Actomyosin based contraction: one mechanokinetic model from single molecules to muscle?

Alf Månsson

Abstract Bridging the gaps between experimental systems on different hierarchical scales is needed to overcome remaining challenges in the understanding of muscle contraction. Here, a mathematical model with well-characterized structural and biochemical actomyosin states is developed to that end. We hypothesize that this model accounts for generation of force and motion from single motor molecules to the large ensembles of muscle. In partial support of this idea, a wide range of contractile phenomena are reproduced without the need to invoke cooperative interactions or ad hoc states/ transitions. However, remaining limitations exist, associated with ambiguities in available data for model definition e.g.: (1) the affinity of weakly bound cross-bridges, (2) the characteristics of the cross-bridge elasticity and (3) the exact mechanistic relationship between the force-generating transition and phosphate release in the actomyosin ATPase. Further, the simulated number of attached myosin heads in the in vitro motility assay differs several-fold from duty ratios, (fraction of strongly attached ATPase cycle times) derived in standard analysis. After addressing the mentioned issues the model should be useful in fundamental studies, for engineering of myosin motors as well as for studies of muscle disease and drug development.

Keywords Striated muscle · Single molecules · In vitro motility assay · Myosin · Actin · Monte-Carlo simulation

Introduction

It is well-known that contraction of striated muscle (skeletal muscle and heart) results from interactions, driven by ATP-turnover, between myosin and actin (Månsson et al. 2015). The arrangement of these proteins in large ordered ensembles, sarcomeres, in striated muscle ensures highly optimized function as indicated by convergent evolution in organisms as distant as cnidarians (e.g. jelly-fish) and mammals (Steinmetz et al. 2012). Despite intense studies, the basis for the high level of perfection of the ordered system remains poorly understood (Batters et al. 2014; Månsson et al. 2015). This fact is not only of fundamental importance. Increased insight in this regard would also benefit the understanding and treatment of diseases, e.g. cardiomyopathies (Ferrantini et al. 2009; Frey et al. 2012; Green et al. 2016; Marston 2011; Spudich 2014; Teekakirikul et al. 2012), a leading cause of sudden death in young people, and heart failure, a leading cause of hospitalization and mortality where myosin-active drugs may be useful (Malik et al. 2011; Teerlink et al. 2011). One reason for remaining knowledge gaps is the difficulty to integrate experimental results as well as key concepts, from studies using different techniques and hierarchical scales ranging from single molecules over small ensembles to muscle (Baker et al. 2002; Månsson et al. 2015; Walcott et al. 2012). One tool that would be valuable in this regard is a mathematical model that bridges the gap while being both simple enough to effectively aid data interpretation and sufficiently detailed to incorporate biochemical actomyosin states that are critical for function.
The in vitro motility assay (Kron and Spudich 1986) is a powerful small ensemble assay that is increasingly used for studies of muscle disorders with potential usefulness in drug development (Aksel et al. 2015; Kohler et al. 2003; Li and Larsson 2010; Sommese et al. 2013; Song et al. 2011). Generally, fluorescence-labeled actin filaments are propelled by surface adsorbed myosin molecules or myosin motor fragments obtained by mild proteolysis or expression in cell systems (Kron et al. 1991). The assay may be combined with genetic engineering (Kubalek et al. 1992; Schindler et al. 2014; Sommese et al. 2013; Tsiavaliaris et al. 2004) and has been adapted for single molecule studies e.g. using optical tweezers (Finer et al. 1994), nm tracking techniques (Wang et al. 2013) or cantilever systems (Ishijima et al. 1996; Kalganov et al. 2013) to measure pN–nN forces and nm displacements.

Mathematical models that cover the scale from single molecules to large ensembles are required to relate results of the in vitro assays to molecular properties on the one hand and muscle contractile function in health and disease on the other. Currently, however, key data obtained from small ensembles and the large ensembles of muscle are generally interpreted using different theoretical frameworks. For instance, elasticity is central in muscle function and, therefore, also in classical models (Hill 1974; Huxley 1957; Huxley and Simmons 1971) of muscle contraction where changes in state of one head or a group of heads are assumed to influence the strain, and thereby strain-dependent kinetics, of other heads. In contrast, certain in vitro motility assay data are interpreted using models (Uyeda et al. 1990; Wang et al. 2013) without such elastic coupling between motors. Furthermore, the precise geometrical arrangement of the myofilament lattice in muscle is absent in the different versions of the in vitro motility assay. On the other hand, this arrangement is implicit in most models of muscle contraction (Eisenberg and Hill 1978; Huxley 1957; Månsson 2010) since the ensemble-averaged forces, turnover rates etc. that are considered in these models rely on the actin-myosin organization of the muscle sarcomere.

