(Dated: May 19, 2022)

We explore the merits of linear-response range-separated time-dependent density-functional theory (TDDFT) for the calculation of photoionization spectra. We consider two variants of range-separated TDDFT, namely the time-dependent range-separated hybrid (TDRSH) scheme which uses a global range-separation parameter and the time-dependent locally range-separated hybrid (TDLRSH) which uses a local range-separation parameter, and compare with standard time-dependent local-density approximation (TDLDA) and time-dependent Hartree-Fock (TDHF). We show how to calculate photoionization spectra with these methods using the Sternheimer approach formulated in a non-orthogonal B-spline basis set with appropriate frequency-dependent boundary conditions. We illustrate these methods on the photoionization spectrum of the Be atom, focusing in particular on the core resonances. Both the TDRSH and TDLRSH photoionization spectra are found to constitute a large improvement over the TDLDA photoionization spectrum and a more modest improvement over the TDHF photoionization spectrum.

I. INTRODUCTION

Time-dependent density-functional theory (TDDFT), applied within the adiabatic linear-response formalism, is a widely used approach for calculating bound-state excitations in electronic systems. Less commonly, linear-response TDDFT has also been used for calculating photoionization spectra (electronic transitions from bound to continuum states) of atoms and molecules. These calculations require an appropriate description of the continuum states (e.g., using grid-based approaches or B-spline basis sets) and an accurate enough exchange-correlation potential and associated response kernel. Semilocal density-functional approximations, such as the local-density approximation (LDA) or generalized-gradient approximations (GGA), do not usually provide accurate atomic and molecular photoionization spectra. These approximations suffer indeed from large self-interaction errors and exponentially decaying exchange-correlation potentials, leading to too low ionization thresholds and resonances that are either too low energies or completely absent. More satisfactory photoionization spectra are obtained with asymptotically corrected exchange-correlation potential approximations (restoring the correct \(-1/\) long-range asymptotic decay) and with the more involved exact-exchange (EXX) potential or the localized Hartree-Fock (HF) exchange potential and its associated kernel. An alternative for overcoming the limitations of TDDFT with semilocal density-functional approximations is given by range-separated TDDFT approaches, which, in the simplest variant, express the long-range part of the exchange potential and kernel at the HF level while a semilocal density-functional approximation is still used for the short-range part of the kernel. Range-separated TDDFT appropriately describes Rydberg and charge-transfer electronic excitations, and has become very much used in calculations of bound-state excitations in molecules. In Ref. 29, some of the present authors started to explore the merits of range-separated TDDFT for the calculation of photoionization spectra and showed that the so-called linear-response time-dependent range-separated hybrid (TDRSH) scheme provides an adequate photoionization spectrum of the He atom. In the present work, we continue the systematic exploration of linear-response TDRSH for the calculation of photoionization spectra. We focus on the Be atom which has a much richer photoionization spectrum than the He atom since it contains both core and valence electrons, leading in particular to a series of core resonances (1s\(\rightarrow\)2p, 1s\(\rightarrow\)3p, etc...) just below the 1s ionization edge. We also test a new variant, called the linear-response time-dependent locally range-separated hybrid (TDLRSH) scheme, in which the range-separation parameter is a position-dependent function, which allows for more flexibility in the description of both valence and core properties.

As in Ref. 29, we use a B-spline basis set for an appropriate description of the continuum. More specifically, in Ref. 29 we used a straightforward diagonalization of the linear-response Casida equations (in the orthogonal occupied/virtual orbital basis) using zero boundary conditions at the edge of the support of the last B-spline function, resulting in a discretization of the continuum spectrum. Whereas in the case of the He atom the relatively simple structure of the photoionization spectrum (only one channel) made it pos-

sible to use a simple interpolation scheme for the oscillator strengths, this approach is not feasible for the more complicated photoionization spectrum of the Be atom and one would have to use an artificial broadening to compensate. In this work, we use instead the linear-response Sternheimer approach \cite{Yu94,Reinhard01} (in the non-orthogonal B-spline basis) using appropriate frequency-dependent boundary conditions, resulting directly in an adequate representation of the continuous spectrum without the need for broadening. This is a much more efficient way of calculating photoionization spectra over a wide energy window, requiring only a relatively small computational box.

The paper is organized as follows. In Section II we review the range-separated hybrid (RSH) and locally range-separated hybrid (LRSH) schemes, and give in some detail the linear-response Sternheimer equations including a nonlocal HF exchange kernel both in real space and in a general non-orthogonal basis set which, to the best of our knowledge, were never given in the literature. We also discuss how the boundary conditions on a finite domain are imposed and our specific implementation using a B-spline basis set. In Section III we give and discuss the results obtained on the Be atom. We explain how to select an optimal range-separation parameter, we discuss the photoionization spectra at the TDRSH and TDLRSH level and compare with linear-response time-dependent local-density approximation (TDLDA) and time-dependent Hartree-Fock (TDHF), and we analyze the positions and the Fano lineshape of the core resonances. Section IV contains our conclusions. Finally, in Appendix A we explain in detail how to obtain the appropriate boundary conditions for atoms, and in Appendix B we compare the present Sternheimer approach with the straightforward Casida method of Ref. \cite{Yu94}.

II. THEORY AND COMPUTATIONAL METHOD

For simplicity, we consider only the case of a closed-shell atomic or molecular system and thus work on the spin-free one-electron Hilbert space \( L^2(\mathbb{R}^3, \mathbb{C}) \). Unless otherwise indicated, Hartree atomic units are used in this work.

A. Range-separated hybrid scheme

Let us briefly recall the range-separated hybrid (RSH) scheme.\cite{Yu94} The RSH orbitals \( \{ \phi_i \} \) and their associated energies \( \{ \epsilon_i \} \) of a \( N \)-electron system are found from the self-consistent Schrödinger-type equation

\[
\int_{\mathbb{R}^3} h[\gamma_0](\mathbf{r}, \mathbf{r'}) \phi_i(\mathbf{r'}) d\mathbf{r'} = \epsilon_i \phi_i(\mathbf{r}),
\]

where \( h[\gamma_0](\mathbf{r}, \mathbf{r'}) \) is the nonlocal RSH Hamiltonian depending on the density matrix \( \gamma_0(\mathbf{r}, \mathbf{r'}) = 2 \sum_{j=1}^{N/2} \psi_j(\mathbf{r}) \psi_j^*(\mathbf{r'}) \). The RSH Hamiltonian has the form, for a generic density matrix \( \gamma \),

\[
h[\gamma](\mathbf{r}, \mathbf{r'}) = T(\mathbf{r}, \mathbf{r'}) + \delta(\mathbf{r} - \mathbf{r'}) v_{\text{ee}}(\mathbf{r}) + v_{\text{Hxc}}[\gamma](\mathbf{r}, \mathbf{r'}),
\]

where \( T(\mathbf{r}, \mathbf{r'}) \) is the kinetic integral kernel such that \( \int_{\mathbb{R}^3} T(\mathbf{r}, \mathbf{r'}) \phi_i(\mathbf{r'}) d\mathbf{r'} = -(1/2) \nabla^2 \phi_i(\mathbf{r}) \), and \( v_{\text{ee}}(\mathbf{r}) \) is the nuclear-electron potential and \( v_{\text{Hxc}}[\gamma](\mathbf{r}, \mathbf{r'}) \) is the Hartree-exchange-correlation potential. The expression of \( v_{\text{Hxc}}[\gamma](\mathbf{r}, \mathbf{r'}) \) is

\[
v_{\text{Hxc}}[\gamma](\mathbf{r}, \mathbf{r'}) = \delta(\mathbf{r} - \mathbf{r'}) v_{\text{H}[\gamma]}/\rho(\mathbf{r}) + v_{\text{HF}}^{\text{LRSH}}[\gamma](\mathbf{r}, \mathbf{r'}),
\]

containing the local Hartree potential \( v_{\text{H}[\gamma]}/\rho(\mathbf{r}) \) written with the density \( \rho(\mathbf{r}) = \gamma(\mathbf{r}, \mathbf{r}) \) and the Coulomb electron-electron interaction \( v_{\text{ee}}(\mathbf{r}) \) and the non-local long-range (lr) HF exchange potential

\[
v_{\text{HF}}^{\text{LRSH}}[\gamma](\mathbf{r}, \mathbf{r'}) = -\frac{1}{2} \gamma(\mathbf{r}, \mathbf{r'}) w_{\text{ee}}^{\text{LRSH}}(\mathbf{r}, \mathbf{r'}),
\]

