Abstract
Nonlocality and quantum entanglement constitute two special aspects of the quantum correlations existing in quantum systems, which are of paramount importance in quantum-information theory. Traditionally, they have been regarded as identical (equivalent, in fact, for pure two qubit states, that is, Gisin’s Theorem), yet they constitute different resources. Describing nonlocality by means of the violation of several Bell inequalities, we obtain by direct optimization those states of two qubits that maximally violate a Bell inequality, in terms of their degree of mixture as measured by either their participation ratio $R = 1/\text{Tr}(\rho^2)$ or their maximum eigenvalue $\lambda_{\text{max}}$. This optimum value is obtained as well, which coincides with previous results. Comparison with entanglement is performed too. An example of an application is given in the XY model. In this novel approximation, we also concentrate on the nonlocality for linear combinations of pure states of two qubits, providing a closed form for their maximal nonlocality measure. The case of Bell diagonal mixed states of two qubits is also extensively studied. Special attention concerning the connection between nonlocality and entanglement for mixed states of two qubits is paid to the so-called maximally entangled mixed states. Additional aspects for the case of two qubits are also described in detail. Since we deal with qubit systems, we will perform an analogous study for three qubits, employing similar tools. Relation between distillability and nonlocality is explored quantitatively for the whole space of states of three qubits. We finally extend our analysis to four-qubit systems, where nonlocality for generalized Greenberger–Horne–Zeilinger states of arbitrary number of parties is computed.

1. Introduction

Schrödinger’s [1] modern notion of entangled states historically appeared within the debate of the paradox posed by Einstein, Podolsky and Rosen (EPR) [2]. EPR pointed out the possible lack of completeness of the newborn theory of quantum mechanics. In their famous paper, they suggested a description of nature (called ‘local realism’) which assigns an independent and objective reality to the properties of separated parties of a composite physical system. EPR applied the criterion of local realism to predictions associated with an entangled state, a state that cannot be described solely in terms of the properties of its subsystems, to conclude that quantum mechanics was incomplete. Schrödinger, instead, regarded entanglement as the characteristic feature of quantum mechanics. Quantitatively though, no measure for this ‘quantum strangeness’ was provided at the time.

The most significant progress toward the resolution of the EPR debate came with Bell’s work. Bell [3, 4] proved the impossibility of reproducing all correlations observed in composite quantum systems using models similar to that of EPR. In fact, Bell showed that local realism, in the form of local variable models (LVM), implies constraints on the predictions of spin correlations in the form of inequalities, also known as Bell’s inequalities, which can be violated by quantum mechanics. That is why quantum mechanics is regarded as being inherently nonlocal.

If quantum mechanics could be described by LVM, then the correlation values measured between parties could be reproduced assuming that the corresponding operators had already a definite value previous to measurement. Let us consider the case of the two-party two-outcome scenario. Two distant observers possessing a distributed state $\rho_{AB}$ exploit the correlations arising from

$$P(a, b|A, B; \rho_{AB}) = \text{Tr}[\rho_{AB}(\Pi^A_a \otimes \Pi^B_b)]$$

quantum mechanically. $\Pi^A_a$ and $\Pi^B_b$ are the positive operators involving measurements of observables $A$ and $B$, with outcomes $a$ and $b$ satisfying $A\Pi^A_a = a\Pi^A_a$ and $B\Pi^B_b = b\Pi^B_b$. If a LVM could mimic the same correlations

$$P(a, b|A, B; \rho_{AB}) = \sum_\lambda P(a|A, \lambda)P(b|B, \lambda)\mu(\lambda),$$

with $\mu(\lambda)$ being a probability measure for the classical variable $\lambda$, and $P(a|A, \lambda)$ and $P(b|B, \lambda)$ local functions, then the use of state $\rho_{AB}$ would provide no improvement over classical resources. Thus, it was clear that the notion of nonlocality of a state $\rho_{AB}$ would emerge if no LVM existed there that through (2) could reproduce the quantum mechanical results of (1). Nonlocality was a character of entangled states via the violation of a Bell inequality.

Ever since Bell’s contribution, entanglement and nonlocality became similar terms. The nonlocal character of entangled states was clear for pure states. In fact, all entangled pure states of two qubits violate the CHSH inequality and therefore are nonlocal [5]. The situation became more involved when Werner [6] discovered that while entanglement is necessary for a state to be nonlocal, for mixed states it is not sufficient. He also introduced the usual (modern) definition of entangled state: given two parties $A$ and $B$, a shared state $\rho_{AB}$ is termed unentangled or separable if it cannot be expressed as the mixture of product states:

$$\rho_{AB} = \sum_{i=1}^{N} p_i |\psi^A_i\rangle\langle \psi^A_i | \otimes |\psi^B_i\rangle\langle \psi^B_i |,$$

that is, when its preparation does not require a nonlocal quantum resource. This definition, in spite of its clear physical meaning, is somewhat impractical, since tests to distinguish separable from entangled states are complicated.
With the advent of quantum-information theory (QIT), the interest in entanglement has dramatically increased over the years since it lies at the basis of some of the most important processes and applications studied by QIT such as quantum cryptographic key distribution [7], quantum teleportation [8], superdense coding [9] and quantum computation [10, 11], among many others which possess no classical counterpart. All these tasks require distributed quantum correlations between parties, and the only means available in nature are entangled states. Using a modern nomenclature, when a quantum state cannot be prepared using only local operations and classical communications (LOCC), it is said that it possesses quantum correlations and the state is entangled. Spatially separated observers sharing an entangled state and performing measurements on them may induce nonlocal correlations which cannot be simulated by local means (violate Bell inequalities).

Confusion between nonlocality and entanglement appeared during the finer study of the usefulness of quantum correlations. Entanglement is commonly viewed as a useful resource for various information-processing tasks. Yet, there exist certain tasks, such as device-independent quantum key distribution [12] and quantum communication complexity problems [13], which can only be carried out provided the corresponding entangled states exhibit nonlocal correlations. Then we are naturally led to the question of whether nonlocality and entanglement constitute two different resources.