Efforts have been made to include elastic coupling between cross bridges in models for actomyosin behavior in the in vitro motility assay (Baker et al. 2002; Erdmann and Schwarz 2012; Hilbert et al. 2013; Ishigure and Nitta 2015; Pate and Cooke 1991; Walcott et al. 2012). Studies have also addressed the role of the hierarchical organization using spatially explicit models of large ensembles of actin and myosin (Campbell 2009; Tanner et al. 2007) with aims to elucidate the roles of the geometrical arrangement in specific situations. However, these models (Baker et al. 2002; Campbell 2009; Erdmann and Schwarz 2012; Hilbert et al. 2013; Ishigure and Nitta 2015; Pate and Cooke 1991; Tanner et al. 2007; Walcott et al. 2012) have used simplified representations of the actin-myosin ATP turnover mechanism. For instance, like several previous large-ensemble muscle models (e.g. (Duke 1999; Eisenberg et al. 1980; Månsson 2010; Pate and Cooke 1989; Persson et al. 2013), the weakly bound actomyosin state has not been explicitly included. Neither has the phosphate release step been separated from the main force-generating event (“the power-stroke”). Further, the full scale from single molecules to the large ensembles of muscle has not been considered. All this makes it difficult to use the models for elucidating e.g. disease mechanisms (see above) or drug effects that involve stabilization of a specific biochemical state suggested by solution kinetics studies.

With the aim to overcome current limitations, we here investigate to what extent a statistical actomyosin cross-bridge model of classical type (Hill 1974; Huxley 1957) with detailed biochemical cycle but without explicit geometrical details can account for contractile behavior from single molecules to large ensembles of muscle. Due to the ample evidence for cooperativity or emergent phenomena during active lengthening and under conditions of varied activation (Brunello et al. 2007; Edman and Flitney 1982; Gordon et al. 2000; Linari et al. 2015; McKillop and Geeves 1993; Rassier 2012b) the studies focus on cases of full activation and isometric contraction or shortening contraction. However, it is briefly considered how activation mechanisms may be introduced as well as certain mechanisms that are specific to lengthening contractions. The model is defined on basis of kinetic parameter values from the literature obtained under as coherent conditions as possible (with regard to temperature, ionic strength, muscle type etc.).

As a basis for the investigations, it is hypothesized that such a coherently defined actomyosin model accounts for generation of force and motion from single molecules to the ordered arrays in muscle without the need to invoke emergent phenomena and/or consider structural details. This hypothesis was largely supported as it was found that the model, surprisingly well, approximates key contractile phenomena on different scales. However, there were remaining limitations in details of model performance. These limitations provide mechanistic insights as discussed in detail below. They also suggest improvements in the details of the model as well as new experimental studies. After such further developments the model should be useful in studies of muscle diseases and in guiding associated drug development. We also consider possible usefulness in guiding engineering of myosin motors (Amrute-Nayak et al. 2010; Nakamura et al. 2014; Schindler et al. 2014; Tsiavaliaris et al. 2004) e.g. for optimized use in nanotechnological applications (Kumar et al. 2016; Månsson 2012; Nicolau et al. 2016).
Materials and Methods

For large ensembles of myosin motors, the model was implemented by solving differential equations in state probabilities using Simnon software (version 1.3; SSPA, Gothenburg, Sweden). For small ensembles and single molecules, the model was implemented using a Monte-Carlo approach (Gillespie 1976). Simulation details are given in the Supporting Information.

In vitro motility assay velocities \( v_f \) as function of the number \( N \) of available myosin head were fitted to the equation (Uyeda et al. 1990):

\[
v_f = \nu^\infty (1 - (1 - f)^N) = \nu^\infty (1 - (1 - f)^{ndl})
\]

Here, \( \nu^\infty \) is the sliding velocity for infinitely long filaments, \( f \) is a myosin duty ratio (fraction of ATP-turnover time spent in strongly bound states). The quantity \( N = \rho dl \), where \( l \) is filament length, \( \rho \) is the surface density of active myosin heads and \( d \) is the width of band around the actin filament where myosin heads reach their attachment sites on the filament. Previously we found, using trimethyl chlorosilane-coated surfaces, that \( \rho \approx 5000 \mu m^{-2} \) and \( d \approx 30 \) nm. Equations were fitted to simulated data using non-linear regression (Marquardt-Levenberg algorithm; GraphPad Prism v. 6.05).

Theory

The model is based on the kinetic scheme in Fig. 1a with abbreviations of different states explained in the legend. The total amplitude of the force-generating power-stroke (“step-length”; from state AM*DL to states AMD and AM) was taken as 7.7 nm, slightly modified from the value of 7.35 nm in a recent model for large ensembles (Persson et al. 2013).The value of 7.7 nm is consistent with an 8 nm step of 6.7 nm. These step-lengths are directly reflected in the diagrams in Fig. 1b that illustrate the free energy of different states as function of the variable \( x \). This variable represents the distance between a reference point on the myosin molecule and the nearest actin filament site, with \( x = 0 \) nm when force in the AMD/AM state is zero. The free energies of two different generic states, i and j, are related to the equilibrium constant \( K_{ij}(x) \) and forward and backward rate constants \( k_{ij}(x) \) and \( k_{ji}(x) \) as follows:

\[
K_{ij}(x) = k_{ij}(x)/k_{ji}(x) = \exp\left((G_i(x) - G_j(x))/k_B T\right)
\]

All rate functions used are defined in detail the Supplementary Theory and related parameter values are given in Supplementary Tables S1 and S2. We did not explicitly include an intermediate AM*DP-state (Dantzig et al. 1992) (between the AMDP and the AM*DL states) in the free energy diagrams in Fig. 1b. However, such a state is implicit in the strain-dependence of the rate constant for the weak-to-strong (AMDP to AM*DL) transition (Supplementary Eq. S2) and the reversal of this transition (Supplementary Eqs. S3 and S4). The strain-dependence of free energy of the implicit AM*DP state is assumed to be identical to that for the AM*DL state (Fig. 1b), but displaced upwards by a quantity \( k_B T \ln(C_C/P_{i}) \).

