Microphthalmia, anophthalmia, and coloboma (MAC) are congenital ocular malformations causing 25% of childhood blindness. The X-linked disorder Focal Dermal Hypoplasia (FDH) is frequently associated with MAC and results from mutations in Porcn, a membrane bound O-acyl transferase required for palmitoylation of Wnts to activate multiple Wnt-dependent pathways. Wnt/β-catenin signaling is suppressed in the anterior neural plate for initiation of eye formation and is subsequently required during differentiation of the retinal pigment epithelium (RPE). Non-canonical Wnts are critical for early eye formation in frog and zebrafish. However, it is unclear whether this also applies to mammals. We performed ubiquitous conditional inactivation of Porcn in mouse around the eye field stage. In PorcnCKO, optic vesicles (OV) arrest in growth and fail to form an optic cup. Ventral proliferation is significantly decreased in the mutant OV, with a concomitant increase in apoptotic cell death. While pan-ocular transcription factors such as PAX6, SIX3, LHX2, and PAX2 are present, indicative of maintenance of OV identity, regional expression of VSX2, MITF, OTX2, and NR2F2 is downregulated. Failure of RPE differentiation in PorcnCKO is consistent with downregulation of the Wnt/β-catenin effector LEF1, starting around 2.5 days after inactivation. This suggests that Porcn inactivation affects signaling later than a potential requirement for Wnts to promote eye field formation. Altogether, our data shows a novel requirement for Porcn in regulating growth and morphogenesis of the OV, likely by controlling proliferation and survival. In FDH patients with ocular manifestations, growth deficiency during early ocular morphogenesis may be the underlying cause for microphthalmia.

Introduction

Congenital ocular malformations—microphthalmia (small eye), anophthalmia (absent eye, also called extreme microphthalmia), coloboma (optic fissure closure defect in the ventral optic cup) (collectively hereafter MAC)—originate from defective morphogenesis during early eye development and cause 25% of childhood blindness (Clementi et al., 1992; Morrison et al., 2002; Graw, 2019). Eye development is initiated during gastrulation in a single domain in the anterior neural plate, the eye field, characterized by expression of eye field transcription factors (EFTFs) that include Pax6, Six3, Six6, Rx, Tbx3, and Lhx2 (Oliver et al., 1995; Zuber et al., 2003; Bailey et al., 2004; Motahari et al., 2016; Liu and Cyk, 2017). In combination with secreted factors inhibiting Nodal, BMP and Wnt/β-catenin signaling, EFTFs form a gene regulatory network to promote eye field specification (Zuber et al., 2003). Subsequently, the eye field separates into two optic pits that evaginate laterally. Bilateral optic vesicles (OVs) are formed, comprised of neuroepithelial progenitor cells giving rise to optic stalk, retina and RPE. The distal domain of the OV contacts the overlying surface (lens) ectoderm, and both OV and ectoderm invaginate to form the optic cup (OC) and the lens vesicle, respectively. While the coordinated interactions regulating regionalization of OC and OV are well studied [for reviews, see (Fuhrmann, 2010; Viczian, 2014; Miesfeld and Brown, 2019)], regulation of the morphogenetic events during OV evagination and OC invagination are less understood.

