 Published online September 16, 2020.

Tuberculosis, an infectious disease caused by Mycobacterium tuberculosis, remains a severe global health problem. According to the World Health Organization, in 2019, approximately 10 million new cases of tuberculosis were reported, and the latest global treatment success rate is 85%. China is one of 30 countries with a high tuberculosis burden [1]. M. tuberculosis is a highly successful pathogen; it has existed on earth for millions of years and has acquired various strategies to escape from host immune responses. Although >2 billion people are infected with M. tuberculosis around the world, active tuberculosis develops in only 10% of them, while the majority remain latently infected without symptom [2], implying that host genetic factors play an important role in determining susceptibility to tuberculosis. In recent years, a number of studies have reported that genetic polymorphisms are associated with tuberculosis susceptibility [3–9]. In our previous studies, we also identified several genetic polymorphisms in interleukin 6, interleukin 1β, and Interferon alpha/beta receptor 1 genes associated with tuberculosis susceptibility in the Chinese population [10–12]. Thus, it is essential to determine the relationships between the genetic variations and susceptibility or resistance to tuberculosis, in order to comprehensively understand the pathogenesis of mycobacterial infection.

Transforming growth factor (TGF) β1 has been shown to regulate a broad spectrum of biological processes, including differentiation, chemotaxis, proliferation, and activation, in many immune cells [13, 14]. Numerous studies have showed that TGF-β1 gene polymorphisms are associated with susceptibility to many different kinds of diseases, including cancers [15–21]. TGF-β1 is produced in excess during tuberculosis and presented at the sites of active M. tuberculosis infection [22, 23]. Furthermore, it has been reported to inhibit T-cell responses and deactivate macrophages in patients with tuberculosis [24, 25]. In a tuberculosis granuloma model, it was shown that knockout of TGF-β1 benefits bacterial clearance by cytotoxic T cells [26]. Treatment with recombinant TGF-β1 significantly increased mycobacterial loads in the tissues of guinea pigs [27]. These observations suggest that TGF-β1 performs immunosuppressive activity and accelerates the progression of pulmonary tuberculosis. However, to date, there are extremely
limited studies investigating the association of TGF-β1 gene polymorphisms with susceptibility to human tuberculosis.

In the current study, owing to the important role of TGF-β1 in the development of tuberculosis, we investigated the association between 10 single-nucleotide polymorphisms (SNPs) in the TGF-β1 gene and tuberculosis susceptibility in 2 case-control cohorts. After clear associations were found in some of these SNPs, we went on to clarify their function in regulating gene expression and elucidate their potential mechanisms.

**MATERIALS AND METHODS**

**Study Participants and Samples**
The discovery cohort including 1533 patients with active tuberculosis and 1445 healthy controls was recruited at The Third People's Hospital of Shenzhen, as reported elsewhere [11]. Among the 1533 patients with active tuberculosis, 1432 had a diagnosis of pulmonary and 101, a diagnosis of extrapulmonary tuberculosis. Members of the validation tuberculosis study cohort—832 case patients with active tuberculosis (367 with pulmonary and 465 with extrapulmonary tuberculosis) and 1084 controls—were recruited at West China Hospital, Sichuan University, in Chengdu, Sichuan province. The study was approved by the ethics committee of The Third People's Hospital of Shenzhen, and informed consent was obtained from each participant. For detailed information, see Supplementary Materials and Methods.

**DNA Extraction, SNP Selection, and Genotyping**
In total, 10 SNPs in TGF-β1 were selected according to methods described elsewhere [28], involving 6 SNPs in the promoter (rs2317130 C>T, rs11466313 DEL>AGG, rs17516265 A>C, rs3087453 C>G, rs4803457 T>C, and rs1800469 C>A) and 4 SNPs in the intron (rs2278422 C>G, rs8110090 A>G, rs4803455 C>A, rs11466334 C>T). SNP genotypes were determined by primer-extension mass spectrometry performed using the Sequenom MassARRAY system. For detailed information, see Supplementary Materials and Methods.