The MgATP-induced detachment \( k_2(x) \) was generally taken as strain-dependent, an issue that is discussed below (see also Supplementary Theory).

The effect of including a fraction of non-cycling “dead” myosin heads (e.g. treated with N-ethyl maleimide; NEM) in the in vitro motility assay (e.g. Aksel et al. 2015; Bing et al. 2000) was simulated by introducing two additional states in the model, one attached to actin (AM\( ^D \), “D” for “dead”) and one detached (MD). The detachment kinetics was taken from optical tweezer results for HMM-actin in rigor (Nishizaka et al. 2000). The MD and AM\( ^P \) states were assumed to have free-energy diagrams similar to that of the MT (not varying with \( x \)) and AM state, respectively with a difference of 18 \( k_B T \) (unless otherwise stated) between the free energy minima of the states. The kinetic scheme governing the transitions between the AM\( ^P \) and MD states was assumed separated from the scheme in Fig. 1a. That is, the only allowed transitions for non-cycling heads were between the MD and AM\( ^P \) states. For further details, see Supplementary Methods.

The present model assumes maximum \( Ca^{2+} \) activation as defined in detail in the Supplementary Theory. It is also assumed (Fig. 1c) that a maximum of one site on the actin filament is within reach of any myosin cross-bridge and that the thin/actin and thick/myosin filaments are infinitely stiff. Furthermore, only one of the two globular units (heads) of each myosin molecule is assumed to bind simultaneously to actin. The neighboring sites on the actin filament are generally assumed to be separated by 36 nm but in some control simulations, we consider the effects of assuming three independent sites per 36 nm.

All strongly bound myosin heads are assumed to have a stiffness of 2.8 pN/nm whereas the stiffness of weakly bound myosin heads is taken as 0.02 pN/nm. This is consistent with the weak non-specific attachment and appreciable rotational freedom of the latter type of heads. In most cases, we assume similar stiffness for positive and negative \( x \) but we also consider non-linear elasticity of strongly bound heads with cross-bridge stiffness, 0.25 pN/nm for \( x < 0 \) nm (see Supplementary Theory).

The model is defined on basis of kinetic parameter values from the literature, obtained under as coherent conditions as possible (with regard to temperature.
In the case of deviations from the pre-selected conditions we either make corrections, when possible, or discuss the consequences of the deviations (Supplementary Tables S1 and S2 and Supplementary Theory).

Results

Simulation of muscle contractile properties gave similar results whether using numerical solution of differential equations or Monte-Carlo simulations (Supplementary Fig. S1). This suggests that the two approaches can be used interchangeably for large ensembles. Unless otherwise stated, the parameter values in Supplementary Tables S1 and S2 were used and [MgATP] = 5 mM. The value used for $k_5$ (Fig. 1a) required particular considerations as discussed below and in Supporting Theory.

Using standard parameter values, the kinetic scheme in Fig. 1a predicts that $V_{max} \approx 89 \text{ s}^{-1}$ for actomyosin ATPase in solution at saturating [actin] (temperature correction from (Brenner and Eisenberg 1986) assuming $Q_{10} = 2.7$). With an effective actin concentration of 1–3 mM (Brenner et al. 1986), a binding constant $K_w = 1$ corresponds to a binding constant $K_a$ in solution in the range $0.4–1.2 \times 10^3 \text{ M}^{-1}$ and $K_M$ in the range
0.4–1.2 mM for the actomyosin ATPase (actin concentration for half-maximum ATPase) (Supplementary Eq. S15). This is similar to experimental results (Woldege et al. 1985). On the other hand, if K_w is an order of magnitude higher (e.g. K_w = 12), then K_a would be overestimated in the model, being in the range 4–12 × 10^3 M^-1 with K_M ≈ 0.04–0.12 mM. However, as pointed out below, if we assume K_w = 12, this gives better fit of the model to the force–velocity relationship and other mechanics data. Whereas K_w = 12 leads to overestimation of K_a if the effective actin concentration is 1–3 mM it is important to note that there is some uncertainty in the latter value (see “Discussion” section).

The model predicts two length steps in single molecule recordings (Fig. 2; cf. Capitanio et al. 2006) with average amplitudes of 6.55 ± 3.33 nm (standard deviation; n = 994) and 1 nm, respectively. Here, the first step varies in amplitude due to a spectrum of x-positions for initial cross-bridge attachment. The results are consistent with total amplitude of ~8 nm at low optical trap stiffness (Kaya and Higuchi 2010). In terms of the model, the 6.6 nm step directly corresponds to the difference in x-position of the free-energy minima for the AM^\ast D_L and the AM^\ast D_H states (Fig. 1b) whereas the 1 nm step corresponds to the x-difference between the minimum free energy of the AM^\ast D_H and the AMD/AM states. This clearly illustrates the correspondence between single molecule length-step data and free-energy diagrams of the Hill type (Hill 1974).