Also, the role of the nonlocality—be it linked or not to the concept of entanglement—has been recently revisited in the light on new concepts and interesting results, such as a tool for inferring information about the state of the system independently of any hypothesis on the dimensionality of the concomitant Hilbert space [14], the concept of dimension witness [15, 16] and even an extension of the previous witness so as to generalize [17] the Grothendieck’s constant that appears in the theory of Banach spaces.

Since the formalization by Werner of the modern concept of quantum entanglement, it has become clear that there exist entangled states that comply with all Bell inequalities. This entails that nonlocality, associated with Bell inequalities violation, constitutes a non-classicality manifestation exhibited only by just a subset of the full set of states endowed with quantum correlations. Later work by Zurek and Ollivier [18] established that not even entanglement captures all aspects of quantum correlations. These authors introduced an information-theoretical measure, quantum discord, that corresponds to a new facet of the ‘quantumness’ that arises even for non-entangled states. Indeed, it turned out that the vast majority of quantum states exhibit a right amount of quantum discord. The tripod nonlocality–entanglement–quantum discord is of obvious interest for a complete understanding of quantum correlations. However, in this work, we shall focus only on the first two parts. Nevertheless, some work has recently appeared that tackles nonlocality and quantum discord (see [19] and references therein).

The purpose of this work is to shed some light upon the relation between entanglement and nonlocality through the maximal violation of a Bell inequality for two-, three- and four-qubit systems. Throughout the paper, and in order to avoid confusion, we will refer to the quantity ‘nonlocality-degree’ as being equivalent to ‘maximum violation of a Bell inequality’. However, the usual meaning of nonlocality (or that of a nonlocal state) as a concept involving the mere violation of a Bell inequality remains the same. Although detection and characterization of entanglement are far from being complete, its status is more developed than that of nonlocality. The problems experienced in defining a unique measure of entanglement in the multipartite case, in the form of partitions in the system, disappear in the nonlocality case since there exist well-defined Bell inequalities for multipartite systems of arbitrary number of qubits. This fact makes the study of nonlocality conceptually and quantitatively easier. By means of a general optimization technique, our intention is to obtain known results for two-qubit states and to
extend this formalism to multiparty-qubit states so as to derive new outcomes, thus providing a natural and unified picture for the study of nonlocality.

This paper is organized as follows. In section 2, we review recent results concerning nonlocality degree in bipartite physical systems and concentrate on the CHSH Bell inequality [20] for two qubits. We also obtain, after a direct optimization over the observers’ settings, the family of two-qubit mixed states that optimizes the violation of the CHSH inequality for a given degree of mixture, as well as the concomitant optimal value for CHSH. This novel approach recovers and extends previous results found in the literature. Our results concerning the connection between nonlocality degree and entanglement for mixed states of two qubits also pay special attention to the case of the so-called maximally entangled mixed states (MEMS). As far as the duality entanglement nonlocality is concerned, these very same results find interesting echoes in a well-known condensed matter system, namely, the infinite XY model.

How nonlocality degree can be present in linear combinations of pure states of two qubits is also reported, where the optimal value of the violation of the CHSH inequality is obtained for any given superposition. Parallelism with the role of entanglement of superposition is also discussed. Section 3 is devoted to the study of entanglement and nonlocality degree for three-qubit systems, employing similar tools. Relation between distillability and nonlocality is explored quantitatively for the whole space of states of three qubits. Section 4 extends the present subject of study to four-qubit systems, where nonlocality degree for generalized Greenberger–Horne–Zeilinger (GHZ) states of arbitrary number of parties is computed. Finally, some conclusions are drawn in section 5.

2. Two qubits

2.1. Nonlocality and the CHSH Bell inequality

LVM cannot exhibit arbitrary correlations. Mathematically, the conditions these correlations must obey can always be written as inequalities—the Bell inequalities—satisfied for the joint probabilities of outcomes. We say that a quantum state \( \rho \) is nonlocal if and only if there are measurements on \( \rho \) that produce a correlation that violates a Bell inequality.

Most of our knowledge on Bell inequalities and their quantum mechanical violation is based on the CHSH inequality [20]. With two dichotomic observables per party, it is the simplest [21] (up to local symmetries) nontrivial Bell inequality for the bipartite case with binary inputs and outcomes. Let \( A_1 \) and \( A_2 \) be two possible measurements on the A side whose outcomes are \( a_j \in \{-1, +1\} \), and similarly for the B side. Mathematically, it can be shown that, following LVM (2), \( |B_{\text{LVM}}^{\text{CHSH}}(\lambda)| = |a_1 b_1 + a_1 b_2 + a_2 b_1 - a_2 b_2| \leq 2 \). Since \( a_1(b_1) \) and \( a_2(b_2) \) cannot be measured simultaneously, instead one estimates, after randomly chosen measurements, the average value \( B_{\text{LVM}}^{\text{CHSH}}(\lambda) \mu(\lambda) = E(A_1, B_1) + E(A_1, B_2) + E(A_2, B_1) - E(A_2, B_2) \), where \( E(\cdot) \) represents the expectation value. Therefore the CHSH inequality reduces to

\[
|B_{\text{LVM}}^{\text{CHSH}}(\lambda)| \leq 2.
\]

Tsirelson showed [22] that CHSH inequality (4) is maximally violated by a multiplicative factor \( \sqrt{2} \) (Tsirelson’s bound) on the basis of quantum mechanics. In fact, it is true that
What is the maximum violation of \( B_{2.2} \)? Maximal violation of the CHSH inequality and mixedness for two qubits in two-qubit systems.

A good witness of useful correlations is, in many cases, the violation of a Bell inequality by a quantum state. But not all entangled states are nonlocal. Although this is the case for pure states of two qubits (CHSH inequality violation), Werner showed that it cannot be generalized to mixed states. After introducing the states which are now called Werner states

\[
\rho_W = \rho|\psi^-(\psi^-)| + (1 - \rho)\frac{I}{4},
\]

where \(|\psi^-\rangle\) is the singlet state and \(I\) is the \(4 \times 4\) identity, he provided a LVM for measurement outcomes for some entangled states of this family. Although promising new results have been obtained recently [24, 25], even in the simplest case of Werner states of two qubits (6), it is in general extremely difficult to determine whether an entangled state has a LVM or not, since finding all Bell inequalities is a computationally hard problem [26, 27].