**Statistical Analysis**
The Hardy-Weinberg equilibrium for TGF-β1 polymorphism distribution was analyzed in healthy controls and case patients. The allele and genotype frequencies of SNPs in case patients and controls are coincident with Hardy-Weinberg equilibrium (> .05). Among them, 5 of 10 SNPs, including 3 in the TGF-β1 promoter region (rs2317130, rs4803457, and rs11466313) and 2 in the TGF-β1 intron (rs4803455 and rs11466334), are significantly associated with tuberculosis susceptibility, while the remaining 5 SNPs (rs17516265, rs3087453, rs1800469, rs2278422, and rs8110090) have no association with tuberculosis susceptibility in the discovery cohort (Table 1). The rs2317130 C allele exhibits higher risk to tuberculosis susceptibility (odds ratio [OR], 1.14; 95% CI, 1.03–1.26; P = .01).

At the genotype level, the patients with rs2317130 genotype CC have increased risk of tuberculosis in the additive and recessive model. Allele T of another SNP, rs4803457, is associated with increased tuberculosis susceptibility using the multiplicative, additive, and recessive model. In addition, allele DEL of rs11466313 is associated with an increased risk of tuberculosis in the multiplicative (OR, 1.17; 95% CI, 1.06–1.30; P = .002) and additive (1.36; 1.11–1.68; P = .003) models, and C allele of rs4803457 is susceptible to tuberculosis, with an adjusted OR of 1.20 (95% CI, 1.08–1.33, P = .001). Specifically, using the recessive model, the rs11466334 genotype CC was estimated to impart a 95% increase in risk (OR, 1.95; 95% CI, 1.52–2.51; P < .001).

**RESULTS**

**Association Between TGF-β1 SNPs and Tuberculosis Susceptibility in Discovery Cohort**
To determine whether TGF-β1 polymorphisms were associated with tuberculosis susceptibility, we selected 10 potential functional SNPs in the TGF-β1 gene, using the strategy described elsewhere [28]. The genotype distributions of the 10 SNPs in case patients and controls are coincident with Hardy-Weinberg equilibrium (P > .05). Among them, 5 of 10 SNPs, including 3 in the TGF-β1 promoter region (rs2317130, rs4803457, and rs11466313) and 2 in the TGF-β1 intron (rs4803455 and rs11466334), are significantly associated with tuberculosis susceptibility, while the remaining 5 SNPs (rs17516265, rs3087453, rs1800469, rs2278422, and rs8110090) have no association with tuberculosis susceptibility in the discovery cohort (Table 1). The rs2317130 C allele exhibits higher risk to tuberculosis susceptibility (odds ratio [OR], 1.14; 95% CI, 1.03–1.26; P = .01).

**Association Between TGF-β1 Haplotypes and Tuberculosis Susceptibility**
Haplotype analysis of the 5 significant SNPs revealed strong linkage disequilibrium between rs2317130 and rs4803457 (Supplementary Figure 1). As shown in Table 2, further analyses of associations between TGF-β1 haplotypes and tuberculosis susceptibility revealed that haplotype H2 (TC, SNPs in the order of rs2317130 and rs4803457) reduces the risk to tuberculosis at P value of .03, with an OR of 0.85 (95% CI .74–.98), compared with haplotypes H1 (CT) and H3 (CC).

**Association of TGF-β1 Polymorphism rs2317130 With Severity of Tuberculosis but Not M. tuberculosis–Specific INF-γ Production**
Next, we went on to investigate the 5 positive SNPs in their relationship with the severity of patients with tuberculosis.
Table 1. Association Between Transforming Growth Factor β1 Single-Nucleotide Polymorphisms and Tuberculosis Susceptibility in the Discovery Cohort