Focal Dermal Hypoplasia (FDH; Goltz Syndrome) is an x-linked dominant disorder resulting from abnormal mesodermal and ectodermal development and is frequently associated with MAC (Goltz et al., 1962; Temple et al., 1990; Wang et al., 2014; Gissman and Herce, 2016). FDH is caused by mutations in Porcn, a membrane bound O-acyl transferase localized to the endoplasmic reticulum (Grieschik et al., 2007; Wang et al., 2007). Porcn is mostly dedicated to palmitoylate the transmembrane receptors (Fzd), and activate canonical (Wnt/β-catenin signaling) and non-canonical pathways. Wnt/β-catenin activation prevents cytoplasmic degradation of β-catenin, thereby allowing its nuclear translocation to activate Tcf/Lef1 transcription factors. Wnt/β-catenin exerts many distinct functions during different phases of eye development [for reviews, see (Fuhrmann, 2010; Fujimura, 2016)]. During early OC morphogenesis, it is required for RPE differentiation (Fujimura et al., 2009; Westenskow et al., 2009; Hagglund et al., 2013) and does ventral patterning (Veien et al., 2008; Zhou et al., 2008). The pathway is tightly regulated; ectopic activation by disruption of the antagonists Dkk1 and Axin2 can result in microphthalmia and coloboma (Lieven and Ruther, 2011; Allredge and Fuhrmann, 2016). During forebrain development, multiple antagonists maintain anterior neural fate. Hyperactive Wnt/β-catenin frequently leads to posteriorization and rostral truncation of the forebrain, with concomitant severe decrease of EFTF expression. The EFTF Six3 can directly suppress Wnt/β-catenin signaling (Lagutin et al., 2003), providing another mechanism for precise coordination of pathway activity.

Non-canonical, β-catenin-independent Wnt signaling occurs via multiple pathways, including intracellular Ca2+ release, activation of JNK and Planar Cell Polarity (PCP). It is essential for eye field formation in non-mammalian vertebrates by different mechanisms; it represses Wnt/β-catenin activity and promotes expression of EFTFs in frog and zebrafish (for review, see (Fuhrmann, 2008)). Close to the caudal border of the eye field, non-canonical Wnt11 (formerly Wnt11) and Wnt4 act through Fzd5 and Fzd3 to promote expression of the EFTFs Pax6 and Rx (Rasmussen et al., 2001; Cavodeassi et al., 2005; Maura et al., 2005). In addition, Wnt11f2 and crosstalk between JNK/PCP and ephrinB1 are required for morphogenetic movements of ocular progenitor cells into the eye field (Heisenberg et al., 2000; Moore et al., 2004; Cavodeassi et al., 2005; Lee et al., 2006; Cavodeassi et al., 2013). However, it is unknown whether non-canonical Wnt signaling functions similarly in mammals; for example, germline disruption of Wnt4, Wnt11, Fzd3 does not cause obvious ocular phenotypes, suggesting either redundancy of pathway components and/or context- and species-dependent mechanisms.

To investigate the role of Porcn before OV morphogenesis, we performed temporally controlled inactivation before and during the eye field stage when Wnts are expressed in the cranial region (Parr et al., 1993; Kispert et al., 1996; Yamaguchi et al., 1999; Kemp et al., 2005). Our results show that Porcn inactivation around eye field formation leads to severely arrested OV 3 days later. Key regulatory genes for RPE differentiation OTX2, MITF, and NR2F2 are absent, proliferation and survival of ocular progenitors in the OV is decreased, and invagination during OC morphogenesis fails. Our studies reveal a novel role for Porcn during earlier stages of mouse eye development, recapitulating severe microphthalmia in FDH.

Materials and methods

Mouse lines were maintained on a mixed genetic C57BL/6 and CD-1 background. For temporally controlled Porcn inactivation, a conditional Porcn allele, tamoxifen-inducible, ubiquitous Gt(ROSA)26Sor-cre/ERT2/+ (hereafter ROSA26Sor-creERT2) and the recombination reporter Rosa26 were utilized, with established genotyping protocols or Transnetyx (Cordova, TN) using Taqman with custom-designed primers.
(Soriano, 1999; Badea et al., 2003; Barrott et al., 2011; Bankhead et al., 2015; Sun et al., 2020). Noon of the day with an observed vaginal plug was counted E0.5. Pregnant dams received tamoxifen (0.1 mg/g) by oral gavage between E6.5 and E7.5 (Park et al., 2008). To detect proliferating cells, pregnant dams received one intraperitoneal EdU injection 2 hours before sacrificing (30 μg/g; Thermofisher/Invitrogen; #E10187). Male embryos with conditional deletion of Porcn (hereafter PorcnCKO) and control litters were processed as previously published (Sun et al., 2020). For antigen retrieval, cryostat sections were treated with 1% Triton X-100 or hot citrate buffer (pH 6). Detailed antibody information is provided in Supplementary Table S1. Filamentous actin was detected using Phalloidin (1: 50; Thermo Fisher Scientific; #A12379). ApoTag Fluorescein In Situ Apoptosis Detection Kit (EMD Millipore, #S7110) was used to detect apoptotic cells. For EdU detection, the Click-it® EdU Imaging Kit (Thermo Fisher Scientific; #C10637) was utilized. Cryostat sections were counter-labeled with DAPI and mounted in Prolong Gold Antifade. No obvious defects in morphology, cryostat sections were counter-labeled with DAPI and mounted.