Therefore, we shall consider the optimization of the violation of the CHSH inequality over the observer’s settings as a definitive measure for both signaling and quantifying nonlocality in two-qubit systems.

2.2. Maximal violation of the CHSH inequality and mixedness for two qubits

What is the maximum violation of \( B_{\text{CHSH}} = \text{Tr}(\rho B_{\text{CHSH}}) \leq 2 \) for a given state \( \rho \)?

This problem was initially addressed for an arbitrary quantum state of two qubits [28], but revisited here as a starting point for further study for more than two parties. Before any attempt to proceed with a definite optimization program, we shall undertake a detailed analysis of the special form for \( B_{\text{CHSH}} = \text{Tr}(\rho B_{\text{CHSH}}) \), the basic quantity we are about to deal with.

The nature of any bipartite mixed state of two qubits is described by a positive, semi-definite matrix, whose eigenvalues \( \{\lambda_i\} \) are such that \( 0 \leq \lambda_i \leq 1 \) and \( \sum \lambda_i = 1 \). In other words, the complete description of the density matrix \( \rho \) necessitates \( 4^2 - 1 = 15 \) real parameters.

Usually, the preferred basis for two-qubit states is the so-called computational basis \([|00\rangle, |01\rangle, |10\rangle, |11\rangle]\). In our case, it will prove convenient to employ the so-called Bell basis of maximally correlated states, which are of the form

\[
|\Phi^\pm\rangle = \frac{(|00\rangle \pm e^{i\theta}|11\rangle)}{\sqrt{2}}, \quad |\Psi^\pm\rangle = \frac{(|01\rangle \pm e^{i\theta}|10\rangle)}{\sqrt{2}}.
\]

Now we raise the question of whether all elements of \( \rho \) intervene in the computation of \( B_{\text{CHSH}} \). Given a state \( \rho \), we make a change of basis so that we work in the Bell basis. For simplicity, and without loss of generality, we shall take real coefficients \( (\theta = 0 \text{ in } (7)) \). Due to the special form of (5), we separate the elements of \( \rho \) (now in the Bell basis) into two contributions, namely

\[
\rho = \rho_I + \rho_\perp = \begin{pmatrix}
\rho_{11} & i\rho_{12} & i\rho_{13} & \rho_{14}^R \\
-i\rho_{12}^* & \rho_{22}^R & \rho_{23}^R & i\rho_{24}^R \\
-i\rho_{13}^* & \rho_{23}^R & \rho_{33}^R & i\rho_{34}^R \\
\rho_{14}^R & -i\rho_{24}^* & -i\rho_{34}^* & \rho_{44}^R
\end{pmatrix} + \begin{pmatrix}
0 & \rho_{12}^R & i\rho_{13}^R & \rho_{14}^R \\
\rho_{12}^R & 0 & i\rho_{23}^R & \rho_{24}^R \\
-i\rho_{13}^R & 0 & \rho_{34}^R & 0 \\
i\rho_{14}^R & \rho_{24}^R & \rho_{34}^R & 0
\end{pmatrix}.
\]
This separation is motivated by the fact that only terms in $\rho_1$ contribute to $\text{Tr}(\rho B_{\text{CHSH}})$, as one can easily check. In other words, $\text{Tr}(\rho B_{\text{CHSH}}) = \text{Tr}(\rho_1 B_{\text{CHSH}}) + \text{Tr}(\rho_2 B_{\text{CHSH}}) = \text{Tr}(\rho_1 B_{\text{CHSH}})$. The superscripts of the matrix elements in (8) refer to the concomitant real (R) and imaginary (I) parts. This observation constitutes the starting point of our study. Let us provide an explicit example. Suppose we are given a state $\rho$ diagonal in the computational basis $\text{diag}(\lambda_1, \lambda_2, \lambda_3, \lambda_4)$, with eigenvalues $\lambda_i$ appearing in the decreasing order. Switching from computational to Bell basis, the state now has the form

$$
\begin{pmatrix}
\frac{\lambda_1 + \lambda_2}{2} & \frac{\lambda_1 - \lambda_2}{2} & 0 & 0 \\
\frac{\lambda_1 - \lambda_2}{2} & \frac{\lambda_1 + \lambda_2}{2} & 0 & 0 \\
0 & 0 & \frac{\lambda_2 + \lambda_3}{2} & \frac{\lambda_2 - \lambda_3}{2} \\
0 & 0 & \frac{\lambda_3 + \lambda_4}{2} & \frac{\lambda_3 - \lambda_4}{2}
\end{pmatrix}.
$$

Comparing state (10) with general decomposition (8), we immediately see that such a state behaves as if it were diagonal in the Bell basis, since other contributions do not intervene. In point of fact, and advancing results, the maximal violation of the CHSH inequality for such states diagonal in the computational basis is $2(2(\lambda_1 + \lambda_4) - 1)]$.

The answer to the initial question of this section involves only the elements of $\rho_1$ for $\rho$ in (8). The latter fact enormously simplifies the computation, but we nevertheless encounter a highly nontrivial optimization enterprise.

Fortunately, we do not require all elements of $\rho_1$. Instead, since we seek maximum nonlocality degree, we will consider states which are diagonal in the Bell basis (null elements off-diagonal in $\rho_1$ (8)), for nonlocal correlations concentrate after some depolarizing process [29].

Previous authors computed the entanglement and the maximum violation for the Bell inequality for Bell diagonal states [30], and the particular form for these states [31]. Also, we find an interesting discussion in [32] within the context of security in device-independent quantum key distribution. In this work, we re-obtain and extend their results by means of a specific optimization technique, which is described in full detail in appendix A. Since the plan of work of this effort is to present a unified view of entanglement and nonlocality degree for several qubits, our results obtained via a precise optimization procedure naturally recover previous ones for two-qubit states, such as the maximum amount of nonlocality degree for Bell diagonal states and the relation between maximum concurrence and nonlocality degree [30, 32] and the form [31] for those states, which is improved here.