The two length-steps separate the tension response into two phases (Fig. 2a). The duration of the first phase (t1) is independent of [MgATP] whereas the second phase exhibits [MgATP]-dependent duration (t2; Fig. 2b) with rate constant proportional to [MgATP] at low [MgATP] (Fig. 2c; cf. Capitanio et al. 2006).

The load-dependence of the ATP induced detachment rates in single molecule recordings shows similarities to experiments (Capitanio et al. 2012; Sung et al. 2015) but differs in the quantitative details (Supplementary Figs. S2A and S2B). This may be partly attributed to different myosin preparations used in the experiments and assumed in the simulations (one-headed vs two-headed; see legend of Supplementary Fig. S2 and “Discussion” section). As in (Capitanio et al. 2012), a new detachment process became important in simulations with imposed resistive loads. However, this process, associated with Pi-binding in the model, was appreciably slower than in the experiments and was not analyzed in detail (see further “Discussion” section).

The model reproduces key aspects of experimental in vitro motility assay results. The general shape of the relationship between velocity and the number of available myosin heads (N; proportional to filament length) is reasonably well predicted. If K_w = 1, the relationship is best predicted for different [MgATP] if the number (n_s) of independent myosin-binding sites is close to 3 per 36 nm (Supplementary Fig. S3). If K_w is increased to 12, the experimental data are instead best predicted with only one myosin binding site per 36 nm (n_s = 1) (Fig. 3). In the following, K_w = 12 instead of K_w = 1 will be used as standard value (see further “Discussion” section) together with n_s = 1.

The predicted ATP turnover rate per head (19 s^-1) in the in vitro motility assay is similar to experimental results (13 s^-1 (Uyeda et al. 1990); see also Toyoshima et al. 1990) and constitutes a similar fraction of the actomyosin ATPase activity.
ATPase in solution (86 s\(^{-1}\) in experiments (Brenner and Eisenberg 1986); and 89 s\(^{-1}\) predicted here (see above).

In order to account for the high maximum velocity at high [MgATP] (Fig. 3) it was necessary to assume a strain-dependent MgATP-induced detachment rate (k\(_2(x)\)). However, the appreciable strain-dependence required is not consistent with experimental findings (Capitanio et al. 2012; Nyitrai et al. 2006) and also leads to too high velocity at low [MgATP]. We therefore attempted to reproduce the data at both low and high [MgATP] with limited strain-dependence of k\(_2(x)\) (cf. Fig. 4d in Capitanio et al. 2012). This was possible if it was also assumed that the cross-bridge elasticity is non-linear, with low stiffness of post-power-stroke cross-bridges (Kaya and Higuchi 2010). Such an idea was previously found to improve the fit to [MgATP]-velocity plots using a biochemically simpler, large-ensemble model (Persson et al. 2013). It can be seen (Fig. 3b; \(\eta = 1\)) that the effect of [MgATP] on maximum velocity is quite well accommodated without sacrificing faithful reproduction of the shape of the velocity–length relationships. This was achieved without other changes than reduced strain-dependence of k\(_2(x)\) and introduction of non-linear cross-bridge elasticity.

Velocity-length data like those in Fig. 3 are often analyzed by fitting the equation of Uyeda et al. (Uyeda et al. 1990) (Eq. 1; lines in Fig. 3) to obtain an estimate of the duty ratio. The latter parameter is the fraction of the ATP-turnover time that a given myosin head spends strongly attached to actin or, in other words, the fraction of strongly attached myosin heads at a given time. Fits of Eq. 1 (Uyeda et al. 1990) to the simulated velocity-length data in Fig. 3 gave duty ratios that correlated positively with the number of attached myosin heads in strongly bound states from simulations plotted against duty ratio from fit of Eq. 1 to the simulated data. The strongly bound heads in the simulations were either taken as all heads in the states AM\(^4\)D\(_N\), AM\(^2\)D\(_H\), AM, and AMT (squares) or only the heads in the states AM\(^4\)D\(_H\), AM, and AMT (circles). The cross-bridge elasticity was either assumed to be linear (filled symbols and full line) or non-linear (open symbols and dashed line). Horizontal error bars are the 95% CIs obtained in the non-linear regression fit of Eq. 1 with maximum velocity and duty ratio as varying parameters in the regression analysis. Dotted line has slope 1. Similar data as in A and C for \(K_w = 1\) are shown in Supplementary Fig. S3.