Therefore, high-resolution computed tomographic (HRCT) scores based on radiographic manifestations were used to directly quantify lung damage in patients with tuberculosis [29, 30]. Among 483 patients, the HRCT scores were significantly higher in carriers with rs2317130 genotype CC than in those with genotypes CT and TT (Figure 1A). In contrast, no significant differences in HRCT score were found in patients carrying other genotypes of rs4803457 and rs11466313 located in the promoter region (Figure 1A) and rs4803455 and rs11466334 located in the intron region (Supplementary Figure 2). However, when we tried to investigate the association between the above 5 SNPs and bacterial load, there were no differences in the allele frequency of these SNPs between patients with sputum culture positivity and those with culture negativity (Supplementary Table 3). In addition, no significant differences in the numbers of spot-forming cells producing interferon γ, erythrocyte sedimentation rates, and C-reactive protein levels were observed among patients with pulmonary tuberculosis carrying 3 TGF-β1 promoter variants (Figure 1B and Supplementary Figure 3). Taken together, these results indicated that the rs2317130 allele C was associated with increased severity of pulmonary tuberculosis.

Table 2. Association Between Transforming Growth Factor β1 Haplotypes and Tuberculosis Susceptibility

| Haplotype ID | Code* | Haplotype | Tuberculosis Group | Control Group | P Value | OR (95% CI) |
|--------------|-------|-----------|--------------------|---------------|---------|-------------|
| H1           | MM    | CT        | 0.57               | 0.53          | ...     | Reference   |

Abbreviations: CI, confidence interval; ID, identifier; OR, odds ratio.

*M represents the major allele; m, the minor allele. (Single-nucleotide polymorphisms are in the order of rs2317130 and rs4803457.)

Figure 1. Transforming growth factor β1 rs2317130 single-nucleotide polymorphism is associated with the severity of pulmonary tuberculosis, but it has no effect on Mycobacterium tuberculosis–specific interferon γ production. A, High-resolution computed tomographic (HRCT) scores in 483 patients with tuberculosis carrying different genotypes of rs2317130, rs4803457, or rs11466313 located in the promoter region (Figure 1A) and rs4803455 and rs11466334 located in the intron region (Supplementary Figure 2). However, when we tried to investigate the association between the above 5 SNPs and bacterial load, there were no differences in the allele frequency of these SNPs between patients with sputum culture positivity and those with culture negativity (Supplementary Table 3). In addition, no significant differences in the numbers of spot-forming cells producing interferon γ, erythrocyte sedimentation rates, and C-reactive protein levels were observed among patients with pulmonary tuberculosis carrying 3 TGF-β1 promoter variants (Figure 1B and Supplementary Figure 3). Taken together, these results indicated that the rs2317130 allele C was associated with increased severity of pulmonary tuberculosis.
Replication of Association Between TGF-β1 SNPs and Tuberculosis Susceptibility in Validation Cohort

Because the rs2317130, rs4803457, and rs11466313 SNPs located in the promoter region showed a pattern of linkage disequilibrium and association with clinical phenotypes, we further verified their association with tuberculosis susceptibility through an independent cohort collected from West China Hospital. According to Supplementary Table 4, under the multiplicative model, significantly higher frequencies of the C allele in rs2317130, T allele in rs4803457, and DEL allele in rs11466313 were observed among patients with active tuberculosis, compared with health controls. In the additive, dominant, or recessive model, the genotype frequency of these SNPs also showed significant differences between tuberculosis and healthy control groups (Supplementary Table 4). Thus, these results confirmed that these promoter SNPs are associated with susceptibility to active tuberculosis in the Chinese population.

Effect of SNP rs2317130 on M. tuberculosis-Specific TGF-β1 and Interleukin 17A Production

Next, we wonder whether these promoter SNPs could affect the production of TGF-β1 in response to M. tuberculosis stimulation. To test this, we assessed the expression of TGF-β1 in peripheral blood mononuclear cells (PBMCs) with or without M. tuberculosis stimulation, using quantitative polymerase chain reaction and enzyme-linked immunosorbent assays among various genotypes. As shown in Figure 2A and 2B, no significant difference was found in the TGF-β1 protein and messenger RNA (mRNA) levels of PBMCs from individuals carrying various genotypes without M. tuberculosis stimulation. After M. tuberculosis stimulation, the TGF-β1 protein and mRNA levels of PBMCs from individuals carrying various genotypes were all increased compared with those without M. tuberculosis stimulation (Figure 2A and 2B). Moreover, Figure 2A and 2B show that PBMCs from individuals carrying rs2317130 CC genotype produce significantly higher levels of TGF-β1 protein and mRNA than those carrying CT or TT genotype in response to M. tuberculosis stimulation. In contrast, PBMCs from individuals carrying different rs4803457 and rs11466313 genotypes with M. tuberculosis stimulation exhibit no significant differences in TGF-β1 production at both protein and mRNA levels.