For diagonal states in the Bell basis

$$
\rho_{\text{Bell}}^{(\text{diag})} = \lambda_1 |\Phi^+\rangle\langle\Phi^+| + \lambda_2 |\Phi^-\rangle\langle\Phi^-| + \lambda_3 |\Psi^+\rangle\langle\Psi^+| + \lambda_4 |\Psi^-\rangle\langle\Psi^-|,
$$

with eigenvalues appearing in decreasing order, we obtain

$$
\max_{a, b} \text{Tr}(\rho_{\text{Bell}}^{(\text{diag})} B_{\text{CHSH}}) = 2\sqrt{2}\sqrt{(\lambda_1 - \lambda_4)^2 + (\lambda_2 - \lambda_3)^2}.
$$

Recall that $2\sqrt{2}$ is the maximum value allowed by quantum mechanics (attained only for states (7)).

We are going to determine the maximum expectation value of the CHSH operator (5) that a two-qubit mixed state $\rho$ with some degree of mixedness, in this case given by the so-called participation ratio $R = 1/\text{Tr}(\rho^2)$, may have. Note that no assumption is needed regarding the state being diagonal or not in the Bell basis, though in order to obtain the specific form for the optimal $\rho^*$ some further information will be required. In order to solve the concomitant variational problem (and bearing in mind that $B_{\text{CHSH}} = \text{Tr}(\rho B_{\text{CHSH}})$), let us first find the state that extremizes $\text{Tr}(\rho^2)$ under the constraints associated with a given value of $B_{\text{CHSH}}$, and the normalization of $\rho$. This variational problem can be cast as
\[ \delta \left[ \text{Tr}(\rho^2) + \beta \text{Tr}(\rho B_{\text{CHSH}}) - \alpha \text{Tr}(\rho) \right] = 0, \]

where \( \alpha \) and \( \beta \) are appropriate Lagrange multipliers.

The solution of the above variational equation is given by

\[ \rho^* = \frac{1}{2} \left[ \alpha I - \beta B_{\text{CHSH}} \right], \]

with \( I \) being the \( 4 \times 4 \) identity matrix. The value of the Lagrange multiplier \( \alpha \) is immediately obtained by the normalization requirement, with \( \alpha = \frac{1}{2} \). That is, we have

\[ \rho^* = \frac{1}{2} \left[ I + \langle B_{\text{CHSH}} \rangle_{B_{\text{CHSH}}} \right]. \]

From (14) we find \( B_{\text{CHSH}} \), multiply it by \( \rho \) and apply the corresponding definition of \( B_{\text{max}}^{\text{CHSH}} \), taking into account that \( \text{Tr}(\rho^2) = \frac{1}{R} \).

We arrive at the result

\[ B_{\text{max}}^{\text{CHSH}} = \text{Tr}(\rho^* B_{\text{CHSH}}) = -\frac{2}{\beta} \cdot \frac{4 - R}{4R}. \]

By either squaring (14) and taking the trace according to the definition of \( R \), or rather multiplying it by \( B_{\text{CHSH}} \) (\( B_{\text{CHSH}} \) is traceless) in order to get \( B_{\text{max}}^{\text{CHSH}} \), both ways lead to \( \beta = -\frac{\rho_{\text{max}}}{8} \). Combining either the former or the latter result with relation (16), we finally arrive at

\[ B_{\text{max}}^{\text{CHSH}} = \sqrt{\text{Tr}[B_{\text{max}}^{\text{CHSH}}]}, \sqrt{\frac{4 - R}{4R}} = 4 \cdot \sqrt{\frac{4 - R}{4R}}. \]

This result is valid for the range \( R \in [2, 4] \). The outcome (17) of the previous variational problem needs not be valid for the whole range of \( R \), since no requirement of this kind is made explicit in the optimization beforehand. Furthermore, since the variation is made on the state \( \rho \) and not on the particular settings of the observers appearing in the operator \( B_{\text{CHSH}} \), the procedure only ensures that \( \rho^* \) (15) will possess the right functional form, which is that of \( B_{\text{CHSH}} \) in the Bloch representation of a two-qubit state. Indeed, expanding terms in \( B_{\text{CHSH}} \), we obtain that

\[ \langle B_{\text{CHSH}} \rangle_{B_{\text{CHSH}}} = \sum_{i,j} T_{ij} \sigma_i \otimes \sigma_j, \]

where \( T_{ij} = \text{Tr}^\dagger(\sigma_i \otimes \sigma_j) \) are components of the correlation tensor, which already expresses the expected fact that no local correlations appear in the final result (15).

The requirement of maximum nonlocality degree implies that state (15), in view of (18), must possess maximally mixed marginals (i.e., the reduced states of individual qubits are completely mixed). Such a state is locally equivalent under some local unitarity of the form \( U_A \otimes U_B \), to the state

\[ \rho' = \frac{1}{4} \left[ I + \sum_{i,j} t_{ij} \sigma_i \otimes \sigma_j \right]. \]

Note that we have zero off-diagonal elements in tensor \( T_{ij} \). Not surprisingly, states (19) are of the type (11), that is, diagonal in the Bell basis. Explicitly, we encounter the concomitant eigenvalues to be

\[ \lambda_1 = \frac{1}{2}(1 + t_1 - t_2 + t_3) \]
\[ \lambda_2 = \frac{1}{2}(1 - t_1 + t_2 + t_3) \]
\[ \lambda_3 = \frac{1}{2}(1 + t_1 + t_2 - t_3) \]
\[ \lambda_4 = \frac{1}{2}(1 - t_1 - t_2 - t_3). \]

\[ 4 \] It can be shown by induction that \( B_{\text{max}}^{2^{n+1}} = 4^n B_{\text{max}}^{\text{CHSH}} \) and \( B_{\text{max}}^{2^n} = 4^n I_4 \), where \( I_4 \) is the \( 4 \times 4 \) identity matrix.
Among all Bell diagonal states that concentrate nonlocality degree in \( R \in [2, 4] \) (that is rank-4 states), the supremum can be reached for several configurations of \( \vec{t} = (t_1, t_2, t_3) \). One such case is \( \vec{t} = (0, 0, t_3) \). Defining \( x = \frac{1}{4}(1 + t_3) \), the corresponding state (14) can now be cast, following (20), in the new form
\[
\rho_{II} = \text{diag} \left( x, x, \frac{1 - 2x}{2}, \frac{1 - 2x}{2} \right),
\]
with \( x \in [0, \frac{1}{2}] \) and diagonal in the Bell basis.