![Fig. 3 Velocity vs filament length in the in vitro motility assay.](image-url)

**Fig. 3** Velocity vs filament length in the in vitro motility assay. a Simulated velocity vs filament length (5000 active myosin heads per \(\mu\)m\(^2\)) for standard conditions assuming \(K_w = 12\) (open symbols, full lines) compared to experimental in vitro motility assay data (filled symbols; Persson et al. 2013). Simulated and experimental data at 1 mM (black), 0.1 mM (red) and 0.01 mM (blue) [MgATP]. Filled lines represent fits of Eq. 1 to the simulated data. Dashed lines represent fits of Eq. 1 to simulation results (not shown) where three independent myosin binding sites are assumed per 36 nm of the actin filament. b Simulation results and experimental results for similar conditions as in A (similar color and format coding of lines and symbols) but assuming non-linear cross-bridge elasticity (i.e. \(k_s = 2.8\) pN/nm for \(x > 0\) and \(k_s = 0.25\) pN/nm otherwise). c Fraction of attached myosin heads in strongly bound states from simulations plotted against duty ratio from fit of Eq. 1 to the simulated data. The strongly bound heads in the simulations were either taken as all heads in the states AM\(^4\)D\(_N\), AM\(^2\)D\(_H\), AM, and AMT (squares) or only the heads in the states AM\(^4\)D\(_H\), AM, and AMT (circles). The cross-bridge elasticity was either assumed to be linear (filled symbols and full line) or non-linear (open symbols and dashed line). Horizontal error bars are the 95% CIs obtained in the non-linear regression fit of Eq. 1 with maximum velocity and duty ratio as varying parameters in the regression analysis. Dotted line has slope 1. Similar data as in A and C for \(K_w = 1\) are shown in Supplementary Fig. S3.
That is, binding of myosin heads to actin, but also detachment and other transitions of attached myosin heads that change total motor force, influence the strain (and thereby strain-dependent kinetics) of other actin-attached myosin heads. This is implemented here by re-equilibrating forces following each state transition (see Supplementary Methods).

The functional relationship between the duty ratio (from Eq. 1) and the number of attached heads at different [MgATP] was very similar for \( K_w = 1 \) and \( K_w = 12 \) (Supplementary Fig. S3).

Key results for short actin filaments and low myosin surface densities are also predicted (Fig. 4) such as the tendency for stops and pauses in motility, intervened by periods of rapid sliding when the number of available myosin heads is reduced below a certain critical value (Hilbert et al. 2013). Furthermore, in accordance with a minimum actin filament length of \( *0.15 \mu m \) for maintained sliding at a myosin head density of \( 1000 \mu m^{-2} \) (Toyoshima et al. 1990), extended periods without attached myosin heads and/or without filament sliding (Fig. 4c), were observed in simulations under these assumptions.

Model predictions for large actomyosin ensembles were also compared to experimental data. First, force–velocity data (Fig. 5a) from fast mouse muscle at 30 °C [more complete, but otherwise similar to rabbit muscle data (Asmussen et al. 1994)] are well predicted and a small difference between the simulated and experimental curve is largely eliminated upon normalization (inset Fig. 5a). This is important because the force–velocity relationship reflects an intricate interplay between cross-bridge attachment and detachment kinetics as well as other features of cross-bridge operation (Albet-Torres et al. 2009; Duke 1999; Edman et al. 1997; Hill 1974; Huxley 1957; Piazzesi et al. 2007). The isometric force on average per attached cross-bridge was 6.95 pN if \( K_w = 12 \) and 6.42 pN if \( K_w = 1 \). These values are within the experimental errors of those (~ 6 pN) found in single molecule studies (Capitanio et al. 2012) using myosin preparations from fast mammalian muscle as well as in experiments on intact muscle fibers from the frog (Piazzesi et al. 2007). If \( K_w = 1 \), as suggested by \( K_M \) of the actomyosin ATPase (see above), the maximum power output (load x velocity) would be underestimated (crosses in Fig. 5a). The normalized force–velocity relationship would not be changed by increasing \( n_s \) from 1 to 3 (not shown) but the average force would increase threefold.

The simulated effects of altered [Pi] on isometric tension are approximately consistent with experimental data (Tesi et al. 2002) (Supplementary Fig. S1D). The prediction that changed [Pi] does not affect the maximum velocity (see Supplementary Fig. S1D for details) agrees with experimental findings under physiological pH (Caremani et al. 2013; Cooke and Pate 1985; Debold et al. 2011). The time course of the isometric tension rise at full activation is well predicted (Fig. 5b) and is determined primarily by \( k_2(x) \), if the concentration of inorganic phosphate is low (Dantzig et al. 1992). If \( K_w \approx 1 \), the rate of rise of force would be affected also by \( K_w \) because the quantity \( K_w (k_2(x)/(K_w + 1)) \) is the effective rate constant

\[
\text{Fig. 4} \text{ Plots of displacement (left vertical axis; full line) and number of attached myosin heads (right axis; dashed line) against time for filaments propelled by low number of myosin motors.} \text{ a} \text{ 0.20 \mu m} \text{ long filament. Note, temporary stops in motility interspersed with phases of rapid displacement.} \text{ b} \text{ One example of simulation assuming 0.15 \mu m} \text{ long filament.} \text{ c} \text{ Second example of 0.15 \mu m} \text{ long filament. Note, switch in position upon myosin head attachment but no net displacement. Assumed motor density, 1000 \mu m^{-2} (see “Materials and Methods” section, text under Eq. 1) corresponding to 4–5 and 6 myosin heads available for interaction with 0.15 and 0.20 \mu m} \text{ long filaments, respectively.}
\]
for transition from the MDP to the AM*D L state. However, it can be seen in Fig. 5b that the effect on the rate of rise of isometric force of reducing \( k_w \) from 12 to 1 would be difficult to detect within the experimental uncertainty.

