ABSTRACT

Pulmonary hypertension (PH) is a debilitating condition defined as mean pulmonary arterial pressure (mPAP) ≥ 25 mmHg. The importance of impaired right ventricular (RV) hemodynamics is increasingly being recognized in treatment of patients with PH. In World Health Organization Group 1 patients with pulmonary arterial hypertension, upfront combination therapy has recently been proposed to improve long-term survival. Also, the mPAP in Group 2 and 3 PH patients has been shown to be strongly associated with clinical outcomes. Thus, screening and monitoring of RV hemodynamics are becoming increasingly important. The gold standard for measuring RV hemodynamics is right heart catheterization (RHC). Although RHC can obtain the most accurate results, it is invasive, cumbersome to patients, and often associated with complications, making it unsuitable for a screening or monitoring modality. Echocardiography is useful in estimating hemodynamic parameters that can be obtained from RHC. Accordingly, the role of echocardiography in evaluating such patients with PH is becoming more important. In this article, we review practical echocardiographic methods in approximating RV hemodynamics for PH.

Keywords: Pulmonary hypertension; Mean pulmonary artery pressure; Echocardiography

INTRODUCTION

Pulmonary hypertension (PH) is defined as mean pulmonary arterial pressure (mPAP) ≥ 25 mmHg at rest measured by right heart catheterization (RHC). PH has numerous different causes with distinct clinical phenotypes. The World Health Organization has thus classified PH into five different categories according to underlying pathophysiology: PH due to pulmonary arterial hypertension (PAH) (Group 1), left heart disease (Group 2), lung disease (Group 3), pulmonary artery obstruction (Group 4), and unclear and/or multifactorial mechanisms (Group 5), as shown in Table 1.

The importance of impaired right ventricular (RV) hemodynamics in relation to clinical outcomes is increasingly being recognized in treatment of patients with PH. The role of echocardiography in hemodynamic screening and monitoring in PH patients is thus emerging. In PAH, the impacts of early screening and upfront combination therapy on...
Table 1. The World Health Organization classification of pulmonary hypertension

| WHO classification | Description                                |
|--------------------|-------------------------------------------|
| Group 1            | Pulmonary artery hypertension              |
| Group 2            | PH due to left heart disease               |
| Group 3            | PH due to lung disease                     |
| Group 4            | Chronic thromboembolic PH                  |
| Group 5            | PH with unclear and/or multifactorial mechanisms |

PH: pulmonary hypertension, WHO: World Health Organization.

Table 2. Echocardiographic methods of estimating mean pulmonary artery pressure

| Measurement            | View (modality) | Formula                                      | Abnormal value                                      | Description                                                                 |
|------------------------|-----------------|----------------------------------------------|------------------------------------------------------|-----------------------------------------------------------------------------|
| Peak TR velocity       | A4C             | RVsP = PASP = 4(peak TR velocity)² + RAP    | RVsP > 37 mmHg                                       | Whether the Doppler angle aligns with the CW is important.                  |
|                        | PSAX            | mPAP = (0.61 × PASP) + 2 mmHg                | mPAP > 25 mmHg                                       | The highest point of the TR envelope should be measured.                    |
| RVOTₜ₀                 | PSAX (PW)       | mPAP = 90 – (0.62 × RVOTₜ₀)                  | RVOTₜ₀ < 130 ms                                      | Obtained at end expiration. Sample volume is placed just proximal to the pulmonary cusp on the RV side. Opening snap is included. Closing snap is not included. Important to measure from beginning to end of flow but not the slope. Correction for HR is required for HR > 110 bpm or HR < 70 bpm. Useful when TR is not observed. |
| Peak PR Doppler signal | PSAX (PW)       | mPAP = 4(peak PR velocity)² + RAP           | Peak PR > 2.2 m/s                                    | May be unreliable in constrictive or restrictive physiology.               |
| PR end velocity        | PSAX (PW)       | mPAP = 2/3 × PADP + 1/3 × PASP               | PADP = (0.61 × PASP) + 2 mmHg                         | End PR velocity is measured in multiple cycles and averaged. May be underestimated in severe PH.      |
| TR TVI                 | A4C             | mPAP = TR pressure gradient (TR TVI) + RAP   |                                                       | TR measurement is not possible in all patients. Values derived from the method are closely related with the mPAP of RHC patients. |
|                        | PSAX            |                                              |                                                       |                                                                            |
| RV inflow (CW)         |                 |                                              |                                                       |                                                                            |