In the region \( R \in [1, 2] \) (that is rank-2 states), one possible optimum configuration is \( \vec{t} = (t_1, -t_1, 1) \). With \( x = \frac{1 - t_1}{2} \), the corresponding state (14) is, after (20), of the form
\[
\rho_I = \text{diag}(1 - x, x, 0, 0)
\]
with \( x \in [0, \frac{1}{2}] \). Note that it is the simplest case of a state diagonal in the Bell basis with low-purity values for \( R \). Relation (12) returns
\[
B_{\text{max}}^{\text{CHSH}}(\rho_I) = 2\sqrt{2}(1 - x)^2 + x^2 = \sqrt{\frac{8}{R}}.
\]

We are now in a position to answer the initial question of this section. We do not find the functional form for \( B_{\text{max}}^{\text{CHSH}}(R) \) for two qubits, but we do obtain the form for those states which are diagonal in the Bell basis. We shall call these states maximally nonlocal mixed states (MNMS). All previous calculations are supported by numerical evidence.

For a given value of the participation ratio \( R \), we can obtain a more general class of states rather than \( \rho_I \) (22) and \( \rho_{II} \) (21) by letting a non-zero phase \( \theta \) in (7). By doing so, and rewriting the concomitant MNMS states \( \rho_I \) (22) in the computational basis, one easily obtains the family of states provided in [31]. But not only this, a whole series of new states possessing maximum nonlocality degree for a given value of \( R \) is obtained by changing the position of the eigenstates of \( \rho_I \) in (22). This is possible since no preferred disposition of states in the Bell basis is required for diagonal states (11) as far as maximum amount of nonlocality degree is concerned (different optimum configurations of \( \vec{t} = (t_1, t_2, t_3) \) are allowed).

Let us summarize all previous results: the maximum amount of nonlocality degree attained by a mixed state \( \rho \) of two qubits is given by

- Mixedness described by the participation ratio \( R = 1/\text{Tr}(\rho^2) \)
  \[
  B_{\text{max}}^{\text{CHSH}}(R) = \sqrt{\frac{8}{R}}, \quad R \in [1, 2]
  \]
  \[
  B_{\text{max}}^{\text{CHSH}}(R) = 4 \cdot \sqrt{\frac{4 - R}{4R}}, \quad R \in [2, 4].
  \]

- Mixedness described by the maximum eigenvalue \( \lambda_{\text{max}}(\rho) \)
  \[
  B_{\text{max}}^{\text{CHSH}}(\lambda_{\text{max}}) = (4\lambda_{\text{max}} - 1), \quad \lambda_{\text{max}} \in \left[ \frac{1}{4}, \frac{1}{3} \right]
  \]
  \[
  B_{\text{max}}^{\text{CHSH}}(\lambda_{\text{max}}) = \sqrt{\frac{\lambda_{\text{max}}^2 + (1 - 3\lambda_{\text{max}})^2}{2}}, \quad \lambda_{\text{max}} \in \left[ \frac{1}{3}, \frac{1}{2} \right]
  \]
  \[
  B_{\text{max}}^{\text{CHSH}}(\lambda_{\text{max}}) = \sqrt{\frac{\lambda_{\text{max}}^2 + (1 - \lambda_{\text{max}})^2}{2}}, \quad \lambda_{\text{max}} \in \left[ \frac{1}{2}, 1 \right].
  \]
For the sake of comparison, Werner states possess a maximum violation of the CHSH inequality of the form \( \frac{1}{2} (4 \lambda_{\text{max}} - 1) \), which lie below all expressions in (25). One must bear in mind that states that reach the maximum possible value for nonlocality-degree measure \( B_{\text{CHSH}} \) greatly depend on what measure for the degree of mixture is employed. That is, states that maximize nonlocality degree versus \( R \) need not be necessarily valid for any other degree of mixture, \( \lambda_{\text{max}} \) in our case. For the \( \lambda_{\text{max}} \) instance, the corresponding variational method is more involved and highly non-trivial. For instance, the second expression in (25) corresponds to the Bell diagonal state \( \text{diag}(x, x, 1-2x, 0) \) for \( x \in \left[ \frac{1}{4}, \frac{1}{2} \right] \), which has no \( R \)-counterpart. That is, maximum nonlocality-degree measure \( B_{\text{CHSH}}^{\text{max}} \) versus \( \lambda_{\text{max}} \) states do not correspond to maximum nonlocality-degree measure \( B_{\text{CHSH}}^{\text{max}} \) versus participation ratio \( R \) states. The only case where both descriptions agree is for those states that strictly violate the CHSH inequality, namely, the MNMS \( \rho_{\text{MNS}} \) (22), which for all practical purposes is the case we are interested in. It can be easily obtained by noting that \( \lambda_{\text{max}} = 1 - x \) for MNMS \( \rho_{\text{MNS}} \) (22), from where we rewrite (23) in the final form of the last expression in (25). Thus, it is implied that for sufficiently low-purity values both descriptions coincide.

2.3. Nonlocality for maximally entangled mixed states

Maximally entangled mixed states (MEMS) constitute a family of states that are maximally entangled for a given degree of mixture, measured by the participation ratio \( \lambda_{\text{max}} \). In practice, one will more often have to deal with mixed states than with pure ones. From the point of view of entanglement exploitation, one should then be interested in MEMS states which are basic constituents of quantum communication protocols. The MEMS states have been studied, for example, in [33–35]. MEMS states have been experimentally encountered [36, 37]. In the computational basis \{\ket{00}, \ket{01}, \ket{10}, \ket{11}\}, they are written as

\[
\begin{pmatrix}
g(x) & 0 & 0 & x/2 \\
0 & 1 - 2g(x) & 0 & 0 \\
x/2 & 0 & 0 & g(x)
\end{pmatrix},
\]

with \( g(x) = 1/3 \) for \( 0 \leq x \leq 2/3 \), and \( g(x) = x/2 \) for \( 2/3 \leq x \leq 1 \). The quantity \( x \) is equal to the concurrence \( C \). The change of \( g(x) \)-regime ensues for \( R = 1.8 \).