Interleukin 17A (IL-17A), the main effector cytokine of T-helper (Th) 17, promotes local inflammatory responses and may lead to the serious lung damage through recruitment of neutrophils, which play a pathogenic role and exacerbate tuberculosis disease [31, 32]. TGF-β1 is known to play a role in inducing the generation of IL-17A–producing cells [33]. We went on to test whether these SNPs were associated with the expression of IL-17A. As shown in Figure 3A and 3B, IL-17A expression showed a similar pattern like TGF-β1 at both protein and mRNA levels, and higher expression of IL-17A was observed in PBMCs carrying rs2317130 CC genotype than in those carrying genotypes TT in response to M. tuberculosis stimulation. In contrast, PBMCs carrying rs4803457 and rs11466313 genotypes exhibit no significant differences in IL-17A production (Figure 3A and 3B).

Furthermore, the relationship between TGF-β1 and IL-17A expression was explored. The correlation coefficients between TGF-β1 and IL-17A expression both in protein and mRNA levels were 0.88 and 0.85, suggesting positive correlation existed in the expression between TGF-β1 and IL-17A (Figure 3C and 3D). In addition, the levels of TGF-β1 and IL-17A in serum samples from patients with active tuberculosis were

![Figure 2](image-url)
also determined. The patients with tuberculosis carrying various genotypes showed no differences in the level of TGF-β1, although there was an increased trend for individuals with rs2317130 CC and rs4803457 TT genotype (Supplementary Figure 4A). However, the IL-17A level in serum was too low to be detected using available kits (Supplementary Figure 4B).

Taken together, these results suggested that SNP rs2317130 affects *M. tuberculosis*–specific TGF-β1 and IL-17A production.

**Influence of SNPs on TGF-β1 Gene Transcription Activity**

To evaluate the effect of promoter SNPs on TGF-β1 gene transcription activity, we constructed different haplotypes among 3 variants, as shown in Figure 4A and assessed these haplotypes using a dual-luciferase reporter assay. As shown in Figure 4B, we used haplotype C-C-AGG (SNPs in the order of rs2317130, rs4803457, and rs11466313) as a template; when the rs2317130 was mutated into protective allele T, the haplotype T-C-AGG showed decreased luciferase activity. In contrast, the site-directed mutation of rs4803457 to susceptible variants T, the haplotype C-T-AGG showed increased luciferase activity. However, after rs11466313 mutation from AGG to DEL, the haplotype C-C-DEL showed no difference in luciferase activity compared with haplotype C-C-AGG. In addition, haplotype C-T-AGG, which consisted of 2 susceptible variants, rs2317130 allele C and rs4803457 allele T, shows the highest transcriptional activity among C-T-AGG, T-C-AGG, C-C-AGG, and C-C-DEL (Figure 4B).

