as discussed above. Rutishauser et al. (26) recently described a cell surface protein of a molecular weight of 150,000 which seems to be related to the adhesion activity of neural retina cells. Inasmuch as the adhesiveness of neural retina cells was protected by Ca$^{2+}$ against trypsinization (28) and because their aggregation depended on the presence of Ca$^{2+}$ (2, 31), both V79 and neural retina cells might have similar mechanisms for cell adhesion. Further studies, however, are necessary to confirm the importance of the 150K protein and to test the possibility of the existence of other components important for adhesion by using different techniques.

In the present study, evidence has been presented showing multiple adhesion mechanisms in one cell type. Presumably, each mechanism plays a different role in cell adhesion and contact. For example, the Ca$^{2+}$-independent property may be important in preserving the cell's general adhesiveness, whereas the Ca$^{2+}$-dependent adhesion sites might play a more dynamic role in cell behavior, such as regulation of contact inhibition of cell overlapping or of cell fusion which requires Ca$^{2+}$ (24).

I would like to thank Dr. R. E. Pagano for his support and interest during the course of this work. I also wish to thank Doctors M. S. Steinberg, T. S. Okada, M. J. Ueda, and H. Urushihara for their critical reading of the manuscript. I am grateful to Miss A. Ishihara for helping in the preparation of this manuscript.

I acknowledge the receipt of a fellowship from the