A4C: apical 4-chamber view, CW: continuous-wave, HR: heart rate, mPAP: mean pulmonary artery pressure, PADP: pulmonary artery diastolic pressure, PASP: pulmonary artery systolic pressure, PH: pulmonary hypertension, PR: pulmonary regurgitation, PSAX: parasternal short axis view, PW: pulse-wave, RAP: right atrial pressure, RHC: right heart catheterization, RV: right ventricle, RVOT: right ventricular outflow tract, RVOTₜ₀: right ventricular outflow tract acceleration time, RVsP: right ventricular systolic pressure, TR: tricuspid regurgitation, TVI: time velocity interval.
Peak tricuspid regurgitation velocity

The mPAP can be calculated by measuring peak tricuspid regurgitation (TR) velocity. TR peak velocity can be analyzed in the inflow view of the parasternal long axis (PLAX), the parasternal short axis (PSAX) view, and the apical 4-chamber (A4C) view using continuous wave (CW) Doppler (Table 2 and Figure 1A).

The peak TR velocity reflects the pressure gradient (PG) between the RV and right atrium (RA). Using a modified Bernoulli equation, the PG between RA and RV can be estimated from the peak velocity of TR between the two chambers: peak PG = 4 × (peak TR velocity)².6,7 Thus, RV systolic pressure (RVsP) is defined as the sum of RAP and peak PG.

The RVsP or pulmonary arterial systolic pressure (PASP) can be estimated by the following formula: RVsP = PASP = 4(peak TR velocity)² + RAP when there is no pulmonary stenosis. RAP in this formula is determined by the diameter of the inferior vena cava (IVC) and the percentage of collapse during inspiration. When IVC diameter ≤ 2.1 cm and collapses > 50% with inspiration, the RAP is assumed to be 3 mmHg (range, 0-5 mmHg). RAP is estimated to be 15 mmHg (range, 10-20 mmHg) when the IVC diameter > 2.1 cm with ≤ 50% collapse by inspiration, or 8 mmHg (range, 5-10 mmHg) for all other conditions.8 The calculated RVsP can then be interpreted by itself or further converted to mPAP using the following formula: mPAP = 0.61 × RVsP + 2 mmHg.9 RVsP > 37 mmHg and mPAP > 25 mm Hg are suggestive of PH.9 A summary is shown in Table 2.

There are several tips for obtaining optimal results for peak TR velocity. First, all available views, such as RV inflow, PLAX, PSAX, and A4C views, should be evaluated to find the plane parallel to the TR jet to avoid underestimation of peak TR velocity. Identifying TR flow
through color flow Doppler is advised. Secondly, it is helpful to understand that some patients have no or trivial TR even in the presence of PH. Agitated saline injection from the peripheral vein can augment the Doppler signal, although TR is often overestimated.

**Peak and end diastolic pulmonary regurgitation velocity**

Although the pulmonary regurgitation (PR) velocity method is not routinely used in clinical practice, it is useful when the TR signal is inadequate. PR is evaluated in the PSAX view using CW Doppler. The Doppler beam should be aligned to the PR jet to avoid underestimation. The beginning and end of the PR signal are measured; the beginning of the PR signal is the peak PR velocity, whereas the end of the PR signal is the end diastolic PR velocity (Table 2 and Figure 1C).