written with the long-range electron-electron interaction \( w_{\text{ee}}^{\text{LRSH}}(\mathbf{r}, \mathbf{r'}) \) as

\[
 w_{\text{ee}}^{\text{LRSH}}(\mathbf{r}, \mathbf{r'}) = \frac{\operatorname{erf}(\mu(\mathbf{r} - \mathbf{r'}))}{|\mathbf{r} - \mathbf{r'}|},
\]

with \( \mu = \bar{\mu}/a_0 \) where \( a_0 = 1 \) a.u. is the Bohr radius and \( \bar{\mu} \in [0, +\infty) \) is the adimensional range-separation parameter, and the local complementary short-range (sr) exchange-correlation potential \( v_{\text{xc}}^{\text{sr}}[\rho](\mathbf{r}) \). For the latter term, we use in this work the LDA

\[
v_{\text{xc}}^{\text{sr}}[\rho](\mathbf{r}) = \frac{\partial v_{\text{xc} \text{, UEG}}(\rho, \mu)}{\partial \rho}
\]

\[
\bigg|_{\rho = \rho(\mathbf{r})},
\]

where \( v_{\text{xc} \text{, UEG}}(\rho, \mu) \) is the complementary short-range exchange-correlation energy density of the uniform-electron gas (UEG) of density \( \rho \), as parametrized in Ref. \cite{43}.

For more flexibility in the description of both valence and core properties, we will also consider an extension of the RSH scheme, referred to as the locally range-separated hybrid (LRSH) scheme, in which the range-separation parameter \( \mu \) in Eqs. (6) and (7) is replaced by a function of position \( \mu(\mathbf{r}) \) (see Refs. \cite{31} \cite{34}). The long-range electron-electron interaction in Eq. (6) now becomes \( w_{\text{ee}}^{\text{LRSH}}(\mathbf{r}, \mathbf{r'}) \) and

\[
 w_{\text{ee}}^{\text{LRSH}}(\mathbf{r}, \mathbf{r'}) = \frac{1}{2} \left[ \frac{\operatorname{erf}(\mu(\mathbf{r})|\mathbf{r} - \mathbf{r'}|)}{|\mathbf{r} - \mathbf{r'}|} + \frac{\operatorname{erf}(\mu(\mathbf{r})|\mathbf{r} - \mathbf{r'}|)}{|\mathbf{r} - \mathbf{r'}|} \right].
\]

Following Ref. \cite{31} we choose \( \mu(\mathbf{r}) \) as

\[
\mu(\mathbf{r}) = \frac{\bar{\mu}}{2} \frac{\nabla \rho(\mathbf{r})}{\rho(\mathbf{r})},
\]

where again \( \bar{\mu} \in [0, +\infty) \) is the adimensional range-separation parameter and we take \( \rho(\mathbf{r}) \) as the fixed HF ground-state density (contrary to Ref. \cite{33} we do not attempt to self-consistently update the density in Eq. (3) during the iterations of the RSH calculation). For the hydrogen atom, \( \rho(\mathbf{r}) \propto e^{-2|\mathbf{r}|/a_0} \) and thus \( \mu(\mathbf{r}) = \bar{\mu}/a_0 \), i.e. the LRSH scheme reduces to the RSH scheme.

For \( \bar{\mu} = 0 \), the long-range interaction \( w_{\text{ee}}^{\text{LRSH}} \) vanishes and \( v_{\text{xc}}^{\text{sr}} \) becomes the usual full-range LDA exchange-correlation potential, and thus the RSH and LRSH schemes reduce to standard Kohn-Sham (KS) LDA. For \( \bar{\mu} \rightarrow \infty \), the long-range
interaction \(w_{\text{ex}}^{\text{lr}}\) becomes the usual Coulomb interaction and \(v_{\text{ex}}^{\text{lr}}\) vanishes, and thus the RSH and LRSR schemes reduce to standard HF. Typically, in between these two limits, one expects to find an intermediate value of \(\bar{\mu}\) leading to properties more accurate than those given by either KS LDA or HF.

**B. Linear-response Sternheimer equations in real space**

We now formulate linear response of the RSH or LRSR scheme using the Sternheimer approach. Even though the Sternheimer approach is well known for TDHF without nonlocal HF exchange [10, 11, 15, 16], we did not find real-space expressions for the case including nonlocal HF exchange in the literature.

We consider the following time-dependent perturbation potential

\[
v_{\text{ext}}(\mathbf{r}, t) = \left[v_{\text{ext}}(\mathbf{r}) e^{-i\omega t} + v_{\text{ext}}(\mathbf{r}) e^{+i\omega t}\right] e^{i\phi'},
\]

where \(v_{\text{ext}}(\mathbf{r}) = \mathbf{r} \cdot \mathbf{E} e\) is the electric-dipole interaction (\(\mathbf{E}\) is the amplitude of the electric field and \(e\) is its unit polarization vector), \(\omega \geq 0\) is the frequency, and \(e^{i\phi'}\) is an adiabatic switching factor with a small parameter \(\eta > 0\) so that \(v_{\text{ext}}(\mathbf{r}, t \to -\infty) = 0\) (see Refs. [17] and [18] for a discussion about the parameter \(\eta\)).

The time-dependent occupied RSH orbitals \(\psi_i\) satisfy the time-dependent Schrödinger-type equation

\[
i \frac{\partial}{\partial t} \psi_i(\mathbf{r}, t) = \int_{\mathbb{R}^3} h[\gamma(t)](\mathbf{r}, \mathbf{r}')\psi_i(\mathbf{r}', t)\,d\mathbf{r}' + v_{\text{ext}}(\mathbf{r}, t)\psi_i(\mathbf{r}, t),
\]

where the RSH Hamiltonian is now evaluated at the time-dependent density matrix \(\gamma(\mathbf{r}, \mathbf{r}', t) = 2 \sum_{i=1}^{N/2} \psi_i(\mathbf{r}, t)\psi_i^*(\mathbf{r}', t)\).

We expand the time-dependent RSH occupied orbitals to first order in the electric field \(\mathbf{E}\) as

\[
\psi_i(\mathbf{r}, t) = (\phi_i(\mathbf{r}) + \mathbf{E} \psi_i^{(1)}(\mathbf{r}, t)) e^{-i\omega t} + O(\mathbf{E}^2),
\]

where \(\phi_i \equiv \psi_i^{(0)}\) are the zeroth-order (time-independent) orbitals. Inserting Eq. (12) into Eq. (11), and keeping only first-order terms, leads to the equation for \(\psi_i^{(1)}\)

\[
\left(i \frac{\partial}{\partial t} + \mathbf{E} \right) \psi_i^{(1)}(\mathbf{r}, t) = \int_{\mathbb{R}^3} h[\gamma_0](\mathbf{r}, \mathbf{r}')\psi_i^{(1)}(\mathbf{r}', t)\,d\mathbf{r}' + \int_{\mathbb{R}^3} \nu_{\text{Hsc}}^{(1)}(\mathbf{r}, \mathbf{r}', t)\phi_i(\mathbf{r}')\,d\mathbf{r}' + \nu_{\text{ext}}^{(1)}(\mathbf{r}, t)\phi_i(\mathbf{r}),
\]

where we have introduced \(\nu_{\text{ext}}^{(1)}(\mathbf{r}, t) = \nu_{\text{ext}}(\mathbf{r}, t) / \mathcal{E}\) and the first-order change in the Hartree-exchange-correlation potential

\[
\nu_{\text{Hsc}}^{(1)}(\mathbf{r}, t) = \int_{\mathbb{R}^3} f_{\text{Hsc}}[\gamma_0](\mathbf{r}, \mathbf{r}_1; \mathbf{r}_2, \mathbf{r}_3)\gamma^{(1)}(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, t)\,d\mathbf{r}_2\,d\mathbf{r}_3, (14)
\]

involving the first-order change in the density matrix

\[
\gamma^{(1)}(\mathbf{r}, \mathbf{r}', t) = 2 \sum_{i=1}^{N/2} [\phi_i^{(1)}(\mathbf{r}, t)\phi_i^{*}(\mathbf{r}', t) + \phi_i(\mathbf{r})\phi_i^{(1)*}(\mathbf{r}', t)], (15)
\]

and the Hartree-exchange-correlation kernel

\[
f_{\text{Hsc}}[\gamma_0](\mathbf{r}, \mathbf{r}_1; \mathbf{r}_2, \mathbf{r}_3) = \frac{\delta v_{\text{Hsc}}[\gamma](\mathbf{r}_1, \mathbf{r}_2)}{\delta \gamma(\mathbf{r}_1, \mathbf{r}_3)} e^{i\phi} \bigg|_{\gamma = \gamma_0}. (16)
\]

