Recently the XENON1T collaboration has released new results on searches for new physics in low-energy electronic recoils. The data shows an excess over background in the low-energy tail, particularly pronounced at about 2 – 3 keV. With an exposure of 0.65 tonne-year, large detection efficiency and energy resolution, the detector is sensitive as well to solar neutrino backgrounds, with the most prominent contribution given by pp neutrinos. We investigate whether such signal can be explained in terms of new neutrino interactions with leptons mediated by a light vector particle. We find that the excess is consistent with this interpretation for vector masses below ≲ 0.1 MeV. The region of parameter space probed by the XENON1T data is competitive with constraints from laboratory experiments, in particular GEMMA, Borexino and TEXONO. However we point out a severe tension with astrophysical bounds and cosmological observations.

I. INTRODUCTION

Dark matter (DM) direct detection experiments have entered the era of ton-size active volumes, and will keep going in that direction in their search for DM signals [1–5]. Combined with high sensitivities at low energy thresholds as well as low and fairly well-understood backgrounds, these experiments offer opportunities in the search for DM signals which cover large classes of DM physics models. Conventional searches using nuclear recoil energy measurements allow searches of DM in the GeV-TeV range, while electron recoil measurements provide a tool for sub-GeV DM and other well-motivated degrees of freedom such as axion-like particles (ALPs) and/or dark photons [6, 7]. Being sensitive to irreducible solar neutrino backgrounds, they will enable as well a better understanding of solar neutrino fluxes [8, 9] and potentially new directions in the search for new physics in the neutrino sector [10–13].

XENON1T is a dual-phase liquid xenon time projection chamber with a one-tonne active target [11]. The detector conceived for WIMP DM searches in regions above ~ 6 GeV can be used as well for searches of ALPs, dark photons and neutrino properties, thanks to the low energy thresholds and background rates. Given its dual-phase character, prompt scintillation and delayed luminescence signals—S1 and S2—can be well measured. Identification of electron and nuclear recoils can be done through S2/S1 ratios, and thus provide a tool for particle identification (e.g. neutron-induced nuclear recoils from β-induced electron recoils). Recently XENON1T has released data taken from February 2017 to February 2018, in which signals above background-induced electron recoil events were searched for [13]. The collaboration has reported an excess below 7 keV with a prominent feature towards 2 – 3 keV. Using this data, three new physics scenarios were explored as possible explanations to the signal: the solar axion model, neutrino magnetic moment and bosonic dark matter. The finding shows that the resulting 90% CL parameter space regions within which the excess can be accounted for are disfavored by astrophysical arguments [15–17]. The collaboration has as well tested this result against possible background from tritium β decays. In this case the statistical significance of the new physics hypotheses is substantially diminished.

Although the background hypothesis cannot be discarded, one can as well entertain the possibility that the excess is driven by new physics. Indeed, seemingly, this has been the approach the collaboration has adopted. If one is to adopt such an approach as well, there is a lesson one should take from the findings the collaboration has reported:Whatever the nature of the new physics is, it should be able to produce localized spectral distortions. Above 7 keV the data is rather well described by the background, e.g. in the range 25 – 50 keV the data points are beautifully accounted for by the radio activity of $^{83m}$Kr [14].

Possible scenarios of new physics are those in which electron recoils are modified by the coupling of new degrees of freedom to electrons. The new degrees of freedom could e.g. involve DM or particles from a dark sector [18–21]. Another possibility, which goes along the lines of the neutrino magnetic moment, is an interaction that locally enhances the elastic scattering neutrino-electron cross section [22]. That is actually what the neutrino magnetic moment does, it adds to the electroweak neutral and charged current neutrino-electron cross section, dominating the scattering process at low recoil energies. Possibilities include neutrino non-standard interactions (NSI) as well as neutrino generalized interactions (NGI) [23–27], both with electrons. In the effective limit—$m_{\text{Med}}^2 \gg q^2$ (q being the exchanged momentum)—these interactions will produce overall enhancements or depletions (de-
The interactions that we consider can be understood as a consequence of a larger complete theory that we do not specify. They could be e.g. the result of an extended gauge group $U_{B-L}$ or $U(1)_X$ [28, 29]. For the purpose of this paper what matters is the presence of a new light vector mediator, coupled to neutrinos and electrons, although one could in principle include the other charged leptons too. Along the same lines one could as well consider a kinetic mixing term, between the hypercharge field of the SM and the new vector. For simplicity—however—we set the tree level coupling to zero, bearing in mind that it then will be generated radiatively and hence it will be suppressed.