Our goal is to uncover interesting correlations between entanglement, nonlocality degree and mixedness that emerge for these states. Indeed, the study of the nonlocality of these states offers an excellent framework to compare the extremal cases for nonlocality degree and entanglement. The MEMS states (26) are written in the Bell basis \{\ket{\Phi^+}, \ket{\Phi^-}, \ket{\Psi^+}, \ket{\Psi^-}\} in the form

\[
\begin{pmatrix}
g(x) + \frac{x}{2} & 0 & 0 & 0 \\
0 & g(x) - \frac{x}{2} & 0 & 0 \\
0 & 0 & \frac{1-2g(x)}{2} & \frac{1-2g(x)}{2} \\
0 & 0 & \frac{1-2g(x)}{2} & \frac{1-2g(x)}{2}
\end{pmatrix},
\]

which is to be compared with the general form for arbitrary states (8) in the Bell basis. The direct comparison of MEMS states in the Bell basis yields the conclusion that states \( \rho_{\text{MEMS}} \) (27) behave as if they were diagonal in the Bell basis as far as nonlocality degree is concerned.

This crucial observation allows us to carry out the simple calculation of the maximum amount of nonlocality degree for MEMS states, which is of the form

\[
B_{\text{CHSH}}^{\text{max}}(x) = \begin{cases}
\frac{1}{2} \left( \sqrt{1 + 9x^2} - 1 \right), & 0 \leq x \leq \frac{1}{2} \\
\frac{1}{2} \sqrt{2x^2}, & \frac{1}{2} < x \leq 1 
\end{cases}
\]

(28)
Recall that \( x = C \), the so-called concurrence. Also, it is clear from relation (28) that any bipartite state possessing \( x > \frac{1}{\sqrt{2}} \) will violate the CHSH inequality, since no state is more entangled than the MEMS states. In other words, our optimization procedure is such that by means of explicitly computing the nonlocality degree for MEMS states, we re-obtain the result of [30, 31]: no arbitrary mixed entangled state of two qubits violates the CHSH inequality unless its concurrence is greater than \( \frac{1}{\sqrt{2}} \).

The concurrence entanglement indicator \( C \) for MNMS states \( \rho_{IJ} \) (22) can be easily calculated to be \( C = 1 - 2x \). Therefore, the relation between nonlocality degree \( B_{\text{CHSH}}^\text{max} \) and \( C \) is such that \( B_{\text{CHSH}}^\text{max} = 2\sqrt{1 + C^2} \), which easily recovers a previous result [30]. In other words, for a given value of \( C \), MNMS states possess the maximum possible violation of the CHSH inequality, while, on the contrary, MEMS possess a minimum amount of CHSH violation \( (2\sqrt{1 + C^2} > 2\sqrt{2}C) \).

As a consequence, we draw the conclusion that maximum entanglement for mixed states of two qubits does not imply maximum nonlocality degree, though in this extremal case nonlocality degree and entanglement are monotonically increasing functions of one another.

2.4. A physically motivated case: the XY model

The general study of nonlocality and entanglement in an infinite quantum system was performed in [38]. In this section, we incorporate new results and generalize previous ones in the light of the bounds encountered for the maximum violation of the CHSH Bell inequality for a given degree of mixture.

The general two-site density matrix for two spins along the XY chain is expressed as

\[
\rho_{ij}^{(R)} = \frac{1}{4} \left[ I + \sum_{u,v} T_{uv}^{(R)} \sigma_u^i \otimes \sigma_v^j \right].
\]  (29)

\( R = j - i \) indicates the distance between spins (not to be confused with the participation ratio \( R = 1/\text{Tr}(\rho^2) \), \{u, v\} denote any index of \{\( \sigma_0, \sigma_x, \sigma_y, \sigma_z \)\} and \( T_{uv}^{(R)} = (\sigma_u^i \otimes \sigma_v^j) \). Due to symmetry considerations, only \( \{T_{xy}^{(R)}, T_{yx}^{(R)}, T_{zz}^{(R)}, T_{zz}^{(R)}\} \) do not vanish. Barouch et al [39] provided exact expressions for two-point correlations, together with all the dynamics associated with an external magnetic field \( h(t) \) along the z-axis. We shall consider the case where \( h \) jumps from an initial value \( h_0 \) to a final value \( h_f \) at \( t = 0 \), that is, a quench (the equilibrium case is easily recovered when \( h_f = h_0 \) and the \( R = 1 \) configuration (nearest neighbors).

The most remarkable result of [38] as far as nonlocality degree is concerned is that the maximum value for the quantity \( B_{\text{CHSH}}^\text{max} \) for states (29), given by twice the expression

\[
\sqrt{\| T^{(R)} \|^2 - \min\{[T_{xx}^{(R)}]^2, [T_{yy}^{(R)}]^2, [T_{zz}^{(R)}]^2\}} + 2[T_{xy}^{(R)}]^2
\]  (30)

with \( T^{(R)} = (T_{xx}^{(R)}, T_{yy}^{(R)}, T_{zz}^{(R)}) \), is always \( \leq 2 \) for any configuration \( R \) and any non-zero value of the entanglement.

Figure 1 depicts several time evolutions for state (29) once a quench in the external magnetic field is applied. As a consequence, we have a nonergodic evolution in time, which translates into diminishing oscillating values for both \( B_{\text{CHSH}}^\text{max} \) and \( R \). This fact is by no means surprising: abrupt changes in the external magnetic field (such as the considered step functions) cause the system to undergo an evolution where the final state \( \rho(t \to \infty) \) differs from the expected equilibrium value. That is why we describe a quantity as being 'nonergodic'. The previous time-dependent cases correspond to figures 1(a) and (b), where \( B_{\text{CHSH}}^\text{max} \) versus \( R \) different configurations evolve in such a way that the maximum possible values defined by MNMS states are never crossed.
Figure 1. (a) Value of $B_{\text{max}}^{\text{CHSH}}$ versus the participation ratio $R = 1/\text{Tr}(\rho^2)$ for several time evolutions of the external perpendicular magnetic field in the time-dependent XY model. The solid (red) curve corresponds to the case ($h_0 = 0.5$, $h_f = 0$). From left to right, both $B_{\text{max}}^{\text{CHSH}}$ and $R$ oscillate around their concomitant final (non-equilibrium) values. The lower dashed (green) curve depicts the case ($h_0 = 0.75$, $h_f = 0$), with similar behavior. Note that in either case the maximum value of $B_{\text{max}}^{\text{CHSH}}(R)$ (upper solid line) is never crossed. This is so because it corresponds to MNMS states.