From Eq. (3), the latter quantity is found to be

\[
f_{\text{Hsc}}[\gamma_0](\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}_1', \mathbf{r}_2', \mathbf{r}_3) = \delta(\mathbf{r}_1 - \mathbf{r}_1')\delta(\mathbf{r}_2 - \mathbf{r}_2')f_{\text{H}}(\mathbf{r}_1, \mathbf{r}_2) + f_{\text{H}}^{\text{HF}}(\mathbf{r}_1, \mathbf{r}_1'; \mathbf{r}_2, \mathbf{r}_2') + \delta(\mathbf{r}_1' - \mathbf{r}_1)\delta(\mathbf{r}_2 - \mathbf{r}_2')f_{\text{Hsc}}^{\text{HF}}[\rho_{\text{sc}}](\mathbf{r}_1, \mathbf{r}_2), (17)
\]

where \(f_{\text{H}}(\mathbf{r}_1, \mathbf{r}_2) = \mathcal{W}_\text{sc}(\mathbf{r}_1, \mathbf{r}_2)\) is the Hartree kernel, \(f_{\text{Hsc}}^{\text{HF}}(\mathbf{r}_1, \mathbf{r}_1'; \mathbf{r}_2, \mathbf{r}_2') = -(1/2)\delta(\mathbf{r}_1 - \mathbf{r}_1')\delta(\mathbf{r}_2 - \mathbf{r}_2')\mathcal{W}_\text{sc}(\mathbf{r}_1, \mathbf{r}_1')\) is the nonlocal HF exchange kernel, and \(f_{\text{Hsc}}^{\text{HF}}[\rho_{\text{sc}}](\mathbf{r}_1, \mathbf{r}_2)\) is the short-range exchange-correlation kernel, which for the LDA [Eq. (7)] takes the local form

\[
f_{\text{sc}}^{\text{HF}}[\rho_{\text{sc}}](\mathbf{r}_1, \mathbf{r}_2) = \delta(\mathbf{r}_1 - \mathbf{r}_2) \frac{\partial^2 \mathcal{P}_{\text{sc}}^{\text{HF}}(\rho_{\text{sc}}, \mu)}{\partial \rho_{\text{sc}}^2} \bigg|_{\rho_{\text{sc}} = \rho_{\text{sc}}(\mathbf{r}_1)} (18)
\]

From the form of the perturbation in Eq. (10), we can write \(\psi_i^{(1)}\) as

\[
\psi_i^{(1)}(\mathbf{r}, t) = \left[\psi_i^{(1)}(\mathbf{r}, \omega)e^{-i\omega t} + \psi_i^{(1)*}(\mathbf{r}, \omega)e^{+i\omega t}\right] e^{i\phi'}, (19)
\]

which, after inserting into Eq. (13), gives the TDRSH or TDLRSR Sternheimer equations for \(\psi_i^{(1)}\) and \(\psi_i^{(1)*}\), written in a common form,

\[
(\pm \omega + i\eta + e_i) \psi_i^{(1)}(\mathbf{r}_1, \omega) = \int_{\mathbb{R}^3} h[\gamma_0](\mathbf{r}_1, \mathbf{r}_1')\psi_i^{(1)}(\mathbf{r}_1', \omega)\,d\mathbf{r}_1' + \int_{\mathbb{R}^3} f_{\text{Hsc}}[\gamma_0](\mathbf{r}_1, \mathbf{r}_1'; \mathbf{r}_2, \mathbf{r}_2')\gamma^{(1)}(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \omega)\phi_i(\mathbf{r}_1')\,d\mathbf{r}_2\,d\mathbf{r}_3 + \nu_{\text{ext}}^{(1)}(\mathbf{r}_1)\phi_i(\mathbf{r}_1), (20)
\]

As long as \(\eta > 0\), the solutions \(\psi_i^{(1)}\) of Eq. (20) are properly square-integrable for any fixed frequency \(\omega\). Note that if we
had introduced $\psi^{(\pm)}(r, \omega)$ in place of $\psi^{(\pm)}(r, \omega)$ in Eq. (19), like in Ref. [38], then we would have obtained an equation similar to Eq. (20) but with imaginary shifts $\pm i\eta$.

The photoexcitation/photoionization cross section can then be calculated as

$$\sigma(\omega) = \lim_{\eta \to 0^+} \frac{4\pi\omega}{c} \text{Im}[\alpha(\omega + i\eta)],$$

where $c = 137.036$ a.u. is the speed of light and $\alpha(\omega)$ is the spherically averaged dipole polarization given by

$$\alpha(\omega + i\eta) = -\frac{1}{2} \sum_{a=1, x, c, z} \int_{\mathbb{R}^3} (\mathbf{r} \cdot \mathbf{u}_a) \rho^{(a)}(r, \omega, \mathbf{r}) \, d\mathbf{r},$$

where $\mathbf{u}_a$ is the unit vector along the direction $a$ and $\rho^{(a)}(r, \omega)$ is the Fourier component of the first-order density at frequency $\omega + i\eta$ of the first-order change of the density [Eq. (21)].

Note that, most often, in the derivation of the Sternheimer equation [25,35], $\psi^{(\pm)}$ are in fact defined so that they are orthogonal to $\varphi_i$, which lead to adding the projector operator onto the space orthogonal to $\varphi_i$. Acting on the last two terms in Eq. (20). While this is probably a good choice for numerical calculations, it is not mandatory for the theoretical derivation, as discussed in Ref. [38] and in any case it leads to the same observable quantities such as the polarizability in Eq. (23).

### C. Boundary conditions on a finite domain

It is instructive to consider the behavior of Eq. (20) far away from the atom or molecule. In this case, since the potential and kernel terms, as well as the occupied orbitals, all go to zero at infinity, the equation reduces to

$$(\epsilon_i + \omega + i\eta - \frac{1}{2} \nabla^2)\psi^{(\pm)}_i(r, \omega) \approx 0.$$  

(24)

In the limit $\eta \to 0^+$, this equation means that the TDRSH or TDLRSH ionization energy from the occupied orbital $i$ is equal to $-\epsilon_i$, which is also the bare RSH or LRSH ionization energy from orbital $i$. When $\epsilon_i + \omega < 0$ (below the ionization threshold), the solutions decay exponentially fast at infinity. When $\epsilon_i + \omega > 0$ (above the ionization threshold), they are oscillatory (behaving like free outgoing waves). As shown in Appendix [A] for the case of atoms, this analysis can be refined to take into account the presence of the effective long-range Coulomb potential and find the exact asymptotic behavior of $\psi^{(\pm)}_i$.

Let us then consider the case where the numerical computation is truncated to a bounded spatial domain $\Omega \subset \mathbb{R}^3$. Using zero (Dirichlet) boundary conditions for $\psi^{(\pm)}_i$ on the boundary $\partial \Omega$ is clearly not appropriate when $\epsilon_i + \omega > 0$, and indeed will artificially discretize the electronic continuum, in turn discretizing the photoionization spectrum. Instead, following the general philosophy of the Dirichlet-to-Neumann approach (see, e.g., Refs. [45] and [46]), we can use frequency-dependent boundary conditions that gives accurate results even for a relatively small domain and $\eta = 0$. For this, we just need to find analytically an approximation $\tilde{\psi}^{(\pm)}_i$ of $\psi^{(\pm)}_i$ which is valid outside of $\Omega$, and then require the normal derivative of $\psi^{(\pm)}_i$ on the interior of $\partial \Omega$ to match the normal derivative of $\tilde{\psi}^{(\pm)}_i$ on the exterior of $\partial \Omega$, which yields a nonlocal Robin boundary condition of the form

$$\forall r \in \partial \Omega, \quad \mathbf{n}(r) \cdot \nabla \psi^{(\pm)}_i(r, \omega) = \int_{\partial \Omega} K_i(r, r', \pm \omega) \psi^{(\pm)}_i(r', \omega) \, d\mathbf{r'},$$

(25)

where $\mathbf{n}(r)$ is the outward normal vector to the surface $\partial \Omega$ at point $r$. In the case of atoms, the Dirichlet-to-Neumann kernel $K_i(r, r', \pm \omega)$ reduces to a simple local radial form (see Appendix [A]).