In accordance with experiments, the model predicts a nearly hyperbolic (Michaelis–Menten type) relationship between \([\text{MgATP}]\) and velocity (Fig. 5c) but with lower \( K_M \) value (\([\text{MgATP}]\) at half maximum velocity) than in experiments. The latter deviation was eliminated, with maintained velocity at saturating \([\text{MgATP}]\), by introduction of non-linear cross-bridge compliance (cf. Persson et al. 2013) together with reduced strain-dependence of \( k_2(x) \) (Capitanio et al. 2012) (see also Fig. 3b). It is also of interest to compare the ensemble data in Fig. 5c to the \([\text{MgATP}]-\)velocity relationship predicted by dividing the step length of 7.7 nm from single molecule data with the on-times from such data (Fig. 2). It is clear from the dashed line in Fig. 5c that the latter velocities are almost tenfold lower than those from ensemble simulations (cf. Brizendine et al. 2015).

A frictional load is often imposed on myosin propelled filaments in the in vitro motility assay (“a loaded motility assay”) (Bing et al. 2000) by transient interaction of actin binding proteins on the surface with the actin filament.
Simulations, assuming NEM-HMM to be the actin-binding protein, are consistent with experiments within the quite appreciable variability (Fig. 6). Furthermore, plots of velocities against the resistive loads produced by the NEM-HMM heads compare well to force–velocity data from simulations of forces developed during iso-velocity shortening (Fig. 5).

Discussion

General issues: relation to other studies

A key finding is that a classical model, of the Huxley–Hill type (Hill 1974; Huxley 1957) with detailed biochemical cycle (Fig. 1) approximates a range of contractile phenomena (e.g. Figs. 2, 3, 4, 5, 6; Supplementary Fig. S1) on experimental scales from single molecules to muscle, without considering details of muscle structure. Related, there is no need to assume emergent properties in the large ordered ensembles or to use different models for different conditions (e.g. Baker et al. 2002).

Steps towards including elastic coupling effects in the modelling of in vitro motility assay results have been taken previously (Baker et al. 2002; Duke 1999; Pate and Cooke 1991; Walcott et al. 2012; Vilfan and Duke 2003). Pate and Cooke (1991) used a slightly modified version of the (Huxley 1957) model to provide general insights into effects of varying number of motors but without detailed connection to key biochemical intermediates in actomyosin ATP turnover. The latter details are likely to be important in studies of pathologies but also for full understanding of normal function. More recent models have included additional details and provided further insight e.g. about the behavior of filaments at very low motor number (Hilbert et al. 2013). They have also reported effects of elastic coupling on the relationship between the number of motors and the average motor on-time, sliding distance and velocity (Baker et al. 2002; Walcott et al. 2012). However, unlike the present work, the previous studies did not consider all hierarchical levels from single molecules to muscle cells. Furthermore, the explicit separation of the Pi-release from both the main force-generating transition and the attachment step to actin, distinguishes the present model from most predecessors both for large (Månsson 2010; Pate and Cooke 1989; Persson et al. 2013) and small (Erdmann and Schwarz 2012; Hilbert et al. 2013; Pate and Cooke 1991; Walcott et al. 2012) ensembles. Whereas such separation is not essential to approximately fit the data in Fig. 5 (e.g. (Pate and Cooke 1989; Persson et al. 2013) the results demonstrate that a separate Pi-release and a realistic biochemical cycle does not compromise the capability of the model to account for a range of mechanical results on different scales (Figs. 2, 3, 4, 5, 6). This is important (e.g. Malnasi-Csizmadia and Kovacs 2010; Månsson et al. 2015) in order for a model to be useful for connecting biochemical transitions to mechanical events in fundamental studies and for elucidating effects of disease-causing mutations and effects of drugs. A separate Pi-release seems essential to account for structural and biochemical findings (Llinas et al. 2015; Sweeney and Houdusse 2010). Further, it seems required to account for findings in muscle fiber studies, e.g. the tension response of changes in temperature (temperature transients) (Ranatunga 2010) and to rapid changes in the concentration of inorganic phosphate (phosphate transients) (Dantzig et al. 1992).