Apoptosis Detection Kit (EMD Millipore, #S7110) was used. For antigen retrieval, cryostat sections were treated with 1% Triton X-100 or hot citrate buffer (pH 6). Detailed antibody information is provided in Supplementary Table S1. Filamentous actin was detected using Phalloidin (1: 50; Thermo Fisher Scientific; #A12379). ApoTag Fluorescein In Situ Apoptosis Detection Kit (EMD Millipore, #S7110) was used to detect apoptotic cells. For EdU detection, the Click-it® EdU Imaging Kit (Thermo Fisher Scientific; #C10637) was utilized. Cryostat sections were counter-labeled with DAPI and mounted in Prolong Gold Antifade. No obvious defects in morphology, proliferation or EdU marker expression were observed in controls: conditional heterozygous female embryos (hereafter PorcnCHET) and embryos with or without Cre. Unless otherwise indicated, a minimum of 3 embryos from at least 2 individual litters were analyzed per genotype, time point and marker. For analyses of E9.5 embryos induced at E6.5, 3 embryos were analyzed and 2 showed indication of ocular development.

Images were captured using a U-CMAD3 camera, mounted on an Olympus SZX12 stereomicroscope, and a X10 camera, mounted on an Olympus BX51 epifluorescence system. For confocal imaging, the Olympus FV1000 or ZEISS LSM 880 systems were used. Images were processed using ImageJ (NIH) and Adobe Photoshop software (versions CS6, 23.5.1). Quantification of EdU-labeled and Tunel-labeled cells was performed on cryostat sections midway through the OV, with separation of dorsal and ventral subdivisions. The percentage of labeled cells was calculated by determining the number of total cells using DAPI-labeled nuclei. Statistical analysis was performed using Prism version 9 (Graphpad) for One-Way ANOVA.

Results

Conditional Porcn inactivation before eye field induction (E6.5) causes abnormal OV morphogenesis