### D. Linear-response Sternheimer equations in a basis set

Let us introduce now a finite (non-orthogonal) basis set $\{\chi_{\nu}\}_{\nu=1,\ldots,M} \subset H^1(\Omega, \mathbb{C})$ (where $H^1$ is the first-order Sobolev space) made of $M$ basis functions (whose behavior on $\partial \Omega$ is arbitrary) to expand the occupied orbitals

$$\varphi_j(r) = \sum_{\nu=1}^M c_{j\nu} \chi_{\nu}(r),$$

(26)

and their first-order changes

$$\psi^{(\pm)}_j(r, \omega) = \sum_{\nu=1}^M c_{j\nu}^{(\pm)}(\omega) \chi_{\nu}(r),$$

(27)

where $c_{j\nu}$ and $c_{j\nu}^{(\pm)}(\omega)$ are (generally complex-valued) coefficients labeled with the composite index $j\nu \equiv (j, \nu) \in \mathbb{N} \times \mathbb{N}$. Integrating Eq. (20) against a basis function $\chi_{\nu}^*$ and using the expansions of Eqs. (26) and (27), leads directly to the basis-set Sternheimer equations in the following block matrix form

$$\begin{pmatrix} \Lambda(\omega) & \mathbf{B} \\ \mathbf{B}^* & \Lambda(-\omega)^* \end{pmatrix} \begin{pmatrix} \mathbf{c}^{(+)}(\omega) \\ \mathbf{c}^{(-)(\omega)^*} \end{pmatrix} = - \begin{pmatrix} \mathbf{V} \\ \mathbf{V}^* \end{pmatrix},$$

(28)

which must be solved at each given frequency $\omega$ for $\mathbf{c}^{(+)}(\omega)$ and $\mathbf{c}^{(-)(\omega)^*}$ which are the column vectors of components $c_{j\nu}^{(+)}(\omega)$ and $c_{j\nu}^{(-)(\omega)^*}$, respectively. In Eq. (28), $\mathbf{V}$ is the column vector of components $V_{j\nu} = \mathbf{e} \cdot \sum_{\nu}^M d_{j\nu}^* c_{j\nu} \chi_{\nu}(r) \mathbf{r}$ where $d_{j\nu} = \int_{\Omega} \chi_{\nu}^*(\mathbf{r}) \chi_{\nu}(\mathbf{r}) \, d\mathbf{r}$ are the dipole-moment integrals, and $\Lambda(\pm \omega)$ and $\mathbf{B}$ are square matrices with elements

$$\Lambda_{\mu,j\nu}(\pm \omega) = \delta_{\mu,j} \left( \epsilon_{\mu,i} + (\pm \omega + i\eta) S_{\nu,j} \right) + 2 \sum_{\nu=1}^M \sum_{\sigma=1}^M c_{\nu\sigma} c_{j\nu}^{*} F_{\mu,j\nu \sigma},$$

(29)

and

$$B_{\mu,j\nu} = 2 \sum_{\nu=1}^M \sum_{\sigma=1}^M c_{\nu\sigma} c_{j\nu}^{*} F_{\mu,j\nu \sigma},$$

(30)

Here $\epsilon_{\mu,i}$ is the energy of the $\mu$th eigenstate of the $i$th orbital. The $S_{\nu,j}$ and $F_{\mu,j\nu \sigma}$ are elements of the overlap and coupling matrices, respectively.
In Eq. (29), $S_{\mu,\nu} = \int_{\Omega} \chi^*_\mu(r) \chi_\nu(r) \, dr$ are the overlap integrals over the basis functions, and $h_{i,\mu,\nu}(\pm \omega)$ are the matrix elements of the RSH or LRSH Hamiltonian

$$h_{i,\mu,\nu}(\pm \omega) = t_{i,\mu,\nu}(\pm \omega) + v_{\mu,\nu}$$

where $t_{i,\mu,\nu}(\pm \omega)$ are the kinetic integrals including the boundary condition [see Eq. (35) below],

$$\int_{\Omega} \chi^*_\mu(r) \chi_\nu(r) \, dr = \sum_{\sigma=1}^{M} \sum_{\nu=1}^{M} P_{\sigma,\lambda,\sigma',\nu} \left( w_{\mu,\lambda,\sigma,\nu} - \frac{1}{2} w_{\mu,\lambda,\sigma,\nu} \right) + v_{\mu,\nu}$$

Choosing for $P_{\sigma,\lambda,\sigma',\nu}$ the density matrix, $w_{\mu,\lambda,\nu} = \int_{\Omega} \chi^*_\mu(r) \chi_\mu(r) \, dr$ are the Coulombic and long-range two-electron integrals, respectively, and $v_{\mu,\nu} = \int_{\Omega} \chi^*_\mu(r) \chi_\nu(r) \, dr$ are the short-range exchange-correlation potential integrals. In Eqs. (29) and (30), $F_{\mu,\lambda,\sigma,r}$ are the matrix elements of the Hartree-exchange-correlation kernel $f_{\text{Hxc}[\gamma_0]}$

$$F_{\mu,\lambda,\sigma,r} = \int_{\Omega} \chi^*_\mu(r_1) \chi_\lambda(r_2) f_{\text{Hxc}[\gamma_0]}(r_1, r_2) \, dr_1 \, dr_2$$

To obtain the expression of the kinetic integrals, we start from the kinetic contribution in Eq. (20), projected on the basis function $\chi^*_\mu$, and perform an integration by parts

$$-\frac{1}{2} \int_{\Omega} \chi^*_\mu(r) \nabla^2 \psi^{(\pm)}(r, \omega) \, dr = \frac{1}{2} \int_{\Omega} \nabla \chi^*_\mu(r) \cdot \nabla \psi^{(\pm)}(r, \omega) \, dr - \frac{1}{2} \int_{\Omega} \chi^*_\mu(r) \, n(r) \cdot \nabla \psi^{(\pm)}(r, \omega) \, dr.$$

Using the boundary condition in Eq. (25), the surface term can then be expressed as

$$-\frac{1}{2} \int_{\partial \Omega} \chi^*_\mu(r) \, n(r) \cdot \nabla \psi^{(\pm)}(r, \omega) \, dr =$$

$$\frac{1}{2} \int_{\partial \Omega} \chi^*_\mu(r) K(r, r') \psi^{(\pm)}(r', \omega) \, d\Omega \cdot d\Omega'.$$

After expanding $\psi^{(\pm)}$ in the basis set, we thus obtain the expression of the kinetic integrals

$$t_{i,\mu,\nu}(\pm \omega) = \frac{1}{2} \int_{\Omega} \nabla \chi^*_\mu(r) \cdot \nabla \chi_\nu(r) \, dr$$

In the limit of a complete basis set, this correctly imposes Eq. (25) on $\psi^{(\pm)}$.

To see this, it is instructive to consider the simplified problem of solving the one-dimensional differential equation $-\psi''(x) + V(x)\psi(x) = F(x)$ on the interval $(-1,1)$, for some real-valued potential $V$ and source term $F$, and boundary conditions $\psi^{(\pm)}(\pm 1) = K_{\pm}(\pm 1)$. Solving this problem is equivalent to requiring that $\psi$ satisfies the variational equation

$$\int_{-1}^{1} \chi(x) \psi''(x) \, dx + \chi(1) K(\psi(1)) - \chi(-1) K(\psi(-1)) + \int_{-1}^{1} \chi(x) V(x) \psi(x) \, dx = \int_{-1}^{1} \chi(x) F(x) \, dx$$

Choosing for $\chi$ a function that is zero on $(-1,1)$ and ramps up linearly to 1 at $x = 1$, we obtain by passing to the limit $n \to \infty$ in the variational equation that $\psi^{(1)}(1) = K_{\pm}(1)$. Similarly, we can choose the function $\chi$ so that $\psi^{(-1)} = K_{\pm}(1)$. The Sternheimer matrix equations in Eq. (28) have essentially the same form as the well-known TDDFT Casida equation [23] except that the latter are normally written in the orthogonal basis of the occupied and virtual orbitals whereas the present Sternheimer matrix equations are written in an arbitrary non-orthogonal basis set.