The elastic neutrino-electron cross section involves the SM charged- and neutral-current contributions as well as a new neutral-current piece induced by the light vector. The cross section has been calculated in several papers [10, 23, 29–31]. Here we use the expression derived in Ref. [29] which applies in $U(1)_X$ models in which neutrino and electron charges $Q_X$ are dictated by anomaly cancellation conditions. It reads

$$\frac{d\sigma}{dE_e} = \frac{m_\ell^2 G_F^2}{4\pi} \left[ g_1^2 + g_2^2 \left( 1 - \frac{E_e}{E_\nu} \right)^2 - g_1 g_2 \frac{m_e E_e}{E_\nu^3} \right],$$

where the couplings $g_{1,2}$ include both the SM and new physics components as follows

$$g_{1,2} = g_{1,2}^{SM} + a_{1,2} + \frac{b_{1,2}}{G_F (2m_e + m_\nu^2)}.$$

In the expression above, $G_F$ stands for the Fermi coupling constant, $E_e$ refers to the electron recoil energy, $E_\nu$ denotes the incoming neutrino energy, $m_e$ is the electron mass and $m_\ell$ the mass of the new vector mediator. In the limit of suppressed mass mixing between the neutral vectors, the SM pieces are given by their standard forms in terms of the weak-mixing angle $\sin^2\theta_W$ as

$$g_1^{SM} = -2\sqrt{2}\sin^2\theta_W,$$

$$g_2^{SM} = \sqrt{2}(1 - 2\sin^2\theta_W) - 2\sqrt{2},$$

with the second term in $g_2^{SM}$ being present only for electron neutrinos. The SM limit is then given by

$$\frac{d\sigma_{SM}}{dE_e} = \frac{d\sigma}{dE_e} \bigg|_{a_1=b_1=0}.$$

The elastic neutrino-electron cross section is driven by vector boson exchange of the SM expectation. Thus, given the typical exchanged momentum, spectral distortions can be generated only by light mediators, of which in this paper we consider the vector case.

The paper is organized as follows. In Sec. II we discuss the relevant interactions, the neutrino-electron differential cross section and the neutrino backgrounds at XENON1T. In Sec. III we present our results: the event rates, the phenomenological constraints on light vector states and a statistical analysis of the parameter space. We summarize in Sec. IV.

II. LIGHT VECTOR MEDIATOR SCENARIOS AND SOLAR NEUTRINO BACKGROUND

FIG. 1. Averaged survival probability $\text{⟨P}_{ee}\text{⟩}$ versus neutrino energy calculated in the two-flavor approximation with neutrino production distribution functions and neutrino fluxes (pp and CNO) as given in the BS05 Standard Solar Model [32]. We have fixed the neutrino oscillation parameters according to their best fit point values [33].

Full expressions for the $a_i$ and $b_i$ parameters are given in Ref. [29]. In the limits assumed in this paper (suppressed kinetic and mass mixing), they have a rather simple form

$$a_1 = a_2 = 0, \quad b_1 = -\frac{1}{4} Q^e c Q^\ell g_V^2, \quad b_2 = -\frac{1}{4} Q^e s Q^\ell g_V^2,$$

where $g_V$ is the coupling associated to the new vector boson and possible charge choices are determined by anomaly cancellation, as in Ref. [28]. Out of the possible choices, $Q^e_c = Q^\ell = -1$ corresponds to the well known $U_{B-L}$ case. In the following we stick to this scenario. From Eq. (3), one can see that a spectral feature in the electron recoil events can be generated by the $q^2 = -2m_e E_e$ dependence, as far as the vector is not decoupled. This is the limit we are interested in.