We observed that Porcn needs to be depleted in multiple ocular and extraocular tissues at the OV stage to recapitulate consistently the ocular abnormalities found in FDH patients (Bankhead et al., 2015). In mouse, the eye field becomes established at E7.5, and Wnts are expressed in tissues adjacent to the eye field. To target both cell autonomous and non-cell autonomous Wnt production, we disrupted Porcn using the ubiquitous ROSA26 CreERT, allowing temporally controlled recombination. To account for delay of pathway inactivation in responding cells due to cell non-autonomous Wnt ligand production, extracellular release and downstream receptor activation, we started inactivating Porcn at E6.5. Rosa26 recombination confirmed ubiquitous Cre activity, as expected (Supplementary Figure S1) (Soriano, 1999). At E8.5–8.75, PorcnCKO show severe posterior truncation (Barrott et al., 2011; Biechele et al., 2013). However, anterior regions do continue to develop, with reduced size of OVs (Figures 1B–H; 8–13 somites). In PorcnCKO, expression of the Wnt/β-catenin readout LEF1 can be slightly decreased in the dorsal OV, consistent with decreased Wnt signaling (Figure 1D). Lhx2 is required for the transition from eye field to OV and is robustly expressed in PorcnCKO (Figure 1F). Otx2 is critical for rostral brain regionalization and early ocular development. In PorcnCKO, Otx2 expression is present in the dorsal OV (Figure 1H). To determine whether the observed alterations could be due to a developmental delay, we examined PorcnCKO embryos 1–2 days later. We observed major developmental abnormalities on E10.5 PorcnCKO embryos, not suitable for further analysis (Supplementary Figure S2). Thus, we continued to examine embryos at E9.5 (20–23 somites); PorcnCKO exhibit more defects compared to E8.5–8.75, including abnormalities in the head region (Figures 1J,K). Morphogenesis of the OVs does not proceed properly; they are arrested and fail to contact the surface ectoderm (Figure 1M,Q). Expression of LEF1 is absent in the dorsal OV, indicating loss of Wnt/β-catenin signaling (Figure 1M). Phalloidin labeling reveals that apicobasal polarity is generally preserved (Figure 1O). Thus, it is possible that non-canonical Wnt pathways such as planar cell polarity are largely maintained. Robust LHX2 expression is maintained in PorcnCKO (Figure 1Q). In contrast, Otx2 is downregulated in the dorsal OV, while weak expression is detectable in the adjacent forebrain (Figure 15). Overall, our results demonstrate that Porcn inactivation starts to affect eye development after approx. 2.5 days, with slightly decreased Wnt/β-catenin signaling in the dorsal OV. Evagination can occur, suggesting that OV identity is maintained, and morphogenesis initiated. However, with ongoing loss of Porcn at E9.5, dorsal regionalization and expansion of the OV is severely affected.

Porcn deletion during eye field induction (E7.5) variably affects brain and eye formation

To bypass major developmental defects before OV morphogenesis (Figure 1), we administered tamoxifen 1 day later (E7.4–7.5). At E10.5, PorcnCKO embryos were recovered with a range of ocular abnormalities, possibly due to developmental variability between litters and embryos at the
time of tamoxifen administration (Figure 2; 9 litters with 26 Porcn<sup>KO</sup> embryos). In 5 Porcn<sup>KO</sup>, no detectable eye phenotype was observed (19%; not shown). In mildly affected Porcn<sup>KO</sup>, telencephalic vesicles are slightly smaller (Figure 2F). Eye size can be reduced, associated with incomplete OC morphogenesis, failure of lens vesicle formation and accumulation of POM between distal OV and surface ectoderm (Figures 2G–J; 27%, n = 7). In mildly affected Porcn<sup>KO</sup>, OVs can be more closely associated with lens ectoderm, occasionally with further advanced invagination (not shown). We also observed Porcn<sup>KO</sup> embryos with a more severe developmental and ocular phenotype (Figures
PorcnCKO embryos exhibit defects in mid- and forebrain development; the mid-hindbrain border is missing and telencephalic vesicles are underdeveloped (Figure 2K). Ocular morphogenesis is consistently arrested with small OVs that fail to expand, with abnormal accumulation of anterior POM preventing close contact between distal OV and lens ectoderm (Figure 2L–O). Consequently, neither the OV nor the surface ectoderm show any signs of invagination (Figure 2M–O). Some thickening of the surface ectoderm is occasionally detectable, suggesting that early aspects of lens morphogenesis can be initiated (Figure 2M). In PorcnCKO embryos with a severe phenotype, overall LEF1 expression is decreased, specifically in the dorsal forebrain, dorsal OV and facial primordia, indicating widespread downregulation of the Wnt/β-catenin pathway (Figures 2Q,S).
Eye field transcription factors are robustly expressed in the arrested OV of severely affected E10.5 Porcn\textsuperscript{CKO}