Finally, in the basis set, the dipole polarizability takes the form

$$\alpha(\omega + i\eta) = \frac{1}{3} \sum_{\omega} \sum_{\mu=1}^{M} \sum_{\nu=1}^{M} \left( P_{\mu,\nu}^{(\omega)} \psi^{(\pm)}_{\mu} \psi^{(\pm)}_{\nu} + P_{\mu,\nu}^{(-\omega)} \psi^{(\pm)}_{\mu} \psi^{(\pm)}_{\nu} \right) \cdot \cdot \cdot$$

with $P_{\mu,\nu}^{(\omega)} = 2 \sum_{\mu=1}^{M} \sum_{\nu=1}^{M} \left( \psi^{(\pm)}_{\mu} \psi^{(\pm)}_{\nu} \right)$. The B-spline basis set for atoms

We specialize now in the case of atoms with radial ground-state densities. Spherical symmetry permits to write the occupied orbitals as

$$\varphi_i(r) = \frac{R_i(r)}{r} Y^m_i(\theta, \phi),$$

with radial functions $R_i$ and spherical harmonics $Y^m_i$. For a dipole interaction with a $z$-polarized electric field, i.e., $\mathbf{E}^{(1)} = r \cdot \mathbf{u}_z$, the corresponding first-order orbital changes are of the form

$$\psi^{(\pm)}_i(r, \omega) = \sum_{\ell \in \mathcal{L}_i} \frac{R^{(\pm)}_i(r, \omega)}{r} Y^{m}_i(\theta, \phi),$$

with $\mathcal{L}_i = \{\ell_i - 1, \ell_i + 1\}$ for $\ell_i \geq 1$ and $\mathcal{L}_i = \{\ell_i\}$ for $\ell_i = 0$.?
We expand the radial functions in a basis set of \(M_s\) B-spline functions \(\{B_r\}_{r=1\cdots M_s}\) of order \(k_s\)

\[
R_s(r) = \sum_{v=1}^{M_s} c_{s,v} B_s(r),
\]

(39)

\[
R_{s,\ell}(r, \omega) = \sum_{v=1}^{M_s} c_{s,\ell,v}(\omega) B_s(r).
\]

(40)

To completely define a basis of B-spline functions, a non-decreasing sequence of \(M_s + k_s\) knot points \(\{r_p\}_{p=1\cdots M_s+k_s}\) (some knot points are possibly coincident) must be given. The B-spline function \(B_s(r)\) is non zero only on the supporting interval \([r_p, r_{p+k_s}]\) (containing \(k_s + 1\) consecutive knot points) and is a piecewise function composed of polynomials of degree \(k_s - 1\) (one polynomial in between two consecutive non-coincident knot points) with continuous first \(k_s - m - 1\) derivatives across each knot of multiplicity \(m\). We have followed the standard choice of taking the first and the last knots to be \(r_{k_s} = 0\) and \(r_{k_s+1} = r_{\text{max}}\), which can be easily imposed by removing the first B-spline function which is the only one non vanishing at \(r = 0\). At \(r = r_{\text{max}}\), for the occupied orbitals, which decay exponentially at infinity, we can also use zero boundary conditions, i.e. \(R_s(r = r_{\text{max}}) = 0\), which can be imposed by just removing the last B-spline functions in the basis set calculation. For the first-order orbital changes \(R_{s,\ell}^{(\pm)}\), as shown in Appendix A, the radial symmetry simplifies the nonlocal boundary condition in Eq. (25) to the local Robin boundary condition

\[
\frac{dR_{s,\ell}^{(\pm)}(r, \omega)}{dr} |_{r=r_{\text{max}}^{(\pm)}} = b_{s,\ell}(\pm \omega) R_{s,\ell}^{(\pm)}(r_{\text{max}}^{(\pm)}),
\]

and the kinetic integrals [Eq. (35)] for \(R_{s,\ell}^{(\pm)}\) become

\[
I_{s,\ell,\mu,\nu}(\pm \omega) = \frac{1}{2} \int_{0}^{r_{\text{max}}} \frac{dR_s(r) dB_s(r)}{dr} \frac{dB_s(r)}{dr} dr + \frac{1}{2} \int_{0}^{r_{\text{max}}} B_s(r) \left(\ell(\ell+1) - \frac{\ell(\ell+1) r^2}{2} + B_s(r) dr \right.
\]

\[
- \delta_{\mu,\ell} \delta_{\nu,s} \frac{b_{s,\ell}(\pm \omega)}{2}(r_{\text{max}}^{(\pm)}),
\]

(41)

where we have used the fact that only the last B-spline basis function is non zero at \(r_{\text{max}}\). The complex-valued function \(b_{s,\ell}\) is given in Eqs. (A.11), (A.12), and (A.13). In this way, the boundary condition is imposed without modification of the basis set. This method is somewhat simpler than the procedure to impose boundary conditions described in Refs. [7] and [35] but conceptually similar to the procedure described in Refs. [12] and [17] for grid-based TDDFT and in Refs. [50] and [51] in the context of the R-matrix method.

F. Further computational details

We apply the present theory to the Be atom \((N = 4)\) in the ground-state configuration \(1s^22s^2\). We use \(M_s = 50\) B-spline basis functions of order \(k_s = 8\) and a maximal radius of \(r_{\text{max}} = 25\) bohr. The occupied orbitals are of symmetry \(s\) \((\ell = 0, m = 0)\) and the perturbed orbitals are of symmetry \(p_\ell\) \((\ell = 1)\).

Radial integrals over B-spline functions are calculated using a Gauss-Legendre quadrature\([29]\). We use the integration-cell algorithm\([23]\) to calculate the Coulomb two-electron integrals, and an extension of it\([29]\) for the long-range two-electron integrals. For the case of LRSH, having a position-dependent range-separation parameter in the long-range two-electron integrals does not introduce any complications since the integration-cell algorithm uses a Gaussian quadrature.

Thanks to the locality of the B-spline basis functions, the construction of the matrices \(A(\omega)\) and \(B\) in Eq. (28) scales as \(O(N^2M_s^2)\), instead of the straightforward scaling \(O(N^4M_s^4)\) that would be obtained for an arbitrary basis set. The Sternheimer equations are usually solved iteratively\([36,37]\). However, we found that the simple iterative scheme of Ref. [7] starting from the bare response, i.e. \(f_{\text{thc}}(\gamma_0) = 0\), works well for TDLLDA but often does not converge for TDHF because the bare HF response is too bad an approximation to the TDHF response. Although this could be cured with more sophisticated iterative methods, on this simple system we found it expedient to simply solve Eq. (28) using a standard dense LU-decomposition linear solver.

Having a non-zero imaginary-shift parameter \(\eta\) is necessary to obtain a non-zero absorption cross section for bound states\([35]\). However, it is not necessary for the continuum part of the spectrum. Indeed, the imaginary part of the dipole polarizability involved in the photoionization cross section in Eq. (22) is not zero in any case due to the complex-valued function \(b\) introduced when imposing the boundary condition in Eq. (41). Moreover, since we are interested in obtaining the precise lineshape of the core resonances, we use \(\eta = 0\) to avoid artificially broadening these resonances.

As shown in Appendix A, the use of the accurate boundary conditions in Eq. (41) is essential to obtain photoionization cross section without spurious oscillations even with the relatively small \(r_{\text{max}}\) that we use. Moreover, in Appendix B we show that the present Sternheimer approach with appropriate boundary conditions is far superior than the straightforward Casida method with zero boundary condition of Ref. [29].

III. RESULTS AND DISCUSSION

We now show and discuss the results on the Be atom.

A. Orbital energies

Figure 1 shows the RSH and LRSH 1s and 2s orbital energies as a function of the adimensional range-separation parameter \(\tilde{\mu}\). Also indicated are the opposite of the experimental
For $\tilde{\mu} \neq 0$, even if we were to use the exact short-range exchange-correlation potential, assuming that we can rigorously define such a quantity, the RSH and LRSH 2s orbital energies would not be exactly equal to the opposite of the experimental IP, since long-range correlation effects are missing in the RSH and LRSH schemes. Also, the RSH and LRSH 1s orbital energies with the exact short-range exchange-correlation potential should not be expected to be exactly equal to the opposite of the experimental 1s ionization edge. However, with the present approximate RSH or LRSH potentials and kernels, we know that the RSH or LRSH ionization energy from each occupied orbital $i$ is the opposite of the orbital energy, $-\epsilon_i$, and is identical to the TDRSH or TDLRSH ionization energy from this orbital $i$ [see Eq. (24)]. In order to obtain correct ionization energies in TDRSH or TDLRSH we can thus choose the adimensional range-separation parameter $\tilde{\mu}$ so that the opposite of the RSH or LRSH occupied orbital energies are as close as possible to the experimental range-separation parameter $\tilde{\mu}$ so that the opposite of the 1s ionization edge, we decide to adjust the value of $\tilde{\mu}$ so that the RSH and LRSH 1s orbital energies are equal to opposite of the experimental 1s ionization edge. This gives $\tilde{\mu}_{\text{RSH}} = 1.608$ for RSH and $\tilde{\mu}_{\text{LRSH}} = 0.478$ for LRSH.