Having introduced the notation, we then move on to the determination of the morphology of the neutrino background at XENON1T. With a 0.65 tonne-year exposure, the expected number of solar neutrino electron recoil events is $220.7 \pm 6.6$ [13]. This background can be obtained by integrating the following differential rate [12]

$$\frac{dR}{dE_e} = \varepsilon N_T \sum_k \int_{E_{\text{min}}}^{E_{\text{max}}} \frac{d\Phi_k}{dE_\nu} \left[ P_{ee} \frac{d\sigma_{ee}}{dE_e} + (1 - P_{ee}) \frac{d\sigma_{\ell\ell}}{dE_e} \right] dE_\nu,$$

with $\alpha$ running over all the neutrino-related subprocesses of the solar pp and CNO chains: pp, $^8$B, hep, two $^7$Be and pep lines, $^{13}$N, $^{15}$O and $^{17}$F. Here $\varepsilon$ refers to the exposure in tonne-year, $N_T = (Z_{Xe}/m_{\text{molar}}) N_A$ to the number of target electrons per tonne of material, $\mathcal{A}$ to the detector efficiency function and $d\Phi_k/dE_\nu$ to neutrino flux in cm$^{-2}$year$^{-1}$MeV$^{-1}$ units. For the solar neutrino fluxes we take the predictions of the BS05 Standard Solar Model [32].
Expression \( \delta \) assumes the two-flavor approximation, a fairly accurate limit given that \( \Delta m^2_{13}/\Delta m^2_{12} \ll 1 \). In this limit one neutrino eigenstate is mainly \( \nu_e \) with flavor contamination suppressed by the reactor mixing angle, while the other—labeled \( \nu_f \)—is a superposition of \( \nu_e \) and \( \nu_x \) with the admixture determined by the atmospheric mixing angle. The survival probability proceeds from an average over the neutrino trajectory and weighted by solar neutrino production distributions determined by the BS05 Standard Solar Model. For its calculation we have proceeded as described in Refs. [12, 34].

Figure 1 shows our result derived for neutrino oscillation parameters fixed according to the best fit point value obtained from global neutrino oscillation data analysis: \( \Delta m^2_{12} = 7.55 \times 10^{-5} \text{eV}^2 \), \( \sin^2\theta_{12} = 0.32 \) and \( \sin^2\theta_{13} = 0.0216 \) [33].

The differential cross section in the first term of Eq. \( \delta \) is given by Eq. \( \delta \), the one in the second term as well but without including the second term in \( g_\text{SM}^2 \) in Eq. \( \delta \). The lower integration limit is related to the recoil energy through

\[
E^\text{min}_\nu = \frac{1}{2} \left( E_r + \sqrt{E_r^2 + 2E_r m_e} \right),
\]

while for \( E^\text{max}_\nu \) we take the kinematic end points of each of the neutrino fluxes. Although the sum in \( \delta \) covers all neutrino emission processes, given the recoil window, we find that the \( pp \) continuous spectrum alone accounts for almost all the solar neutrino background. This is somehow expected given the low energy threshold achieved by the detector, 1 keV, and the size of the different components of the neutrino flux. Figure 2 shows the differential event rate calculated with Eq. \( \delta \). There one can see that \( pp \) neutrinos dominate the signal only over \( E_r \).

Other contributions are subdominant, including the \( ^7\text{Be} \) line at 0.861 MeV (the second relevant contribution) and \(^{8}\text{B} \) which for CEvNS will be the dominant source [35].

Expression \( \delta \) shows the differential event rate calculated with Eq. (6). There are two main components of the neutrino flux, low energy threshold achieved by the detector, 1 keV, and the emission processes, given the recoil window, we find that the \( pp \) neutrinos dominate the signal all over \( E_r \). Other contributions are subdominant, including the \( ^7\text{Be} \) line at 0.861 MeV (the second relevant contribution) and \(^{8}\text{B} \) which for CEvNS will be the dominant source [35].

III. CONSTRAINTS AND PARAMETER SPACE ANALYSIS

In what follows we assume that only \( \nu_e \) couples to the light new vector boson while \( \nu_f \) is subject only to SM couplings. Including coupling to \( \nu_f \) will not change our conclusions qualitatively. Although the new interaction can affect neutrino propagation in matter, here it is reasonable to consider only effects in detection. Forward coherent scattering is responsible for matter effects, which given the solar electron density are prominent (resonantly enhanced) only for \(^8\text{B} \) neutrinos. Since the signal is driven by the \( pp \) flux, propagation effects can be safely ignored. Under those well-justified assumptions, the second term in Eq. \( \delta \) is negligible. However, for completeness, we keep the full expression in our calculation.