Directly related to the above issue, the present study also differs from most earlier model studies by explicitly considering a weakly bound actomyosin state (AMDP) that is distinguished from a start of the power-stroke state without Pi (AMP*D_L). The properties of the weakly bound AMDP state have potentially important implications motivating that it is considered separately. For instance, different affinities of this state to actin noticeably affect (Fig. 5A) the force–velocity relationship. Furthermore, cross-bridges in the weakly bound state may also impose a viscoelastic load on actin filaments with a magnitude that varies with the experimental conditions and possibly between muscle cells and in vitro motility assays (Homsher et al. 1992) (however see Vihorev et al. 2008). Finally, certain myosin head mutations [e.g. positively charged amino acids in surface loops (Colegrave and Peckham 2014)] may affect the weak-binding properties. It is therefore important to

![Fig. 6 Sliding velocity in the in vitro motility assay vs [NEM-HMM]/[HMM] ratio where NEM-HMM is N-ethyl maleimide treated HMM. Simulated data (black) compared to experimental data (purple) from (Kim et al. 1996) (circles; fast rabbit HMM; 25 °C; ionic strength <50 mM) and (Amitani et al. 2001) (triangles; fitted with cubic polynomial; fast rabbit HMM, 25 °C; ionic strength <50 mM). Simulated behavior of long (20 μm) filaments assuming binding energy of NEM-HMM to actin of either 18 k_BT (filled circles) or 7 k_BT (open circles). The latter case also simulated for 1 μm long filaments (triangles). Note appreciable variability among experimental results but also variability among simulated data depending on exact conditions for the simulations. Experimental data points were obtained by measuring from figures in the cited papers.](https://example.com/image-url)
include the weakly bound state in a model intended to be useful for studies of diseases and drug development. Uncertainties regarding the actin affinity in the weak-binding state and their implications are considered below.

The present model overcomes existing barriers in data interpretation by allowing integration of results from experimental systems on different scales. Particularly, mechanical and kinetic results obtained using isolated proteins, e.g. solution studies, studies of single molecules or in vitro motility assays (Aksel et al. 2015; Sung et al. 2015; Wang et al. 2013), may be readily extrapolated to contractile properties of muscle. This will aid mechanistic insights into the physiology, pathology and pharmacology of striated muscle contraction. Whereas the model is largely based on states derived from mechanical experiments and biochemical kinetics, the states have coarse-grain structural equivalents, e.g. with lever arm up or down (insets of Fig. 1b) and the actin-binding cleft open or closed. Therefore, the model should be useful for correlating atomic resolution structural data (e.g. reviewed in Sweeney and Houdusse (2010), Månsson et al. (2015)) and contractile function from single molecules to large actomyosin ensembles.

For studies of pathologies, additional states, e.g. the so called super-relaxed state (Hooijman et al. 2011; Linari et al. 2015) may be important to include as well as effects of regulatory proteins and time varying activation. Inclusion of new states into the model is trivial. It is more complex to include time varying activation. This property is attributed to regulatory/modulatory proteins associated both with the thin filaments (troponin, tropomyosin) and the thick filaments, e.g. myosin regulatory light chains and myosin binding protein C (reviews in Kamm and Stull 2011; Moore et al. 2016; van Dijk et al. 2014). The issue may be treated either phenomenologically by time varying values of rate constants (Homsher et al. 2000; Månsson 2014; Webb et al. 2013) or explicitly using expanded Monte-Carlo approaches (Mijailovich et al. 2012; Rice and de Tombe 2004). However, due to computation time constraints, the latter approach will require extensive optimization for speed both of computational platforms and algorithms.

The effect of lengthening during activity is not in focus here. However, this is an important physiological phenomenon that also needs to be taken into account when studying e.g. pathologies (Månsson 2014). A simple approach to account for key aspects of the mechanics of lengthening contraction is therefore illustrated in Supplementary Fig. S4. However, undoubtedly, both effects of other proteins than actin and myosin e.g. titin, and emergent properties related to sarcomere non-uniformities will need to be considered in a complete treatment (Campbell et al. 2011; Edman 2012; Higuchi and Umazume 1985; Rassier 2012a; Wang et al. 1984).

Limitations of the model: related biological insights and suggestions for further studies

As mentioned above, no attempts were made to fit conditions of time-varying activation or lengthening contractions. However, additional experimental results are not accounted for in full quantitative detail. This may either be attributed to experimental uncertainties or limitations in the model representation of biological mechanisms. Such limitations necessarily exist in any model and are important because they point out poorly understood mechanisms and prompt testing of alternative ideas. Below, the discrepancy between predictions of the present model and experimental data is considered in relation to experimental uncertainties and alternative models.

One limitation related to poorly understood characteristics of the cross-bridge elasticity (whether it is linear or non-linear) is the requirement for significantly greater strain/load dependence of k2 in the model than suggested by the load-dependence of the ATP-induced detachment in single molecule measurements (Capitanio et al. 2012; Supplementary Fig. S2). This was necessary to account for the high maximal velocity at saturating [MgATP] but led to overestimation of velocity at lower [MgATP] (with too low K0-value). Interestingly, however, both the magnitudes of the maximum velocity and K0 for the [MgATP]–v relationship are accounted for with very low (or no) strain dependence of k2 if the cross-bridge compliance for x < 0 nm is assumed to be ~1/10 of that at x > 0 nm, simulating non-linear cross-bridge elasticity (Kaya and Higuchi 2010). On the other hand, evidence suggesting a non-linear elasticity has been obtained only in certain in vitro assays (Brizendine et al. 2015; Kaya and Higuchi 2010; Persson et al. 2013) and there is currently no firm evidence that the cross-bridge elasticity is non-linear in muscle cells. Clearly, the latter issue will be of outmost importance to clarify.