Since the range-separation parameter $\mu$ represents an inverse electron-electron distance [see Eq. (9)], for general atoms we expect the parameter $\tilde{\mu}_{\text{RSH}}$ optimized for the 1s RSH orbital energy to be approximately proportional to the nuclear charge $Z$, i.e. $\tilde{\mu}_{\text{RSH}} \approx O(Z)$. In contrast, since for a 1s orbital we have $|\nabla \rho|/\rho \approx O(1)$, we expect the LRSH optimal parameter $\tilde{\mu}_{\text{LRSH}}$ to be roughly independent from $Z$ [see Eq. (9)].

In Section III B, we show the TDRSH and TDLRSH photoionization spectra using the optimal adimensional range-separation parameters $\tilde{\mu}$ as determined above. Note that although we fit the single parameter $\tilde{\mu}$ to adjust the position of the 1s ionization edge, we make predictions for the whole photoionization spectrum.

### B. Photoionization spectrum

Figure 2 reports the photoionization cross section calculated by TDLDA, TDHF, TDRSH, and TDLRSH (using the optimal adimensional range-separation parameters determined in Section III A). We will just comment on the main features of these spectra, without trying to compare with experimental spectra. Indeed, the experimental spectra display many more peaks and structures due to double and higher excitations, which are not taken into account in the level of theory that we use.

The TDLDA photoionization spectrum starts at a too low ionization threshold (the same value as the opposite of the LDA 2s orbital energy) and the cross section is zero at the threshold, just like for the He atom. There is a large peak just above the TDLDA threshold, roughly in the energy range...
that should correspond to the 2s\to3p transition, followed by a minimum where the cross section vanishes, which is reminiscent of the well-known Cooper minimum (the present minimum may originate from the fact that the 2s orbital has a radial node, see e.g. Ref. 68). We have verified that this minimum is not present in the bare LDA photoionization spectrum and appears when the Hartree kernel is taken into account. The TDLDA 1s ionization edge occurs at a much too low energy, in fact exactly the same value as the opposite of LDA energy, and appears when the Hartree kernel is taken into account. The TDLDA photoionization spectrum contains only the first 1s→2p core resonance, the other core single-excited resonances (1s→3p, 1s→4p, etc...) having dissolved into the continuum beyond the 1s ionization edge, due to the exponentially decaying exchange-correlation LDA potential.

The TDHF photoionization spectrum starts at a slightly too low ionization threshold (again the same value as the opposite of the HF orbital 2s energy) and the cross section is very small but not zero (about 0.07 Mb) at the threshold (not shown). The TDHF 1s ionization edge occurs at a too high energy, again the same value as the opposite of HF 1s orbital which means that the HF kernel does not affect this value. In contrast to TDLDA, the TDHF photoionization spectrum not only contains the 1s→2p core resonance but also a series of single-excited core resonances to Rydberg states (1s→3p, 1s→4p, etc...) converging toward the 1s ionization edge. We note that our TDHF photoionization spectrum is in good agreement with previous non-relativistic and relativistic TDHF calculations (note that linear-response TDHF is also called random-phase approximation with exchange).

The TDRSH and TDLRSH photoionization spectra (using the optimal adimensional range-separation parameters determined in Section IIIA) display roughly the same features. They both start at a slightly too low ionization threshold. In both cases, the 1s ionization edge is positioned at the exact value, as expected since it corresponds to the opposite of the 1s orbital energy which has been adjusted at the exact value by tuning the adimensional range-separation parameter. Similar to TDHF, both the TDRSH and TDLRSH photoionization spectra display a series of core resonances, the TDLRSH resonances being systematically at higher energies than the TDRSH resonances. In comparison to TDRSH, TDLRSH gives smaller cross sections in the 2s continuum region (near...
TABLE I. Resonance energy $E_R$, width $\Gamma$, Fano asymmetric parameter $q$, total background cross section $\sigma_0$, background ratio parameter $\rho^2$, background linear drift $a$, and maximum value of the cross section at the resonance energy $\sigma(E_R)$ for the 1s→2p and 1s→3p core resonances of the Be atom calculated by TDLDA, TDHF, TDRSH, and TDLRSH (using the optimal adimensional range-separation parameters determined in Section III A) i.e. $\tilde{\mu}_{\text{TDRSH}} = 1.608$ for TDRSH and $\tilde{\mu}_{\text{TDLRSH}} = 0.478$ for TDLRSH. In some cases, the background linear drift $a$ was fixed to exactly zero in order to obtain convergence. As references, we also report experimental values and accurate results from R-matrix$^a$, SPCR$^b$, and CMRCI$^c$ calculations.

20 eV) and larger cross sections in the 1s continuum region (above the 1s ionization edge).

C. Core resonances

The core resonances (1s→2p, 1s→3p, etc...) are sharp Feshbach resonances, which can be understood as bound states embedded in a continuum turned into quasi-bound states with finite lifetimes due to electron-electron interactions. Figure 3 shows the first 1s→2p resonance obtained with TDLDA, TDHF, TDRSH, and TDLRSH. In all cases, the cross section follows a characteristic asymmetric Fano line-shape which can be fitted to the analytical expression\(^a\)

$$\sigma = \sigma_0 (1 + a \epsilon) \left[ \rho^2 (q + \epsilon)^2 + \frac{1}{1 + \epsilon^2} \right]^{-1},$$

(42)

where

$$\epsilon = \frac{\omega - E_R}{\Gamma^{1/2}}.$$  

(43)

Here, $E_R$ is the resonance energy, $\Gamma$ is the resonance width (or inverse lifetime), $q$ is the asymmetry Fano parameter, $\sigma_0$ is the total background cross section, $a$ is a coefficient for the total background linear drift, and $\rho^2$ is the ratio between the background cross section for transitions to continuum states that
interact with the discrete resonant state and the total background cross section. The fitted parameters for the 1s→2p and 1s→3p resonances are given in Table I. For the fitting procedure, the cross section at the resonance energy \( \sigma(E_R) \) was included in the data as the asymmetry parameter \( q \) is very sensitive to the value of the cross section at the peak. Furthermore, we have verified that, for each resonance, the complex energy \( \omega_R = E_R - i\frac{\Gamma}{2} \) is a solution of the non-Hermitian linear-response equation \( \text{Eq. (28)} \) without external perturbation

\[
\begin{pmatrix}
\Lambda(\omega_R) & B \\
B^* & \Lambda(-\omega_R)
\end{pmatrix}
\begin{pmatrix}
c_R^{(+)}

c_R^{(-)}
\end{pmatrix}
=
\begin{pmatrix}
0 \\
0
\end{pmatrix},
\]

with the \( \omega_R \)-dependent kinetic integrals in Eq. (41) which impose the boundary condition in Eq. (A9). For complex \( \omega_R \) with \( \text{Im}[\omega_R] < 0 \), this is indeed a Siegert-type boundary condition selecting resonant states that exponentially diverge at infinite distance (see, e.g., Refs. 78 and 79).

As references, we have included in Table I the experimental resonance energies, as well as accurate results obtained with the R-matrix method, the saddle-point complex-rotation (SPCR) method, and the complex-scaled multireference configuration-interaction (CMRCI) method. These three theoretical methods are all essentially configuration-interaction-type approaches including many electronic configurations and where the description of continuum states is done by using proper boundary conditions in the R-matrix method, or bypassed using complex scaling in the SPCR and CMRCI methods. In addition, we note that reference 1s→2p and 1s→3p resonance cross-section profiles obtained with the SPCR method can be found in Fig. 2 of Ref. 75.

The TDLDA 1s→2p resonance occurs at a much too low energy (by 12.5 eV), stemming from the fact that the LDA 1s orbital energy is at a too high energy, as discussed in Sec. IIA. The TDHF 1s→2p and 1s→3p resonances occur at too high energies (by 2.8 eV and 5.0 eV), which is consistent with the fact that the HF 1s orbital energy is at a too low energy. The positions of the TDHF resonances (118.3 and 126.4 eV) turn out to be in almost perfect agreement with the values obtained by TDHF calculations using a fairly small Slater basis set, showing that the determination of only the positions of these resonances does not in fact require a large basis set capable of describing continuum states. For comparison, we point out that linear-response time-dependent exact exchange (TDEXX) gives much too low 1s→2p and 1s→3p resonance positions, estimated at about 109 and 111 eV, respectively (see also Ref. I1 for EXX results). Both TDRSH and TDLRSH give more accurate 1s→2p and 1s→3p resonance positions than TDALDA and TDHF, slightly underestimated by 2.2 eV and 0.1 eV for TDRSH and by 0.7 eV and 0.03 eV for TDLRSH.