Figure 3 shows the effect of the new interaction on the neutrino-electron differential event rate, along with the data points of XENON1T and the background \( B_0 \), assuming a fixed value of \( g_\nu \) and scanning over \( m_\nu \) in the range [1, 50] keV (width of the light blue band). The signal peaks at low energies with decreasing vector boson masses, for fixed coupling. This behavior is expected from the structure of the differential cross section. The third term in Eq. \( \delta \) has a recoil energy dependence, which becomes irrelevant for sufficiently large \( m_\nu \). However, in the limit \( 2m_\nu E_r \gg m^2_\nu \) that term behaves like \( \sim E_r^{-1} \). Therefore, in that regime, the \( E_r \) dependence is basically the same of the \( \nu - e \) neutrino magnetic moment cross section [36, 38].

To statistically determine the regions favored/disfavored by XENON1T data we define a simple spectral \( \chi^2 \) function as...
Following XENON1T analysis, we have added \( B_0 \) to the vector contribution. The allowed 1σ region (pink) and 2σ excluded region (light blue region) resulting from our analysis are shown in Fig. 4. At the 1σ level, the allowed vector boson masses are always below \( \sim 800 \text{ keV} \) with couplings that never exceed \( 6 \times 10^{-7} \). In this region the largest enhancements in the \( 2 - 7 \text{ keV} \) energy range are found. As \( m_V \) increases, the \( E_r^{-1} \) behavior of the cross section diminishes and the differential recoil spectrum flattens out towards \( B_0 \).

At this point then the question is whether the 1σ allowed region is consistent with existing bounds on light vector mediator scenarios, for example those in [10, 29, 39, 51] (some of them relevant also for CEsNS [52, 53]). These bounds can be separated in laboratory, astrophysical and cosmological constraints. In the region of interest, the most stringent laboratory limits are set by TEXONO, GEMMA and Borexino [41, 45], as shown in Fig. 4. XENON1T improves the constraints on light vector mediators for \( m_V \lesssim 0.2 \text{ MeV} \), compared to TEXONO and Borexino. GEMMA limits are tighter but still leave unconstrained a fraction of the 1σ region. Overall, the regions within which XENON1T excess can be accounted for are consistent with laboratory bounds.

Astrophysical and cosmological constraints are instead much more severe. The light vectors can be produced in environments like horizontal branch stars and the Sun leading then to energy losses [46, 48, 54]. The presence of a vector neutrino coupling can affect the neutrino mean free path in supernovae, eventually disrupting the neutrino diffusion time [55]. These arguments lead to stringent bounds within the region of interest (see Fig. 4). In general, these limits might be evaded if the vector boson couples to light scalars that undergo condensation in the corresponding environment. Under these conditions the vector mass becomes environmental dependent and so its production is no longer possible [56]. Further relevant bounds come from cosmology. In the early Universe the vector boson can thermalize through neutrino or electron annihilation or scattering processes. This will alter the expansion history of the early Universe and eventually lead to a sizeable contribution to the effective number of neutrino species, \( \Delta N_{\text{eff}} \) [57, 61]. While the exact evaluation of these bounds will depend on the specific model and thermal history of the Universe, they appear to exclude the full XENON1T 1σ-region here derived.

**IV. CONCLUSIONS**

We have considered light vector mediator scenarios in the light of the recent XENON1T data [14]. We have addressed the question of whether these interactions can account for the spectral distortion observed by the collaboration. Light vector mediators generate spectral features, modifying the recoil energy dependence of the differential cross section, which increases at low \( E_r \) for sufficiently small vector boson masses. We have performed a statistical analysis taking into account the complete set of solar neutrino fluxes and the neutrino survival probability from oscillations. We have shown that XENON1T bounds are competitive with those from other laboratory experiments. Astrophysical and cosmological observations place instead more severe constraints, which potentially exclude the regions of parameter space which can explain the XENON1T excess. With increasing exposures, multi-ton LXe detectors will keep on testing other parameter space regions of these scenarios.

**Note added in proof**

While completing this work, Ref. [22] appeared in the arXiv database. In addition to light vector mediators, this paper considered as well light scalar mediators. Our findings are consistent with those this reference has reported.