The peak PG between the RV outflow tract and the main pulmonary artery (MPA) is added to the RAP to estimate mPAP when using the peak PR velocity. The mPAP is approximated by the following formula: mPAP = 4(peak PR velocity)$^2$ + RAP. When end diastolic PR is measured, mPAP is estimated by the following formula involving pulmonary artery diastolic pressure (PADP): mPAP = 2/3 × PADP + 1/3 × PASP. PADP is defined as the sum of end diastolic PG and RAP: PADP = 4(end diastolic PR velocity)$^2$ + RAP. The formulas are summarized in Table 2. Peak PR velocity > 2.2 m/s is regarded as elevated mPAP.

**Right ventricular outflow tract acceleration time**

The RV outflow tract acceleration time (RVOT$_{AT}$) is measured in the PSAX view using pulse-wave (PW) Doppler. It is measured at the end of expiration by placing the sample volume just proximal to the pulmonary valve. The RVOT$_{AT}$ is measured from the beginning of the flow to the peak of the flow (Table 2 and Figure 1B).

The mPAP using RVOT$_{AT}$ is estimated using formulas suggested by Dabestani et al. In a patient with a heart rate between 60 and 100 beats per minute and RVOT$_{AT}$ < 120 msec, mPAP is estimated by the following formula: mPAP = 79 – (0.45 × RVOT$_{AT}$). In cases of severe PH, the RVOT$_{AT}$ shortens, such that the following formula gives more accurate estimations of mPAP: mPAP = 90 – (0.62 × RVOT$_{AT}$). RVOT$_{AT}$ > 130 ms is considered normal, while < 100 ms is regarded as elevated mPAP.

It is important to know that the time of acceleration, but not the slope, is measured in RVOT$_{AT}$. Thus, locating the beginning and peak is of critical importance, rather than identifying the slope between the beginning and peak of the signal.

**Tricuspid regurgitation time velocity integral**

An alternative method using TR for mPAP estimation was suggested by Aduen et al., for 1) the paucity of patients with PR or 2) the low reproducibility and correlation between pulmonary systolic time intervals and RHC-measured mPAP. The echocardiographic process of measuring mPAP using the current method is identical with that of the peak TR velocity method for estimating RVsP, except for the time velocity integral (TVI) of the CW TR envelope (Table 2 and Figure 1D).

The mPAP is the RAP added to the PG between the RV and RA: mPAP = PG + RAP. The PG is measured by the TVI of the CW TR flow. Agitated saline injection may be helpful in patients with an incomplete TR envelope.
ECHOCARDIOGRAPHIC FEATURES SUGGESTIVE OF IMPAIRED RV FUNCTION

In the following section, aspects other than the mPAP for estimating RV dysfunction are introduced. Echocardiographic methods that analyze RV dysfunction in terms of pulmonary artery size, RV size, RV longitudinal motion, and global RV performance are reviewed (Table 3, Figure 2, and Figure 3).

Pulmonary artery diameter
Dilated MPA is a sign of PH. MPA is analyzed in PSAX view and measured midway between the pulmonary valve and pulmonary arterial bifurcation (Table 3 and Figure 2A). Dilated MPA is defined as MPA > 25 mm by guidelines.

Left ventricular eccentricity index
In patients with PH, flattening of the interventricular septum (IVS) or a D-shaped left ventricle (LV) is observed due to the high RV pressure and delay in the time to peak RV contraction causing asynchrony between ventricles. The LV eccentricity index is measured in the PSAX view between the mitral valve and the papillary muscle level. The axis parallel to the IVS (D1) and the minor axis perpendicular to the IVS (D2) are measured (Table 3 and Figure 2B).