The resonance widths \( \Gamma \) and Fano asymmetric parameters \( q \), which determined the shape of the resonances, are very sensitive to the method employed. All the present TDDFT/TDHF-type methods give much too small resonance widths \( \Gamma \), by about one to three orders of magnitude. This must be due to the neglect of double electronic excitations. Indeed, it is known that the 1s→np resonance (for \( n = 2, 3 \)) in the Be atom predominantly decays through the Auger process 1s2s2p 3P → 1s2np + e, the last configuration corresponding to a double excitation with respect to the ground-state configuration 1s2 2s2. Thus, we cannot expect the present methods to give physical resonance widths for the Be atom. Among the present methods, TDLDA gives a 1s→2p resonance with the largest width \( \Gamma \) and a positive Fano parameter \( q \). We note that a similar resonance shape is also obtained when employing more accurate asymptotically corrected exchange-correlation potentials or the EXX potential and its adiabatic kernel. TDHF gives a sharper 1s→2p resonance with a width \( \Gamma \) an order of magnitude smaller and a large negative Fano parameter \( q \). The TDHF 1s→3p resonance is even sharper. We note that the shape of the TDHF resonances that we obtain are in agreement with previous relativistic TDHF calculation. TDRSH gives quite sharp resonances with large positive Fano parameters \( q \). TDLRSH gives even sharper resonances with large negative Fano parameters \( q \).

Finally, Figure 4 shows how the resonance energy \( E_R \), width \( \Gamma \), and Fano asymmetry parameter \( q \) of the 1s→2p resonance calculated by TDRSH and TDLRSH vary with the adimensional range-separation parameter \( \mu \), going from the TDLDA limit (\( \mu = 0 \)) to the TDHF limit (\( \mu \to \infty \)). For both TDRSH and TDLRSH the resonance energy increases with \( \mu \), until it saturates at the TDHF value. For both TDRSH and TDLRSH, the resonance width does not vary monotonically with \( \mu \). In particular, there is a value of \( \mu \) (around \( \mu \approx 2.5 \) and 0.2 for TDRSH and TDLRSH, respectively) for which the resonance width vanishes. Within the Fano model analysis, it means that the coupling between the discrete state corresponding to the resonance and the continuum states vanishes. In this case, the resonance state becomes a truly bound state (with infinite lifetime) embedded in the continuum. At the same critical value of \( \mu \), the Fano parameter \( q \) jumps from a large positive value to a large negative value. Again, within the Fano model analysis, this may be interpreted as a change of sign of the coupling between the discrete state and the continuum states.

IV. CONCLUSION

In this work, we have continued the systematic exploration of linear-response range-separated TDDFT for the calculation of photoionization spectra. We have considered two variants of range-separated TDDFT, namely TDRSH which uses a global range-separation parameter and TDLRSH which uses a local range-separation parameter, and compared with standard TDLDA and TDHF. We have shown how to calculate photoionization spectra with these methods using the Sternheimer approach formulated in a non-orthogonal B-spline basis set and using appropriate boundary conditions. We have illustrated these methods on the photoionization spectrum of the Be atom, focusing in particular on the core resonances.

When the adimensional range-separation parameter is adjusted on the 1s ionization edge, both the TDRSH and TDLRSH photoionization spectra constitute a large im-
evement over the TDLDA photoionization spectrum and a more modest improvement over the TDHF photoionization spectrum. In particular, TDRSH and TDLRSH improve the accuracy of core resonance energies, with a slightly greater accuracy in favor of TDLRSH. Neither TDRSH nor TDLRSH compete in terms of accuracy with sophisticated configuration-interaction-type approaches such as the R-matrix, SPCR, or CMRCI methods, in particular for calculating resonance widths. However, TDRSH and TDLRSH have the advantage of being much simpler methods that can potentially be applied to large molecular systems.

In future works, the TDRSH and TDLRSH methods, as well as possibly other range-separated TDDFT variants, could be improved by adding the effect of the double excitations through a frequency-dependent long-range correlation kernel. Also, the Sternheimer formulation of these methods should be extended to open-shell atomic systems, and, in a second step, to arbitrary molecular systems. This last goal requires to implement general nonlocal Robin boundary conditions. Finally, in order to calculate nonlinear optical properties, a time-propagation version of the present approach could be designed by generalizing the boundary conditions to the time domain.

Appendix A: Boundary conditions for atoms

In this Appendix, we explain how we impose appropriate boundary conditions at \( r = r_{\text{max}} \) for atoms.

We first need to study the large-\( r \) asymptotic behaviors of the radial solutions \( R_{l,f}^{(\pm)} [\text{Eq. (A8)}] \) of the Sternheimer equations. For sufficiently large \( r \), \( R_{l,f}^{(\pm)} \) behaves as

\[
R_{l,f}^{(\pm)}(r, \omega) \sim R_{l,f}^{(\pm)}(r, \omega),
\]

where \( R_{l,f}^{(\pm)} \) are radial asymptotic solutions of the Sternheimer equations [Eq. (20)] which satisfy hydrogen-like Schrödinger equations

\[
\left( -\frac{1}{2} \frac{d^2}{dr^2} + \frac{\ell (\ell + 1) - Z_{\text{eff}}}{r} \right) R_{l,f}^{(\pm)}(r, \omega) = (\epsilon_i \pm \omega + i\eta) R_{l,f}^{(\pm)}(r, \omega),
\]

with effective charge \( Z_{\text{eff}} = Z - N + \zeta \). In the expression of \( Z_{\text{eff}} \), the nucleus charge \( Z \) and the electron number \( N \) come from the nucleus-electron potential \( v_{\text{ne}} \) and the Hartree potential \( v_{\text{H}} \), respectively, in the RSH Hamiltonian \( \hat{H}[\gamma_0] \). The contribution \( \zeta \) comes from the long-range HF exchange kernel \( f_{\text{ex}}^{\text{HF}} \) and we have \( \zeta = 1 \) for a non-zero range-separation parameter, i.e., \( \mu \neq 0 \) for the RSH/LRSH scheme. In the LDA limit (\( \mu = 0 \)), we have \( \zeta = 0 \). The general solution of Eq. (A2) may be written as, for \( \omega \geq 0 \),

\[
R_{l,f}^{(\pm)}(r, \omega) = c_1 f_{l,f}(r, \pm \omega) + c_2 g_{l,f}(r, \pm \omega),
\]

where \( c_1 \) and \( c_2 \) are two arbitrary complex-valued coefficients, and the functions \( f_{l,f} \) and \( g_{l,f} \) are defined as, for a general frequency variable \( z \in \mathbb{C} \),

\[
f_{l,f}(r, z) = F_l(-Z_{\text{eff}}/k_i(z), k_i(z)r),
\]

\[
g_{l,f}(r, z) = G_l(-Z_{\text{eff}}/k_i(z), k_i(z)r),
\]

where \( F_l \) and \( G_l \) are the regular and irregular Coulomb functions, and \( k_i(z) = \sqrt{2(\epsilon_i + z + i\eta)} \) is the complex-valued momentum. The asymptotic behavior of the Coulomb functions are

\[
f_{l,f}(r, z) \sim \sin \theta_{l,f}(r, z), \quad r \to \infty
\]

\[
g_{l,f}(r, z) \sim \cos \theta_{l,f}(r, z), \quad r \to \infty
\]

with

\[
\theta_{l,f}(r, z) = k_i(z)r + \frac{Z_{\text{eff}}}{k_i(z)} \ln(2k_i(z)r) - \frac{\ell}{2} \pi + \sigma_{l,f}(z),
\]

and \( \sigma_{l,f}(z) = \arg \Gamma(\ell + 1 - iZ_{\text{eff}}/k_i(z)) \). As \( r \to \infty \), \( \theta_{l,f}(r, \pm \omega) \sim k_i(\pm \omega)r \) and due to the fact that \( \text{Im}[k_i(\pm \omega)] > 0 \) (for \( \eta > 0 \)), we see that the general solution \( R_{l,f}^{(\pm)} \) in Eq. (A3) \( R_{l,f}^{(\pm)} \) does not diverge as \( r \to \infty \) only for the coefficient ratio \( c_1/c_2 = 1 \), so we have

\[
R_{l,f}^{(\pm)}(r, \omega) = c_2 [i f_{l,f}(r, \pm \omega) + g_{l,f}(r, \pm \omega)],
\]

and then \( R_{l,f}^{(\pm)}(r, \omega) \sim c_2 \exp(i \theta_{l,f}(r, \pm \omega)) \).

