ABSTRACT

We address the deficiency of odd-Z elements P, Cl, K and Sc in galactic chemical evolution models through an investigation of the nucleosynthesis of interacting convective O- and C shells in massive stars. 3D hydrodynamic simulations of O-shell convection with moderate C-ingestion rates show no dramatic deviation from spherical symmetry. We derive a spherically averaged diffusion coefficient for 1D nucleosynthesis simulations which show that such convective-reactive ingestion events can be a production site for P, Cl, K and Sc. An entrainment rate of $10^{-3} M_\odot/s$ features overproduction factors $OP_s \approx 7$. Full O-C shell mergers in our 1D stellar evolution massive star model have overproduction factors $OP_m > 1$ but for such cases 3D hydrodynamic simulations suggest deviations from spherical symmetry, $\gamma$-process species can be produced with overproduction factors of $OP_m > 1$, e.g. for $^{130,132}$Ba. Using the uncertain prediction of the $15 M_\odot$, $Z = 0.02$ massive star model ($OP_m \approx 15$) as representative for merger or entrainment convective-reactive events involving O- and C-burning shells, and assume that such events occur in more than 50% of all stars, our chemical evolution models reproduce the observed Galactic trends of the odd-Z elements.

Key words: stars: abundances - stars: evolution - stars: interiors - hydrodynamics - galaxy: abundances

1 INTRODUCTION

Massive stars are the main producers of intermediate-mass elements below the Fe peak (e.g. Woosley et al. 2002). However, the odd-Z elements K and Sc in galactic chemical evolution (GCE) models of the Milky Way based on yields of Kobayashi et al. (2006, K06) or Nomoto et al. (2013) are up to 1 dex lower compared to halo and disk stars. Several promising production scenarios have been considered for Sc, such as the ejecta of proton-rich neutrino winds (Fröhlich et al. 2006), jet-induced core-collapse supernova explosions (e.g. Tominaga 2009) and hypernovae (e.g. Sneden et al. 2016). However the impact of these mechanisms on GCE models has not yet been demonstrated.

Massive stars are also considered the main source of rare p-rich stable isotopes beyond iron, although the underproduction in simulations compared to the solar abundances has always been recognized (see Pignatari et al. 2016a, and references therein).

While previous attempts to explain the production of odd-Z elements focussed on explosive nucleosynthesis environments, we are proposing that odd-Z elements, as well as possibly p-process species, are forming in convective-reactive events in pre-supernova stellar evolution. In 1D stellar models the mixing-length theory (Cox & Giuli 1968) describes convection in a time and spatially averaged way that provides realistic results in conditions where the nuclear reaction time scale is much larger than the convective mixing timescale, i.e. the Damköhler number $Da = \tau_{\text{mix}}/\tau_{\text{reac}} << 1$. In that case the convective region is instantaneously mixed compared to the reaction time scale and the detailed shape of the mixing profile is not important. However, in convective-reactive nucleosynthesis $Da \sim 1$ and the combined mixing and nuclear processes at each radial location determines the overall nuclear production of the region. In more extreme cases the energy feedback from nuclear reactions on the convective turn-over time scale may be dynamically

relevant. This situation can be encountered in the late phases of stellar evolution of both low-mass and massive stars, such as in simulations of combustion of H-rich material ingested into He-shell flash convection in post-AGB stars. This can lead to a 3D non-radial simulation of combustion of H-rich material ingested into He-shell stellar evolution models.

2 METHODS

We perform 3D simulations of the first convective O shell as in Jones et al. (2017, J17). We adopt the same radial stratification based on a 25 $M_\odot$ stellar evolution model (M25Z0.02J, Table 1) and the same numerical approach (3D hydrodynamics code PPMstar, Woodward et al. 2015). We run simulations in 4$\pi$ geometry on a 768$^3$ grid of the ingestion of C-rich material from a stable layer atop the O shell. Instead of driving the convection with a constant volume heating term, we now use a realistic O burning prescription according to Eq. 18.75 in Kippenhahn et al. (2012).