Since OC morphogenesis is consistently and impaired the most, we proceeded with analyzing severely affected E10.5 Porcn\textsuperscript{CKO} (Figures 2F–J). The pan-ocular transcription factor PAX6 is expressed in the arrested Porcn\textsuperscript{CKO} OV and also present in the surface ectoderm (Figure 3B). The eye field transcription factor Six3 is required for neuroretinal specification the mammalian eye (Liu et al., 2010; Liu and Cvekl, 2017). SIX3 expression is not altered in the OV and surface ectoderm of Porcn\textsuperscript{CKO} (Figure 3D). LHX2 is expressed throughout the OC and OV, respectively. (Figure 3F). In Porcn\textsuperscript{CKO}, PAX2 expression is maintained throughout the OV (Figure 3H), consistent with failure of OC formation and dorsoventral regionalization. During normal eye development, proximodistal regionalization into RPE and retina occurs in the advanced OV (Fuhrmann, 2010; Fuhrmann et al., 2014; Miesfeld and Brown, 2019). In Porcn\textsuperscript{CKO} with loss of close contact due to POM accumulation between the distal OV and surface ectoderm (Figure 2), the strictly retina-specific CVC homeodomain transcription factor VSX2 is not expressed (Figure 3J).

Porcn mutant embryos display defective regionalization of the arrested OV at E10.5

The paired homeobox transcription factor PAX2 is initially expressed throughout the OV and is later confined to the ventral OC and optic stalk (Nornes et al., 1990; Burns et al., 2008). In Porcn\textsuperscript{CKO}, PAX2 expression is maintained throughout the OV (Figure 3H), consistent with failure of OC formation and dorsoventral regionalization. During normal eye development, proximodistal regionalization into RPE and retina occurs in the advanced OV (Fuhrmann, 2010; Fuhrmann et al., 2014; Miesfeld and Brown, 2019). In Porcn\textsuperscript{CKO} with loss of close contact due to POM accumulation between the distal OV and surface ectoderm (Figure 2), the strictly retina-specific CVC homeodomain transcription factor VSX2 is not expressed (Figure 3J).
However, if close contact occurs in PorcnCKO, some cells in the presumptive retina can express VSX2 (Figure 3K), consistent with the requirement of lens-derived FGF for retina specification (Cai et al., 2013).

Concerning proximal regionalization, we observed a complete loss of the key regulatory transcription factors NR2F2, OTX2, and MITF (Figure 3M,O,Q) that are required for RPE differentiation (Hodgkinson et al., 1993; Bumsted and Barnstable, 2000; Nguyen and Arnhetter, 2000; Martinez-Morales et al., 2001; Tang et al., 2010). NR2F2 expression confirms abnormal abundance of POM between distal OV and lens ectoderm (Figure 3M). Together, our results

(Burmeister et al., 1996; Green et al., 2003). However, if close contact occurs in PorcnCKO, some cells in the presumptive retina can express VSX2 (Figure 3K), consistent with the requirement of lens-derived FGF for retina specification (Cai et al., 2013). Concerning proximal regionalization, we observed a complete loss of the key regulatory transcription factors NR2F2, OTX2, and MITF (Figure 3M,O,Q) that are required for RPE differentiation (Hodgkinson et al., 1993; Bumsted and Barnstable, 2000; Nguyen and Arnhetter, 2000; Martinez-Morales et al., 2001; Tang et al., 2010). NR2F2 expression confirms abnormal abundance of POM between distal OV and lens ectoderm (Figure 3M). Together, our results
demonstrate that dorsoventral and proximodistal regionalization is impaired in the arrested OV of PorcnCKO at the time when OC morphogenesis normally commences.

**Decrease of proliferation, survival and local NR2F2 and OTX2 expression in the PorcnCKO OV at E9.5**

To elucidate a potential mechanism underlying abnormal ocular growth obvious in E10.5 PorcnCKO, we analyzed embryos 1 day earlier, following tamoxifen induction at E7.4-E7.5. At E9.5, PorcnCKO show slightly decreased telencephalic vesicles and mid-hindbrain regions (Figure 4B). LEF1 expression in the dorsal OV and adjacent dorsal forebrain neuroepithelium in PorcnCKO embryos is unaltered, suggesting that Wnt/β−catenin signaling is intact at this age (Figure 4D). MITF expression is not affected in the presumptive RPE of PorcnCKO (Figure 4F). However, other RPE markers NR2F2 and OTX2 start to be reduced dorsally in the distal OV domain (Figures 4H,J) suggesting that some aspects of regionalization can be affected at this age.