We can thus impose a Robin boundary condition for the radial part \( R_{l,f}^{(\pm)} \) of the solutions of the Sternheimer equations [Eq. (20)] at \( r = r_{\text{max}} \) of the form

\[
\frac{d \ln \tilde{R}_{l,f}^{(\pm)}(r, \omega)}{dr} \bigg|_{r=r_{\text{max}}} = b_{l,f}(\pm \omega),
\]

with \( b_{l,f}(\pm \omega) = d \ln \tilde{R}_{l,f}^{(\pm)}(r, \omega)/dr \bigg|_{r=r_{\text{max}}} \). Even though this expression of \( b_{l,f}(\pm \omega) \) works for both \( R_{l,f}^{(+)} \) and \( R_{l,f}^{(-)} \) and for any \( \omega \), it is insightful to further look at the physical content of
the asymptotic behavior of $R_{i,f}^{(+)}$ and $R_{i,f}^{(-)}$, separately, in the limit $\eta \to 0^+$. As regards $R_{i,f}^{(+)}$, for $\omega \geq -\varepsilon_i$, we have $k_i(\omega) = \text{Re}[k_i(\omega)] = \sqrt{2(\varepsilon_i + \omega)}$, and the asymptotic solution $R_{i,f}^{(+)}$ is an outgoing spherical wave. In this case, the explicit expression of $b_{i,f}(\omega)$ that we use is

$$b_{i,f}(\omega) = \left. \frac{i df_{i,f}(r,\omega)/dr + dg_{i,f}(r,\omega)/dr}{if_{i,f}(r,\omega) + g_{i,f}(r,\omega)} \right|_{r=r_{\text{max}}},$$

if $\omega \geq -\varepsilon_i$. \hspace{1cm} (A11)

For $\omega < -\varepsilon_i$, we have $k_i(\omega) = i \Im[k_i(\omega)] = i \sqrt{2(\varepsilon_i - \omega)}$, and the asymptotic solution $R_{i,f}^{(-)}$ decays exponentially. Instead of using Eq. (A11), we can more simply use

$$b_{i,f}(\omega) = 0, \text{ if } \omega < -\varepsilon_i,$$

which corresponds to imposing Neumann boundary condition at $r = r_{\text{max}}$. Similarly, for $R_{i,f}^{(-)}$, since we always have $\varepsilon_i - \omega < 0$ (because $\varepsilon_i < 0$ for occupied orbitals), we have $k_i(-\omega) = i \Im[k_i(-\omega)] = i \sqrt{2(\varepsilon_i - \omega)}$, thus the asymptotic solution $R_{i,f}^{(-)}$ decays exponentially, and we can use again

$$b_{i,f}(-\omega) = 0.$$ \hspace{1cm} (A13)

For a neutral system such as like the Be atom, we have $Z_{\text{eff}} = 1$ for the TDHF method and using the exact Coulomb-wave (ECW) boundary condition in Eq. (A9) for $\omega \geq -\varepsilon_i$ proves crucial to obtain converged results with a modest maximal radius $r_{\text{max}}$. To show this, we compare in Figure 5 two alternative types of boundary conditions for the same maximal radius of $r_{\text{max}} = 25 \text{ bohr}$. First, we can keep the correct long-range behavior but make the asymptotic approximation in Eqs. (A6)-(A8), valid for $k_i(\omega)r \gg 1$, resulting in the approximate Coulomb-wave (ACW) boundary condition

$$R_{i,\text{ACW}}^{(+)}(r,\omega) = c_2 \exp \left[ i \left( k_i(\omega)r + \frac{Z_{\text{eff}}}{k_i(\omega)} \ln(2k_i(\omega)r) \right) \right].$$ \hspace{1cm} (A14)

At the scale of the plot, the part of the spectrum corresponding to the 2s ionization is barely affected, but this creates oscillations beyond the 1s ionization edge. A more drastic approximation is to further ignore the Coulomb potential, i.e., setting $Z_{\text{eff}} = 0$. In this case, we get the plane-wave (PW) boundary condition

$$R_{i,\text{PW}}^{(+)}(r,\omega) = c_2 \exp(i k_i(\omega)r).$$ \hspace{1cm} (A15)

This creates strong and rapid oscillations near both ionization thresholds. However, far from the ionization thresholds, the effect is less pronounced. In particular, the 1s $\rightarrow$ 2p resonance is still well reproduced. This is because this resonance results from the interaction of a bound state with continuum states at a relatively large energy, which behave almost like plane waves. This can be understood from Eq. (A8), which implies that the plane-wave approximation is reasonable when

$$k_i(\omega)^2 r_{\text{max}} \gg Z_{\text{eff}} \ln(2 k_i(\omega) r_{\text{max}}),$$ \hspace{1cm} (A16)

i.e. when the wavelength of the outgoing wave is small compared to $\sqrt{r_{\text{max}}/Z_{\text{eff}}}$. In both cases, these oscillations can be reduced by either increasing the computational box size $r_{\text{max}}$ or by using a non-zero broadening factor $\eta$. The former increases the computational effort while the latter may lead to a loss of features in the spectrum. The use of the exact Coulomb-wave boundary condition removes these oscillations without the need of increasing $r_{\text{max}}$ or using a non-zero $\eta$.

In the case of TDLD, we use the boundary condition in Eq. (A9) with $Z_{\text{eff}} = 0$, giving a free spherical outgoing wave (the Coulomb functions reduce to the Riccati-Bessel functions). This is a better boundary condition than using the plane-wave approximation in Eq. (A15), the latter giving slight oscillations for TDLD.

Finally, we use the boundary condition in Eq. (A9) with $Z_{\text{eff}} = \text{erf}(\mu r_{\text{max}})$ for TDRSH and with $Z_{\text{eff}} = \text{erf}(\mu(r_{\text{max}})r_{\text{max}})$ for TDLRSH, which goes smoothly from $Z_{\text{eff}} = 0$ for $\mu \ll 1/r_{\text{max}}$ or $\mu(r_{\text{max}}) \ll 1/r_{\text{max}}$ to $Z_{\text{eff}} = 1$ for $\mu \gg 1/r_{\text{max}}$ or $\mu(r_{\text{max}}) \gg 1/r_{\text{max}}$.

Appendix B: Comparison with the Casida approach with zero boundary condition

In this Appendix, we compare the present Sternheimer method with appropriate boundary condition with the straightforward Casida method using zero boundary condition used in Ref. [29].

In the Casida method of Ref. [29] one diagonalizes the linear-response equations in the orthogonal occupied/virtual orbital basis using a zero boundary condition at $r = r_{\text{max}}$. One obtains a discrete set of excitation energies $\omega_n$ and oscillator strengths $f_n$. The photoionization spectrum is then approximated as a set of cross sections at frequencies $\omega_n \geq 1$P

$$\sigma_n = \frac{2\pi^2}{c} f_n,$$ \hspace{1cm} (B1)

where the renormalized oscillator strengths $\tilde{f}_n = \rho_{\text{DOS}}(\omega_n) f_n$ takes into account the density of states ($\rho_{\text{DOS}}(\omega_n)$) at the
excitation energy $\omega_n$, which is estimated by finite differences as $\rho_{\text{DOS}}(\omega_n) = \frac{1}{2}(\omega_{n+1} - \omega_{n-1})$.

Figure 6 reports the TDHF photoionization cross section for the He and Be atoms calculated with the present Sternheimer method with the exact Coulomb-wave boundary condition and calculated with the Casida method with zero boundary condition. In all cases, we use the same computational parameters: $M_e = 50$ B-spline basis functions and a maximal radius of $r_{\text{max}} = 25$ bohr. For the He atom, we see that the Casida method works correctly. For the Be atom, however, beyond the 1s ionization threshold, the cross-section contains contributions from two channels (1s and 2s); as a result the cross-section contains contributions from two channels (1s and 2s); as a result the excitation energies $\omega_n$ are irregularly spaced (being the superposition of two regularly spaced sets of energies), and the two distinct densities of states cannot be approximated by finite differences. The renormalization scheme is also unable to account for resonances, which originate from a hybridization of bound and continuum states. This clearly demonstrates the superior efficacy of the present Sternheimer method with appropriate boundary condition, which reproduces all these features.