Our initial nucleosynthesis analysis of C-shell material ingestion into the O shell with a 1-zone simulation showed that the $^{12}$C($^{12}$C,$\alpha$)Ne (Cahill & Fowler 1988) and the $^{16}$O($\alpha$,p)$^{20}$Ne reactions produce most of the energy over most of the O shell. We assume that each $\alpha$ particle liberated by the first reaction immediately triggers the second since plenty of $^{16}$O is available. Thus, the energy release of C burning is the sum of $Q$ values of the two reactions. The mass fraction of $^{12}$C in the C shell of the stellar model M25Z0.02J is 0.026. We use five times that value for the fluid in the top stable layer in the PPMstar simulations to shorten the simulations’ transition to a stationary state, which reduces the overall computational costs. In addition to this simulation (I2) we perform additional runs with enhanced O- and C-burning energy release (Table 1).

The $^{16}$O + $^{12}$C reaction, which we ignore in this initial set of hydro simulations, may also become relevant, sensitively depending on the temperature, the mixing efficiency and the amount of entrained C-shell material. Indeed, in the I2 (113) hydro simulations the C-shell fluid is mixed fast to the hottest layers in quantities such that the reaction provides a factor 8 (0.7) more energy than the reactions included in the hydro network. A detailed analysis of this complex, non-linear problem is beyond the scope of this work and will be addressed elsewhere (Andrassy et al. in prep).

The detailed nucleosynthesis is computed with the 1D multi-zone post-processing code mppnp as in Herwig et al. (2011). The stratification is the same as in the hydrodynamic simulation I2, which is based on the stellar model M25Z0.02J. C-shell material with an abundance distribution of the post-processed stellar model M25Z0.02R at a range of rates is injected into the upper part of the convective shell. Mixing is modelled based on a diffusion coefficient determined from the 3D simulations I2 (Fig. 2).

We model the chemical evolution of the Milky Way with a one-zone, open-box model with galactic inflows and outflows in OMEGA (Côté et al. 2016, 2017) which is part of the NuGrid chemical evolution framework at http://nugrid.github.io/NuPyCEE. Here we use yields of AGB and massive star models from NuGrid (Pignatari et al. 2016b; Ritter et al. 2017, in prep.), and alternatively for massive stars from K06, as well as for PopIII stars (Heger & Woosley 2010) and SNIa (Sethenzahl et al. 2013). The initial mass function of Kroupa (2001) is adopted over the initial mass range from 0.1 $M_\odot$ to 100 $M_\odot$, and we assume the ejection of stellar yields between the initial masses of 1 $M_\odot$ and 30 $M_\odot$.

Table 1. Overview of simulations and their properties. Given are the entrainment rates $M_\alpha$, time-averaged O- and C-burning luminosities $L_\odot$ and $L_C$, the increase of the Q values of O-shell and C-shell fluid burning by factors $f_{QO}$ and $f_{QC}$ and an indication whether the entrainment process can be considered stationary. The luminosities of I11 and I11 vary in the time interval adopted for averaging by up to a factor of ∼4. The entrainment rate in I11 was derived using a different method to be described in (Andrassy et al. 2017, in preparation) and corresponds to the last 2.5 min before the flow became so violent that the simulation had to be stopped. Stellar evolution tracks of R17 with mean overproduction factors of convective O-C shell mergers has been mentioned in the literature (Rauscher et al. 2017, in prep.) and corresponds to the last 2.5 min before the flow became so violent that the simulation had to be stopped. The entrainment process of R17 with mean overproduction factors of convective O-C shell mergers has been mentioned in the literature (Rauscher et al. 2017, in preparation) and corresponds to the last 2.5 min before the flow became so violent that the simulation had to be stopped. The entrainment process of R17 with mean overproduction factors of convective O-C shell mergers has been mentioned in the literature (Rauscher et al. 2017, in preparation) and corresponds to the last 2.5 min before the flow became so violent that the simulation had to be stopped. The entrainment process of R17 with mean overproduction factors of convective O-C shell mergers has been mentioned in the literature (Rauscher et al. 2017, in preparation) and corresponds to the last 2.5 min before the flow became so violent that the simulation had to be stopped.
over 110 convective turn-over times of 132s. The burning of the
entrained material is turned off in the code for the first 34 turnovers.
The entrained fluid reaches the bottom of the convective O shell
(Fig.1) and, after C burning has been turned on, its spherically
averaged abundance develops towards a stationary state with an
entrainment rate of $3.13 \times 10^{-7} \text{M}_\odot/\text{s}$. This rate is lower than that
measured by J17 because (1) the luminosity is lower in our case and
(2) our experience to date with the code’s present version
indicates a decline in ingestion rate at very low luminosities that falls
below well established trends that we observe at higher luminosities.
We suspect this fall-off to be due to numerical rather than physical
causes at the grid resolution of run I2, namely $768^3$ cells. Checking
that the ingestion rate has converged using simulations of double the
grid resolution of run I2 is quite expensive, and such checks have been
successfully carried out already for high luminosity cases (cf. J17).
We are addressing this issue instead by modifying the code to
compute in future a potentially fully nonlinear perturbation to the
star’s very rapidly varying base state.