(b) Similar curves for ($h_0 = 1$, $h_f = 0$) (red solid curve) and ($h_0 = 2$, $h_f = 0$) (lower green dashed curve).

The static case ($h_f = h_0$) is depicted in figure 2(a), where nonlocality degree improves for states approaching the Ising case ($\gamma = 1$). Several time evolution plots appear in figure 2(b) for $B_{\text{max}}^{\text{CHSH}}$ and the entanglement of formation for states (29), together with the thermodynamic magnetization $M_z$ after a quench from $h_0 = 0.5$ to $h_f = 0$. All these three quantities possess nonergodic behavior, which is not surprising for they ultimately depend on two-point spin correlators, which in turn are nonergodic quantities [38].

In figure 3, we consider the maximum value for $B_{\text{max}}^{\text{CHSH}}$ and the concurrence $C$ that any state of the type (29) can have. The value for the factorizing field $h_s = \sqrt{1 - \gamma^2}$ for which states (29) are separable [39] corresponds to zero concurrence, that is, a line at the bottom of the plot. In the language of mixedness, the magnetic field $h$ and the mixture of the state go in opposite directions: the greater the former, the lesser the latter. This is so because as $h \to \infty$, we approach a pure state ($R = 1$) with both spins down. In the surface $\gamma = \text{constant}$ we encounter that both $B_{\text{max}}^{\text{CHSH}}$ and $C$ diverge (their first derivative with respect to $h$), thus signaling a quantum phase transition (except for the isotropic case $\gamma = 0$).

As we can see, the notion of nonlocality degree and entanglement as different resources appear in a real physical system. The necessity of the violation of some Bell inequality for some information-theoretic tasks and its relation to entanglement makes the whole picture a bit more intriguing with this physical case.

2.5. Nonlocality versus entanglement for linear combinations of pure states of two qubits

Nonlocality degree may also exhibit interesting features for pure states. In our case, we shall consider states of the form

$$|\phi\rangle = \sqrt{\lambda_1}|\Phi^+\rangle + \sqrt{\lambda_2}|\Phi^-\rangle + \sqrt{\lambda_3}|\Psi^+\rangle + \sqrt{\lambda_4}|\Psi^-\rangle,$$

(31)
Figure 2. (a) $B_{\text{max}}^\text{CHSH}$ versus the participation ratio $R = 1/\text{Tr}(\rho^2)$ plots for several anisotropy values (from bottom to top) $\gamma = 0, 0.1, 0.3, 0.5, 1$. As the magnetic field $h$ increases from 0 to $\infty$ (which entails no time evolution), the curves follow a path from right to left (decreasing $R$-values for the two-qubit states). It is plain from this series of plots that no violation of the CHSH Bell inequality occurs (all curves lie below 2). (b) Time evolution of $B_{\text{max}}^\text{CHSH}$ (lower solid red curve), entanglement $E$ (long-dashed green curve) and the magnetization $M_z$ (short-dashed blue curve) after the quench ($h_0 = 0.5, h_f = 0$). $E$ and $M_z$ have been shifted two units upwards. All these three quantities are nonergodic.

with real coefficients $\{\sqrt{\lambda_i}\}$. This particular form clearly constitutes an extension of the analysis performed for two-qubit mixed states diagonal in the Bell basis. All the details of the optimization of the CHSH inequality for states (31) is given in appendix A. The final result is

$$2\sqrt{2}\sqrt{(\lambda_1 + \lambda_4)^2 + (\lambda_2 + \lambda_3)^2}. \quad (32)$$

We know by virtue of Gisin’s theorem [5] that pure bipartite entanglement implies violation of the CHSH inequality. The question is wether that dependence changes when we consider the case of linear combinations. The corresponding answer is no, because otherwise it would imply a prefered choice for the state basis.

The value (32) for maximum violation of the CHSH inequality is to be compared with the measure of entanglement for state (31)

$$C^2 = 4\det \rho_{A/B} = 1 - 4(\lambda_1 + \lambda_4)(\lambda_2 + \lambda_3). \quad (33)$$

Strictly speaking, the concurrence and its squared value $C^2$ are not proper measures of entanglement, for they do not comply with the usual basic requirements [40]. However, they are widely used as useful entanglement quantifies (they are monotonic functions of the entanglement of formation $E_f(\cdot)$ [41], which is a good measure).

Taking into account the form for $C^2$ (33), and the value for $B_{\text{max}}^\text{CHSH}$ (32), we derive the relation

$$B_{\text{max}}^\text{CHSH} = \sqrt{4C^2 + 4}, \quad (34)$$

which is the same result we would obtain for a pure state of two qubits written in the Schmidt basis. Had we assumed result (34) to hold for any state (which is the case), we would have obtained the relation (32) for the maximum violation of the CHSH inequality without recourse to any optimization technique.
Figure 3. Plot of the nonlocality-degree measure $B_{\text{max}}^{\text{CHSH}}$ (upper surface) and twice the concurrence $C$ (lower surface) for any value of the anisotropy $\gamma$ and the external perpendicular magnetic field $h$ for two-qubit states (nearest neighbors) in the $XY$ model. It is plain that no violation of the CHSH Bell inequality occurs, regardless of the non-zero value for the entanglement indicator $C$.

Formula (32) has interesting echoes when compared to the entanglement of the same superposition of states. Entanglement of superposition of states was originally conceived in [42], where interesting bounds for the superposed state were obtained in terms of their constituents. In our case, result (32) permits us to establish similar bounds for maximum violation of the CHSH inequality. This framework offers a link between the characterization of nonlocality degree and entanglement, where their mutual intricacies become more apparent.