One further problem is that the detailed course of events associated with transitions between the MDP and the AM*DL states cannot be represented in full detail due to ambiguities in available experimental data (reviewed in Månsson et al. 2015). These poorly understood details might account for the failure to perfectly reproduce the relationship between [Pi] and isometric tension as well as for lack of key ATP-independent detachment processes in single molecule data (Capitanio et al. 2012). The latter findings seem to suggest additional states between the AMDP and the AM*DL states. Here, it is of interest to consider ideas (Caremani et al. 2013; Ford et al. 1986; Geeves et al. 1984; Smith and Mijailovich 2008) that mechanical transitions between high force and low force conformations occur in different biochemical states. For instance, a mechanical transition (similar to that from the
AM*DL to AM*D H state) may occur also in an AM*DP biochemical state. This would add a high-force state from which rapid ATP independent detachment may occur. Additionally, it would fit with at least two tensing steps as suggested recently (Offer and Ranatunga 2013) and it may fit into a framework to explain high maximum power-output of muscle (Caremani et al. 2013) without the need for a high value of \( K_w \) as used here. However, again, the available experimental data is ambiguous with regard to both the existence and the properties of these postulated states and transitions (Månsson et al. 2015).

One additional reason for discrepancies between the model predictions and experimental results (Capitanio et al. 2012) for load-dependence of cross-bridge detachment (Supplementary Fig. S2) could be that the model is defined primarily on the basis of data for two-headed myosin whereas the experiments use one-headed myosin. Peculiarities in relation to other experimental results (see Supplementary Fig. S2) lend support to that idea.

As discussed above, the weakly bound myosin state is not included as a separate state in most models. The striking effects of a tenfold change in actin affinity is therefore of interest. For instance, the need to assume a higher value of \( K_w \) to account for high power-output of muscle than expected from actin-binding in solution (association constant \( K_a \)), could mean that cooperative or other phenomena operate during shortening against intermediate loads (Caremani et al. 2013; Edman et al. 1997; Månsson 2010). On the other hand, there may be some uncertainty (Brenner et al. 1986; Eisenberg et al. 1980) in the effective actin concentration, in the muscle sarcomere, which relates \( K_w \) to \( K_a \). Alternatively, the affinity of weakly bound actomyosin cross-bridges might vary between conditions as suggested for actomyosin bonds in other states (Guo and Guilford 2006). Further, as an additional alternative, the surface attachment of myosin motors, either to the motility assay surface or the thick filament backbone, may account for increased affinity of the weakly bound actomyosin state in mechanical experiments. It would therefore be valuable if current estimates of the affinity of weakly bound heads with myosin tethered on a surface are verified under physiological conditions and full activation.

**Implications for the interpretation of in vitro motility assay data at different motor densities**

In terms of the model of Uyeda et al. (1990) (Eq. 1) the velocity varies with the number (N) of available motors due to the fraction of time that at least one motor propels the actin filament; no elastic coupling effects between motors are considered as in classical muscle models (Hill 1974; Huxley 1957). The present study and the results in recent work (Walcott et al. 2012) strongly suggest that, if such elastic coupling is present, the parameter values obtained in fits of Eq. 1 (Uyeda et al. 1990) do not adequately describe the system. This is important because of the extensive use of the Uyeda model (Uyeda et al. 1990) for analysis of in vitro motility assay data. The present results (Fig. 3) accord with 1–3 myosin binding sites per 36 nm of the actin filament which indicates that myosin heads only bind to target zones at 36 nm spacing. This accords with single molecule mechanics data (Capitanio et al. 2006; Steffen et al. 2001) but is generally not considered in the analysis of in vitro motility assays for small ensembles.

**Relation to engineering approaches involving actomyosin**

An interesting development in the recent decade is engineering of myosin motors to incorporate radically new functionalities, e.g. with regard to the movement direction along actin filaments (Tsiavaliaris et al. 2004) or even the remote switching of this directionality, e.g. by illumination (Nakamura et al. 2014). In addition to potential uses in nanotechnological applications (Kumar et al. 2016; Månsson 2012; Nicolau et al. 2016) the engineering results pose new questions about how certain functions relate to structural elements in the motor. The present model, by virtue of coarse-grain structural equivalence of different states, would be useful for elucidating how the engineered elements give rise to some of their functional consequences. Conversely, the model may also be useful for guiding engineering of motors with certain properties, e.g. for use in nanotechnology.

**Conclusions**

The results demonstrate that actomyosin contractile function, from single molecules to large ensembles, is reasonably well approximated by one unifying chemo-mechanical model with a realistic biochemical cycle. Observed limitations in model predictions identify needs for new experimental studies. This includes the transitions between the MDP state over the weak-binding actomyosin state to the start of power-stroke AM*D L state, i.e. the properties of the weakly bound actomyosin state and the temporal relationship between Pi-release and the main force-generating transition. Furthermore, detailed characterization of the cross-bridge elasticity is essential. Particularly, it is important to clarify if non-linear elasticity is limited to certain in vitro assays or is present in living muscle. A future version of the model for analysis of diseases and drug effects would benefit from new experimental evidence.
to fully clarify the mentioned issues. Finally, the study has also given new insights important for the interpretation of in vitro motility assays and for engineering of motors.