The energy release from C burning does not significantly affect
the flow properties in I2. The stationary nature and approximate
spherical symmetry of the convective shell justify approximating
the 3D mixing with a diffusion coefficient (see J17 for details) and
applying it in 1D nucleosynthesis models.

Significantly higher ingestion rates might occur when the O-
shell merges with the C-shell, or in a later and more luminous
pre-supernova O shell (J17, Meakin & Arnett 2006). For this phase
the 1D stellar models of R17 do show in fact O-C shell mergers for
several cases (Table 1). In order to start exploring 3D hydrodynamic
properties of such high-entrainment or even merger regimes we ar-
tificially increase the O-burning luminosity in simulation I13 by
$\approx 2$ dex to $5.1 \times 10^{12} \text{L}_\odot$ by increasing the Q value of the O-burning
reaction by a factor of 67.5, which corresponds to the increase be-
tween the first and second O shell of the stellar model M15Z0.02
(Table 1). The average entrainment rate is $1.07 \times 10^{-4} \text{M}_\odot/\text{s}$ in this
case, in agreement with the entrainment-luminosity law of J17.
The flow is more inhomogeneous and the convective boundary is sig-
nificantly more deformed than in I2 (Fig. 1), but we do not find any
global entrainment instability (c.f. Herwig et al. 2014). Therefore,
at this high entrainment rate nucleosynthesis may still be estimated
from spherically symmetric mppnp simulations.

Although the mass exchange in shell mergers could initially
be hindered by the entropy gradient between the shells it has to be
considered that strong non-spherical instabilities similar to the
GOSH can occur with an unknown range of effective C-burning
luminosities. In order to explore such scenarios we perform as an
experiment simulation I11 (Table 1) were we enhance the energy
release from O and C burning fluid by factors of 13.5 and 10.0
respectively. In this case a violent, global, non-radial oscillation
does emerge, in which case the 1D approach would break down.

3.2 Nucleosynthesis in 1D

We perform 1D mppnp simulations for a range of ingestion rates
(Table 1), from $1.2 \times 10^{-7} \text{M}_\odot/\text{s}$ to $1.2 \times 10^{-3} \text{M}_\odot/\text{s}$, at which point
the whole C shell would be entrained in 1000s which is approxi-
mately eight overturning timescales. In the limit of near-sonic mass
transport the mass exchange rate could even reach $\text{1 M}_\odot/\text{s}$.