**Binding Activity of rs2317130 SNP to Nuclear Extracts**

To determine whether the effects of SNPs rs2317130 and rs4803457 on TGF-β1 transcriptional activity were due to the alteration of binding efficiency to the nuclear extracts, electrophoretic mobility shift assay was performed. Biotin-labeled or unlabeled oligonucleotides containing specific alleles were incubated with nuclear extracts from human acute monocytic leukemia cell line-1 cells stimulated with or without *M. tuberculosis*. As shown in Figure 5A, both alleles of rs2317130...
showed several shifted bands when incubated with nuclear protein extracts. Furthermore, these shifted bands could be blocked by unlabeled oligonucleotide competitors (Figure 5A, lanes 5, 6, 9, and 10). Interestingly, *M. tuberculosis* stimulation induced more complex 1 and additional complex 2 formation on the rs2317130 C oligonucleotide (Figure 5A, lanes 4 and 8) compared with T oligonucleotide (Figure 5A lanes 3 and 7, and Figure 5C), suggesting that SNP rs2317130 could alter nuclear extracts binding activity to TGF-β1 promoter region. On the other hand, distinct bands (complex 3) were shifted when biotin-labeled rs4803457 C probe were incubated with the nuclear extracts (Figure 5B, lanes 4 and 8), which was specifically blocked by unlabeled competitors (Figure 5B, lanes 5, 6, 9, and 10). However, no significant difference in complex 3 was observed between unstimulated and stimulated cells (Figure 5B, lanes 4 and 8, and Figure 5C).

**DISCUSSION**

TGF-β1 has been reported to be up-regulated during tuberculosis and presented at sites of active *M. tuberculosis* infection [22, 23]. However, few studies have examined the relationships between TGF-β1 gene variations and tuberculosis susceptibility. Previous studies showed that the TGF-β1 gene polymorphism at −509C/T (rs1800469) and +869T/C (rs1800470) is correlated with the progression of several diseases [34–36]. So far, 3 TGF-β1 SNPs have been extensively investigated in tuberculosis among different populations, involving +869T/C+915G/C (rs1800471) and −509C/T. It was reported that the +869T/C genotype was significantly associated with increased tuberculosis susceptibility in India [37], but no association was observed in patient with tuberculosis from Japan [38]. In addition, the allele distribution of +915G/C shows no difference in Colombian patients with tuberculosis and healthy controls [39], and in Hong Kong Chinese adults, gene polymorphisms at −509C/T and +869T/C are not associated with tuberculosis susceptibility [40].

The ethnic differences in various populations may lead to these divergent findings, and another reason may be the lack of suitable functional SNP selection strategy. In the current study, SNP selection was as described previously [28], which is different from the usual way of tagging SNPs, in which SNPs were usually selected based only on the linkage disequilibrium in a genomic region. The SNP selection process focuses more
on efficiency, which maximizes the coverage but minimizes the cost [41]. We focused on the SNPs located in putative transcription factor binding sites or microRNA target sites. Among these 10 selected potential functional SNPs in the TGF-β1 gene, 5 (50%) were efficiently identified to be significantly associated with tuberculosis susceptibility through this strategy.

In addition, TGF-β1 was required for development of Th17 cells that could produce IL-17A–regulating inflammatory responses [33, 42, 43]. In this study, we performed this correlation analysis between TGF-β1 polymorphisms and tuberculosis susceptibility. Our functional assay demonstrated that PBMCs from individuals carrying rs2317130 C allele in TGF-β1, which is associated with increased susceptibility to tuberculosis, produce significantly higher TGF-β1 in response to M. tuberculosis stimulation, which is consistent with a previous report that TGF-β1 is up-regulated during tuberculosis [22]. Moreover, similar to TGF-β1, PBMCs carrying rs2317130 C allele also produced higher levels of IL-17A in response to M. tuberculosis stimulation. Series of findings have suggested the involvement of IL-17A in tuberculosis pathology. In humans, IL-17 expression in lymphocytes from patients with active tuberculosis is correlated with disease severity [44]; in line with this, it was reported that enhanced Th17 responses were associated with high antigen load in drug-resistant tuberculosis [45]. From the viewpoint of human genetics, the high IL-17A–expressing rs2317130 C allele was associated with tuberculosis susceptibility and disease severity, indicating that persistent IL-17A production causes sustained lung damage and decreased protective immunity against M. tuberculosis infection.