Table 3. Echocardiographic methods of estimating impaired right ventricular function

| Measurement                  | View (modality) | Measured location                                                                 | Formula and abnormal value                              | Description                                                                 |
|------------------------------|-----------------|-----------------------------------------------------------------------------------|----------------------------------------------------------|-----------------------------------------------------------------------------|
| Pulmonary artery diameter    | PSAX (2D)       | Measured at the mid-level between pulmonary valve and bifurcation of right and left pulmonary arteries | Pulmonary artery diameter > 25 mm measured at end-diastole | Dilates in volume or pressure overload conditions                           |
| LV eccentricity index        | PSAX (2D)       | Measured in the middle of pulmonary valve and bifurcation of right and left pulmonary arteries | D1: axis parallel to IVS                                 | At end-diastole, D2/D1 > 1.1 suggests volume overload                      |
|                              |                 |                                                                                   | D2: axis perpendicular to IVS                             | At end-systole, D2/D1 > 1.1 suggests pressure overload                      |
|                              |                 |                                                                                   | LV eccentricity index = D2/D1                            |                                                                             |
|                              |                 |                                                                                   | D2/D1 > 1.1 suggests either pressure or volume overload   |                                                                             |
| TAPSE                        | A4C (M-mode)    | Measured by the cursor aligned in the direction of the lateral tricuspid annulus in M-mode. | TAPSE < 1.7 suggests RV dysfunction                      | Longitudinal motion is measured.                                            |
|                              |                 | The distance of the tricuspid annulus level between peak systole and end-diastole is measured. |                                                                 | Results are unreliable in patients with volume overload.                   |
| RV FAC                       | RV-focused A4C  | Planimetered area of the RV is measured at end-systole and end-diastole.         | RV FAC = (RVA_s - RVA_d) / RVA_d × 100                   | Measures an estimate of global RV function.                                |
|                              | (2D)            |                                                                                   | RV FAC < 35% suggests RV systolic dysfunction            |                                                                             |
| RV dimensions                | RV-focused A4C  | Diameters at the base (RVD1) and mid (RVD2) level are measured at end-diastole.   | RVD1 > 41 mm                                            | Progressive dilatation of RV is measured in patients with PH.              |
|                              | (2D)            |                                                                                   | RVD2 > 35 mm                                            |                                                                             |
| RV pulsed tissue Doppler S wave (S') velocity | A4C (PW and TDI) | Measured by the cursor aligned in the direction of the lateral tricuspid annulus in TDI mode in systole | S’ < 9.5 cm/s suggests RV dysfunction                    | Lateral RV free wall and the lateral tricuspid annulus must be aligned with the tissue Doppler direction. |
| RV wall thickness            | Subcostal view  | RV wall should be aligned perpendicular to the ultrasound beam at the level of the tricuspid valve leaflet. | RV wall thickness > 0.5 cm                              | M-mode can be used to measure RV thickness at end-diastole                 |
The D2 to D1 ratio is defined as the eccentricity index: Eccentricity index = D1/D2. The end-systolic LV eccentricity index is increased in pressure-overload situations, whereas the end-diastolic LV eccentricity index is increased in volume-overload conditions. LV eccentricity index > 1.1 in end-systole is considered abnormal.

1) Tricuspid annular plan excursion
The longitudinal RV motion along the axis can be assessed for RV function evaluation. One of the most widely used methods is tricuspid annular plane excursion (TAPSE), defined as the maximal excursion of the M-mode cursor with the cursor in the direction of the RV lateral annulus, between the end-diastole and peak systole (Table 3 and Figure 2C).

Figure 2. Echocardiographic methods for evaluating RV function. Assessment of MPA diameter (A); left ventricular eccentricity index (B); TAPSE (C); and RV fractional area change by measuring RVA\textsubscript{d} and RVA\textsubscript{s} for assessment of RV function (D). D1: axis parallel to interventricular septum, D2: axis perpendicular to interventricular septum, MPA: main pulmonary artery, RV: right ventricle, RVA\textsubscript{d}: RV area at diastole, RVA\textsubscript{s}: RV area at systole, TAPSE: tricuspid annular plane excursion.