With entrainment rates corresponding to hydro run I2 no rel-
vant production of odd-Z elements is observed. For an entrain-
ment rate of $1.2 \times 10^{-5} \text{M}_\odot/\text{s}$ the O shell may reach the C shell in
291.7 min, without any significant element production (Sm5,Sm5L).
For entrainment rates that correspond to 3D simulation I13 (mppnp
run Sm4, Table 1) and above considerable amounts of $^{35}\text{Cl}$, $^{39}\text{K}$
and $^{45}\text{Sc}$ (Fig. 2) as well as $^{31}\text{P}$ are produced in the lower part of

Figure 1. Volume fraction of the C-rich fluid in a sphere slice of 3D convective
O-shell simulations on a $768^3$ grid. Top: Simulation I2 after 148min.
Bottom: Run I13 after 10.5min. The entrainment rate is 342 times higher
than in I2.

Figure 2. Abundance profiles of run Sm4 after 16.5 min of ingesting C-
shell material at a rate of $1.2 \times 10^{-4} \text{M}_\odot/\text{s}$. For comparison, the abundances
produced over the same time with no ingestion (ni). The diffusion coefficient
D is extracted from the 3D hydrodynamic simulation I2.
production of Fryer et al. (2012). The remnant coordinate is below the peak star remnant coordinate based on the delayed explosion prescription CCSN prescription for the stellar model M15Z0.02 with a neutron-core-collapse SN explosion and affected by fallback. We use the overproduction factors in our synthetic models (Table 1). In comparison the overproduction factors OP_{fs} in the O-C shell merger of the stellar model M15Z0.02.

Figure 3. Abundance profiles during entrainment of C-shell material into the O shell about 4 min after the end of convective Si core burning in model M15Z0.02. The blue shades indicate convective regions. The black vertical line shows the position of the remnant mass of the CCSN explosion model.

The O shell through convective-reactive entrainment and burning of 20Ne. The element production of Cl, K and Sc is larger for higher convective velocities and for higher entrainment rates (Table 1).

Through repeated multi-zone simulations with individual rates turned off it emerges that burning of ingested Ne leads to the production of odd-Z isotopes 31P, 35Cl, 39K and 45Sc at different depths in the convective zone. (γ,p) reactions, such as 31P(γ,p), release protons which produce odd-Z elements through reactions such as 38Ar(γ,3p)35K. A further detailed investigation of this convective-reactive nucleosynthesis site is required to fully determine the nucleosynthesis paths that involve conditions at several layers simultaneously.

In order to consider properly contributions from all burning shells to the total stellar yields we compare the material produced in an O-shell with ingestion (Y_{int}) to the material that would result without ingestion (Y_{tot}) relative to the total yields Y_{int} of the stellar model M25Z0.02R (Fig. 4). Thus, the overproduction factor for 1D mppv runs is OP = (Y_{int} + Y_{tot})/(Y_{int} + Y_{tot}).

Figure 4. Overproduction factors OP due to C-shell ingestion for different entrainment rates of C-shell material, total run times and diffusion coefficients in our synthetic models (Table 1). In comparison the overproduction factors OP_{fs} in the O-C shell merger of the stellar model M15Z0.02.

The 1D stellar model M15Z0.02 experiences an O-C shell merger about 4 min after the end of convective Si core burning. After an initial partial mixing phase both convective shells merge (Fig. 3), and large amounts of 33Cl, 39K and 45Sc are produced (Fig. 4). Again, the 1D simulations are not reliable at such high entrainment rates, but merely indicative (see Section 3.1). For stellar models the overproduction factors are calculated as OP_{fs} = Y_{int}/Y_{tot} where Y_{int} and Y_{tot} are the total amounts of material above the mass cut at onset and after inter-shell mixing, respectively (Table 1). Fallback is taken into account with the adoption of the mass cut of the delayed explosion prescription as in R17. The overproduction factors due to the O-C shell merger in the stellar model are qualitatively similar to what we found in our 1D mppv ingestion simulations (Fig. 4).