The functional SNPs located in the promoter region may affect transcriptional activity, those in the exon region may result in increased or decreased expression of the gene. These findings provide insights into the role of genetic variation in the development and outcome of tuberculosis.
in variant translation, and those in the 3′ untranslated region may alter the miRNA-target interaction. The SNP rs2317130 is located in the promoter region of TGF-β1, and the luciferase reporter assay demonstrated that the rs2317130 C allele increased transcriptional activity of the TGF-β1 promoter in Hela cells. Moreover, electrophoretic mobility shift assay performance showed that the rs2317130 C allele affected recruitment of nuclear proteins to the promoter region of TGF-β1 in response to M. tuberculosis infection. Previous work has found that TGF-β1 expression could be regulated by various transcription factors, such as specificity protein 1, CCAAT-enhancer-binding protein β, activation protein-1, NF-κB, and Kruppel-like factor 4 (gut), in various experimental model systems [46–49]. However, we could not detect binding by these transcription factors of the TGF-β1 promoter region recruited by rs2317130 C allele (data not shown). Thus, binding proteins to the TGF-β1 promoter region recruited by the rs2317130 C allele need further investigation. In short, our data suggested that the rs2317130 C allele resulted in high levels of TGF-β1 and IL-17A in response to M. tuberculosis stimulation, by affecting TGF-β1 promoter transcriptional activity.

Given that TGF-β can inhibit immune cell proliferation and regulate CD4+ T cell differentiation into Foxp3+ regulatory T cells and Th17 cells that are thought to restrain the antituberculosis effector cell functions, TGF-β has been considered an attractive therapeutic target and shown to be an effective immunomodulatory strategy by absence of TGF-β expression or inhibition TGF-β effects with drugs or therapeutic antibodies in vitro and in vivo [50]. However, TGF-β, as a major fibroblast growth factor, is crucial to stimulating the necessary extracellular matrix proteins required for repairing tissue damaged by M. tuberculosis infection [50]. Therefore, reasonable therapeutic approaches are required to shift the balance in favor of a more protective immune response. Meanwhile, other nonimmune yet protective host responses will also be considered [50]. More research is needed to sufficiently balance the overall benefits, considering the full spectrum of host responses to M. tuberculosis infection.

To sum up, we have identified several SNPs of TGF-β1 gene that have significant association with tuberculosis susceptibility. We also found that the functional rs2317130 C allele up-regulating TGF-β1 and IL-17A expression was associated with disease severity. In addition, the rs2317130 C allele determines the promoter activity by affecting the binding activity with nuclear extract. However, our study also had some drawbacks. The cohort was limited to the Chinese populations, there was no retrospective follow-up study to assess variation in TGF-β1 after treatment, and allele-mediated transcription factors regulating TGF-β1 expression have not been identified. Even so, our findings provide critical genetic evidence of the pathogenic role of TGF-β1 in human tuberculosis in the Chinese population, suggesting that host-directed therapy targeting TGF-β1/IL-17A signaling could be an alternative therapeutic strategy, mitigating the severity of tuberculosis and improving clinical outcomes, particularly among individuals with increased TGF-β1–production genotypes.

Notes

Acknowledgments. We extend our appreciation to the physicians and nurses in the department of tuberculosis at The Third People’s Hospital of Shenzhen for recruiting and following up the donors in this study.

Author contributions. S. Z., J. B., Q. G., W. W., S. L., G. X., M. O., J. Z., X. H., and F. L. conducted the experiment, collected the data, and designed the figures; Guobao Li, X. F., and Guanqiang Li collected and analyzed the data; and C. G. F., X. C., and G. Z. designed the study and wrote the manuscript.

Financial support. This work was supported by the Natural Science Foundation of China (grants 81873958 and 8192031), the Shenzhen Scientific and Technological Foundation (grants JCYJ20180228162321234 and JCYJ20180228162511084), the National Science and Technology Major Project for Control and Prevention of Major Infectious Diseases of China (grant 2017ZX10103004), the National Key Research and Development Plan (grant 2019YFC0840602), and the Sanming Project of Medicine in Shenzhen (grants SZSM201911009 and SZSM201612025).

Potential conflicts of interest. All authors: No potential conflicts. All authors have submitted the ICMJE Form for Disclosure of Potential Conflicts of Interest. Conflicts that the editors consider relevant to the content of the manuscript have been disclosed.