Figure 3. Additional echocardiographic methods for evaluating RV function. RV function can be estimated by evaluating the RV dimensions (A); and RV pulsed tissue Doppler S wave (S') velocity (B). RV: right ventricular, RVD1: basal diameter of RV measured at the basal one-third of the RV, RVD2: RV diameter measured at the left ventricular papillary muscle level.

The D2 to D1 ratio is defined as the eccentricity index: Eccentricity index = D1/D2. The end-systolic LV eccentricity index is increased in pressure-overload situations, whereas the end-diastolic LV eccentricity index is increased in volume-overload conditions. LV eccentricity index > 1.1 in end-systole is considered abnormal.\textsuperscript{1)
TAPSE < 1.7 cm is regarded as RV systolic dysfunction.\(^{20}\)

**Right ventricular fractional area change**

The RV fractional area change (RV FAC) is measured in the A4C view by the planimetered area of the RV end-systole and end-diastole (Table 3 and Figure 2D). This gives an estimate of the global RV systolic function that has good correlation with RHC-measured mPAP.\(^{19}\) The RV area is obtained by tracing the RV endocardium from the annulus, along the free wall to the apex, and then back to the annulus, along the IVS.\(^{29}\) However, it is difficult to measure RV FAC in patients with prominent RV trabeculation because it is hard to define endocardial borders in such patients.\(^{20}\)

The RV FAC is measured by manually tracking the endocardial border of the RV in end-systole and end-diastole. The RV FAC is defined by the following formula: RV FAC = (RV area at end-diastole – RV area at end-systole)/RV area at end-diastole × 100.\(^{10}\) RV FAC < 35% is considered RV systolic dysfunction.\(^{10}\)

**Right ventricular dimensions**

In patients with PH, the RV is usually dilated due to the increase of preload and afterload.\(^{36,47}\) PH can be estimated using linear measurements of the RV dimensions in the RV-focused A4C view (Table 3 and Figure 3A).\(^{10}\) There may be technical difficulties because RV is a three-dimensional structure in which the RV outflow tract protrudes out of the echocardiographic A4C plane.

The RV diameter 1 (RVD1) is defined as the basal diameter of the RV, measured at the basal one-third of the RV. The RV diameter 2 (RVD2) is measured at the LV papillary muscle level. RVD1 > 41 mm and RVD2 > 35 mm are considered abnormal.\(^{13}\) All measurements are performed in end-diastole.

**Right ventricular tissue Doppler systolic (S’) velocity**

Measurement of the systolic (S’) velocity of the tricuspid lateral annulus using tissue Doppler imaging is similar to that of TAPSE. As in TAPSE measurement, the PW cursor is placed in the direction of the lateral tricuspid annulus in the RV-focused A4C view, and tissue Doppler imaging is performed (Table 3 and Figure 3B).\(^{21}\) The lateral RV free wall and the lateral tricuspid annulus have to be aligned with the Doppler direction to avoid underestimation of the S’ signal.\(^{8}\) Although the current method is reproducible and easy to perform, some studies have shown that decreased S’ may not be representative of whole RV function in patients with regional wall abnormality of the RV.\(^{8}\) S’ velocity < 9.5 cm/sec is regarded as abnormal RV systolic function.\(^{9,30}\)

**Right ventricular wall thickness**

RV thickness can be measured as a surrogate for PH, although a thick RV wall can be present in the absence of PH, such as in infiltrative diseases.\(^{23}\) In the subcostal view, the RV wall should be aligned perpendicular to the ultrasound beam at the level of the tricuspid valve leaflet. M-mode can be used to measure RV thickness at end-diastole.\(^{9}\) One should be cautious to exclude pericardial fat or thickened pericardium from RV thickness measurements. The normal cut-off value is 0.5 cm in the subcostal or PLAX view.\(^{9}\)
CONCLUSIONS

The importance of evaluating PH in patients with heart or lung diseases is emerging. Echocardiography can play a critical role in detecting or screening PH, as various methods have been introduced. It is important to understand the basic concepts and methodology for performing such echocardiographic measurements.