To determine effects on proliferation, we quantified the number of E9.5 OV cells incorporating EdU (Figures 4K–O). In PorcnCKO, the number of EdU-labeled cells show a trend in decrease in the entire OV (Figures 4L,M). This effect is specifically due to a significant reduction in the ventral OV by 24% and 29%, compared to PorcnCHET and Porcnf+/y, respectively (Figure 4O). We also examined apoptotic cell death in ocular progenitors. Compared to PorcnCHET, the percentage of Tunel-labeled cells is significantly upregulated by 78% in the ventral OV of PorcnCKO (Figures 4R,T). Unexpectedly, we observed a considerable effect of Porcn gene reduction on survival of ocular progenitors; PorcnCHET OV show an overall significant increase in Tunel-labeled cells, compared to Porcnf+/− (Figures 4Q,S,T). These results suggest that already 2 days after tamoxifen administration loss of Porcn negatively impacts both survival and proliferation of ocular progenitors in the ventral OV. These changes occur before major defects in expression of the Wnt/β−catenin readout LEF1, regionalization markers and abnormal morphogenesis become obvious.

**Discussion**

Our results show that Porcn inactivation either before or during eye field formation leads to severely arrested OVs, likely due to an increase in cell death and downregulation of proliferation. In PorcnCKO, the RPE key regulatory transcription factors OTX2, MITF and NR2F2 are downregulated. POM accumulates between distal OV and adjacent surface ectoderm, preventing tight association, and the retina-specific gene VSX2 is not properly expressed. Arrested eye vesicles in PorcnCKO do not invaginate, resulting in failed invagination of the OV into an OC. Our studies reveal a novel role for Porcn in the OV as the earliest obvious morphological stage of eye development and a continued requirement during OC morphogenesis, recapitulating severe microphthalmia in FHD.

**Effect of Porcn disruption on Wnt signaling**

We first determined when potential effectors of Wnt signaling are affected by Porcn inactivation at E6.5. Wnt/β−catenin signaling is normally not active until OV invagination starts; the pathway readouts Axin2 and BATgal reporter are absent in the OV around E8.75 (8 somites) (Liu et al., 2010). Here, we observed that another readout, LEF1, starts to become weakly expressed around E9.0 in the dorsal OV of controls (13 somites; Figure 1C). In PorcnCKO embryos, LEF1 is slightly downregulated in the dorsal OV (Figure 1D) suggesting commencement of a pathway response. Indeed, in the E9.5 OV, LEF1 is absent, demonstrating complete shutdown of the pathway, and OV morphogenesis is abnormal (Figure 1M). Thus, it takes at least 2.5 days after tamoxifen treatment to detect initial effects of Porcn inactivation on Wnt/β−catenin signaling and approximately 3 days to observe defects in gene expression and eye morphogenesis.

Since Wnt/β−catenin signaling needs to be suppressed in the anterior neural plate, we reasoned that any requirement for Porcn would be likely due to a need for the non-canonical Wnt pathway. Inactivation of Porcn also prevents potentially confounding, concomitant upregulation of Wnt/β−catenin signaling. Consistent with this, arrested growth of the OV has not been observed by early Wnt/β−catenin pathway inactivation in other studies (Hagglund et al., 2013). We observed that the putative non-canonical Wnt pathway readout pJUN is normally not robustly expressed in the E9.5 OV (not shown), and F-actin shows normal apicobasal localization in PorcnCKO (Figure 1). However, we cannot exclude effects on other potential non-canonical Wnt targets in PorcnCKO. In addition, Porcn can exert Wnt-independent roles in regulating cancer growth and AMPA receptor assembly and function in rate hippocampal neurons (Covey et al., 2012; Erlenhardt et al., 2016). While we cannot exclude Wnt-independent roles of Porcn during early eye development, it needs to be shown whether these functions are critical for early forebrain development.