Due to its deep location, the O shell is significantly modified by the core-collapse SN explosion and affected by fallback. We use the CCSN prescription for the stellar model M15Z0.02 with a neutron-star remnant coordinate based on the delayed explosion prescription of Fryer et al. (2012). The remnant coordinate is below the peak production of 31P, 33Cl, 39K and 45Sc (Fig. 3). The overproduction factors based solely on the explosive nucleosynthesis indicate that P, Cl, K and Sc are little affected in our explosion model.

The γ process occurs in Ne and O shell burning in the CCSN explosion of massive star models through photo-dissintegration reactions on heavy elements (Woosley & Howard 1978; Pignatari et al. 2016a). During an O-C shell merger, “fresh” heavy elements are constantly transported down to the O-burning shell, providing new seeds for photo-disintegration.

We compare the overproduction factors of the classical 35 p nuclei of the O-C shell merger in the stellar models M15Z0.02, M20Z0.01, M15Z0.01 and M12Z0.01 (Fig. 5). In these models we find strong variations in the overproduction factors with stellar mass and metallicity. Light p nuclei are destroyed while heavier species are effectively produced. Most of those species have the largest overproduction factors in the stellar model M15Z0.02. We confirm the results of Rauscher et al. (2002) that p nuclei can be made in an O-C shell merger. At this level of production, the impact of O-C shell mergers may change the GCE scenario of at least some of the p nuclei.

3.3 K and Sc trends in the Milky Way

Some stellar models of R17 at Z = 0.01 and Z = 0.02 show O-C shell mergers (Table 1). These shell mergers cause the rise in [K,Sc/Fe] above [Fe/H] > −1 with NuGrid yields in Fig. 6. We infer that the K06 and Nomoto et al. (2013) yields do not have significant O-C shell mergers.

NuGrid models from R17 at Z < 0.01 show convective O and C shells separated only by a thin radiative layer which might be overcome in the real 3D star, as suggested by the convective boundary mixing reported in 3D hydrodynamic simulations (J17). Dedicated 3D hydrodynamic simulations will have to determine under which conditions O-C shell mergers occur in real stars.

We explore the assumption that shell mergers can happen in all
they also inhibit larger O and C shells which boost the more massive stars are affected by fallback (Fryer et al. 2012), we neglect the dependence on initial mass and metallicity. While because 3D effects will likely play an important role. In addition 1D stellar evolution model The 1D model predictions are uncertain 1D simulations will be required to determine how O-C shell mergers proceed, whether they are ultimately dominated by non-radial, global oscillations, and how the nuclear burning energy feedback alters the flow.

In our 3D hydrodynamic simulations, we observe approximately spherically symmetric, quasi-steady-state behaviour for entrainment rates that lead to noticeable odd-Z element production. However, it appears that to fully explain the lack of Sc and K in present yields for GCE models actual mergers of the O and C shells are required. Our preliminary 3D simulation experiments suggest that the assumption of spherical symmetry may break down for such conditions. GCE simulations which assume that O-C shell mergers as in model M15Z0.02 occur in 10% to 50% of all massive stars can account for the observed abundance of K and Sc in Milky Way stars.

Our 1D nucleosynthesis models so far display a wide range of $^{39}$K/$^{41}$K and $^{35}$Cl/$^{37}$Cl ratios, depending on mixing and thermo-dynamic details, some of them within a factor of a few and some much larger compared to the solar ratios. The isotopic ratios will be an important constraint for more realistic 3D models with updated nuclear physics.

With the entrainment of C-shell material heavy-element seeds are swept into the O shell and serve as a boost for the p-nuclei production. In 1D stellar models we find a variety of production efficiencies which vary with initial mass and metallicity and the overproduction factors are more than 1 dex for many isotopes beyond Ba. Such strong production might influence the GCE of p-process isotopes. A future investigation will be required to test this scenario.