Porcn is not required for maintenance of EFTF expression in the OV and OC

Eye field formation with expression of EFTFs in mouse starts around E7.5. To determine Porcn’s role during the
Porcn is required for ocular growth by promoting proliferation and survival of ocular progenitors

Our study demonstrates that Porcn inactivation results in severe morphogenesis defects 3 days later, either at the OV (E9.5) or OC stage (E10.5). The Porcn<sup>cko</sup> OV or OC is small and OV expansion or OC invagination fails, respectively. Analysis of cell death (TUNEL) and proliferation (EdU incorporation) showed robustly downregulated proliferation and survival of ocular progenitors in the ventral OV 1 day earlier when morphology and expression of the Wnt/β-catenin readout appear normal (Figure 4K–T). Wnt signaling can directly regulate proliferation and survival of ocular progenitors (Burns et al., 2008; Hagglund et al., 2013). Interestingly, during embryonic morphogenesis, Wnt signaling may support metabolic demands by preventing a cellular stress response, which could affect proliferation and survival (Poncet et al., 2020). A reduction of Porcn gene dosage in the embryo may impact the overall stress response and affect general survival as observed in the dorsal Porcn<sup>Chet</sup> OV and surrounding tissues (Figure 4Q).

Significantly reduced proliferation during OC morphogenesis has been observed in embryos with germ line mutation of early ocular regulatory genes, for example Pax6<sup>−/−</sup>, Lhx2, BMP7, Hes1 and Mab21L2 (Grindley et al., 1995; Porter et al., 1997; Yamada et al., 2004; Lee et al., 2005; Morcillo et al., 2006; Yun et al., 2009). However, PAX6 and LHX2 are expressed in the OV of Porcn<sup>cko</sup>, and Pax6, Bmp7, Hes1 and Mab21L2 mutants do not show a robust morphogenesis defect until E10.5. Therefore, to our knowledge, the ocular phenotype in Porcn<sup>cko</sup> is unique because it shows an earlier requirement for proliferation and survival of ocular progenitors.

Porcn inactivation around the eye field stage recapitulates microphthalmia and anophthalmia in FDH patients

Porcn<sup>cko</sup> display severe microphthalmia 3 days after tamoxifen treatment before or during the eye field stage. Porcn<sup>cko</sup> embryos induced at E6.5 and harvested at E10.5 showed severe developmental abnormalities not feasible for further analysis at later time points (Supplementary Figure S2). Lhx2 mutants exhibit a similar OV morphogenesis defect leading to anophthalmia subsequently (Porter et al., 1997). Thus, we hypothesize that Porcn inactivation before the OV stage ultimately results in anophthalmia, consistent for an early role of Porcn in FDH. A case report for 18 FDH patients revealed a high incidence of ophthalmologic abnormalities (77%), including microphthalmia (44%) and anophthalmia (11%) (Giseman and Herce, 2016). We...
propose that Porcn inactivation around the eye field stage represents a novel mouse model recapitulating severe microphthalmia and anophthalmia in humans. Porcn<sup>CHET</sup> female embryos do not display an apparent ocular phenotype compared to few embryos with germline inactivation of one Porcn allele (Bankhead et al., 2015). The late dosage reduction of Porcn, combined with variable mosaic X inactivation, may cause a failure to induce ocular defects in Porcn<sup>CHET</sup> at this critical developmental stage.

**Conclusion**

Using temporally controlled, conditional inactivation in mouse, our studies reveal a novel role for Porcn in regulating growth and morphogenesis of the optic vesicle and optic cup, via a requirement in proliferation, survival, and regionalization of ocular gene expression, recapitulating severe microphthalmia in FDH.