Figure 6. Comparison of the predictions of P, Cl, K and Sc of our Milky Way model with observational data (if available). Predictions with 10%, 50% and 100% addition of material produced in the O-C shell merger of the stellar model M15Z0.02 to all massive stars without O-C shell merger. For comparison, we show GCE predictions based on yields from K06, P and K data are from the APOGEE survey (Wilson et al. 2010; 5DSS Collaboration et al. 2016), and Sc data from Ishigaki et al. (2012, 2013, crosses), Roederer et al. (2014, dots) and Battistini & Bensby (2015, stars).

massing star models at all Z by applying the material produced in the O-C shell merger of model M15Z0.02 to all massive star models which do not experience O-C shell mergers. We add the material to a fraction of 10%, 50% and 100% of these stars. If the merger fraction defined in this way is between 10% and 50% the observed amounts of K and Sc can be reproduced (Fig. 6).

An increased γ-process production via O-C shell mergers might also boost the Galactic γ-process contribution of massive stars. Since Rayet et al. (1995) a global underproduction of p nuclides in massive stars compared to what is necessary to explain the solar-system distribution is found. We speculate that the shell merger production could enable us to match the solar distribution when assuming a wide spectrum of entrainment rates, 3D hydrodynamic merger conditions and stellar structures.

4 DISCUSSION AND CONCLUSION

Our results have a number of limitations. In our GCE model test we add material produced in one particular O-C shell merger from a 1D stellar evolution model The 1D model prediction are uncertain because 3D effects will likely play an important role. In addition we neglect the dependence on initial mass and metallicity. While more massive stars are affected by larger fallback (Fryer et al. 2012), they also inhibit larger O and C shells which boost the γ-process production. A larger convective C shell enables the entrainment of more material which boosts the production of elements such as P, Cl, and K. can be transported further outwards and will be less affected by fallback. The time span between the onset of an O-C shell merger and core collapse is also crucial to enable sufficient element production.

Higher temperatures in the O shells of lower mass stars might lead to a stronger production of lighter p nuclei which are transported into the upper part of the C shell. For the highest masses, such as the 25 $M_\odot$ R17 models at all metallicities, the C-shell convection is either patchy or absent (especially at lower Z), which may help or hinder ingestion of C-shell material.

More generally, stellar evolution models indicate that O-C shell mergers may happen. In some cases they do, in others the shells are just stopping short of a merger. How do these results depend on various uncertain modeling assumptions in 1D, as well as on numerical convergence criteria? But even if the stellar evolution uncertainties are addressed to the best of our ability the question of whether a merger will happen in a particular, possibly marginal, case requires sufficiently realistic 3D hydrodynamic simulations. Once it is clear under which conditions O-C shell mergers happen, 3D simulations will be required to determine how O-C shell mergers proceed, whether they are ultimately dominated by non-radial, global oscillations, and how the nuclear burning energy feedback alters the flow.

In our 3D hydrodynamic simulations, we observe approximately spherically symmetric, quasi-steady-state behaviour for entrainment rates that lead to noticeable odd-Z element production. However, it appears that to fully explain the lack of Sc and K in present yields for GCE models actual mergers of the O and C shells are required. Our preliminary 3D simulation experiments suggest that the assumption of spherical symmetry may break down for such conditions. GCE simulations which assume that O-C shell mergers as in model M15Z0.02 occur in $\approx$ 10% to 50% of all massive stars can account for the observed abundance of K and Sc in Milky Way stars.

Our 1D nucleosynthesis models so far display a wide range of $^{39}$K/$^{41}$K and $^{35}$Cl/$^{37}$Cl ratios, depending on mixing and thermo-dynamic details, some of them within a factor of a few and some much larger compared to the solar ratios. The isotopic ratios will be an important constraint for more realistic 3D models with updated nuclear physics.

With the entrainment of C-shell material heavy-element seeds are swept into the O shell and serve as a boost for the p-nuclei production. In 1D stellar models we find a variety of production efficiencies which vary with initial mass and metallicity and the overproduction factors are more than 1 dex for many isotopes beyond Ba. Such strong production might influence the GCE of p-process isotopes. A future investigation will be required to test this scenario.
edges support from the Klaus Tschira Stiftung. We acknowledge Brad Gibson for reminding us to check the isotopic ratios of our models.