As obtained before, we know by virtue of Gisin’s theorem [5] that nonlocality implies entanglement (and vice versa) for pure two-qubit states, but nothing is said regarding their particular characterization. Let us illustrate, before embarking on our study, what happens when we consider the nonlocality degree present in the superposed state

$$|\theta\rangle = \alpha|01\rangle + \beta|\Phi^+\rangle,$$

with $B_{\text{max}}^{\text{CHSH}}(|01\rangle) = 2$ and $B_{\text{max}}^{\text{CHSH}}(|\Phi^+\rangle) = 2\sqrt{2}$. Presumably, the nonlocality degree of the state $|\theta\rangle$ should be lowered by the action of non-correlated $|01\rangle$. Indeed, we have

$$B_{\text{max}}^{\text{CHSH}}(|\theta\rangle) = 2\sqrt{2} - \alpha^2(2 - \alpha^2) = 2\sqrt{2} - \sqrt{2}\alpha^2 + O(\alpha^4).$$

This example shows that $B_{\text{max}}^{\text{CHSH}}$ and the fidelity between states within the linear combination simultaneously and continuously change, a fact that does not occur for the entanglement of linear combination of states [42].

**Theorem 1.** Given a set of $M$ orthogonal pure states of two qubits $|\phi_i\rangle_{i=1}^M$, with $\sum_{i=1}^M \alpha_i^2 = 1$ ($\alpha_i \in R$), the concomitant maximum nonlocality-degree measure obeys

$$B_{\text{max}}^{\text{CHSH}} \left( \sum_{i=1}^M \alpha_i |\phi_i\rangle \right) \geq \sum_{i=1}^M (\alpha_i)^4 B_{\text{max}}^{\text{CHSH}}^2 (|\phi_i\rangle).$$

13
Proof. Spanning the set of states \(|\phi_i\rangle\) in the Bell basis, by recourse to (32) and expanding quadratic terms, the remaining part on the right-hand side is a strictly positive quantity, from whence we directly compute the nonlocality degree of superposition as stated in theorem 1. The upper bound for \(B_{\text{max}}^{\text{CHSH}}(\sum_i \alpha_i |\phi_i\rangle)\) is easily obtained by individually optimizing each term in the argument \(|\phi_i\rangle\), and taking into account each contribution arising from \(2\text{Re}[B_{\text{max}}^{\text{CHSH}}(|\phi_i\rangle)]\), \(\forall i \neq j\). □

Theorem 1 and the concomitant upper bound connect the way the nonlocality degree of a superposed state is distributed among its constituents, in a similar fashion as entanglement in [42]. More details on superposition of states will be described elsewhere [43].

3. Three qubits

3.1. Nonlocality for three-qubit states

We shall explore nonlocality in the three-qubit case through the violation of the Mermin inequality [44]. This inequality was conceived originally in order to detect genuine three-party quantum correlations impossible to reproduce via LVMs. The Mermin inequality reads as

\[
\text{Tr}(\rho B_{\text{Mermin}}) \leq 2,
\]

where

\[
B_{\text{Mermin}} = B_{a_1a_2a_3} - B_{a_1b_2b_3} - B_{b_1a_2b_3} - B_{b_1b_2a_3},
\]

with \(B_{uvw} \equiv u \cdot \sigma \otimes v \cdot \sigma \otimes w \cdot \sigma\), with \(\sigma = (\sigma_x, \sigma_y, \sigma_z)\) being the usual Pauli matrices, and \(a_j\) and \(b_j\) unit vectors in \(\mathbb{R}^3\). Note that the Mermin inequality is maximally violated by GHZ states. As in the bipartite case, we shall define the following quantity:

\[
\text{Mermin}^{\text{max}} \equiv \max_{a_j, b_j} \text{Tr}(\rho B_{\text{Mermin}})
\]

as a measure for the nonlocality degree of the state \(\rho\). While in the bipartite case the CHSH inequality was the strongest possible one, this is not the case for three qubits. The Mermin inequality is not the only existing Bell inequality for three qubits, but it constitutes a simple generalization of the CHSH one to the tripartite case. Therefore, it will suffice to use this particular inequality to illustrate the basic results of this work.

In view of the previous definitions, we are naturally led to the question of what class of three-qubit mixed states possesses a maximum amount of nonlocality degree (39), how does it look like and what it amounts for. Let us recall that the family of pure states of three qubits \(|\Psi_j^\pm\rangle = (|j\rangle \pm |7-j\rangle)/\sqrt{2}\) forms a basis, the so-called GHZ basis or Mermin basis, and that these states maximally violate the Mermin inequality. But what is the state of affairs for the general, mixed case? Given a state \(\rho\), it can always be transformed into the state

\[
\rho_{\text{Mermin}}^{(\text{diag})} = \sum_{j=0}^{3} \lambda_j^+ |\Psi_j^+\rangle \langle \Psi_j^+ | + \lambda_j^- |\Psi_j^-\rangle \langle \Psi_j^- |,
\]

a state which is diagonal in the Mermin basis, for nonlocal correlations concentrate after the action of some depolarizing process [29]. Without loss of generality, we can assume the eigenvalues of (40) to be sorted in decreasing order, that is, \(\lambda_0^+ \geq \lambda_0^- \geq \cdots \geq \lambda_3^+ \geq \lambda_3^-\), since otherwise it could be adjusted by a local unitary operation.

The details of the optimization are given in appendix B. However, the maximum violation of the Mermin inequality is given by the quantity

\[
\text{Mermin}^{\text{max}} \leq 4 \sqrt{\sum_{j=0}^{3} (\lambda_j^+ - \lambda_j^-)^2}.
\]
The exact form for Mermin$^{\text{max}}$ is rather unpleasant. In practice, the previous bound is an excellent one, differing from the exact one by a small amount and being equal in those cases where we have a high degree of symmetry in the state. For most practical purposes, one can consider the equality in (41) to hold.

We can also encounter interesting nonlocality degree features if we focus our attention on the case of pure states of three qubits being linear combinations in the Mermin basis $|\Psi^\pm_j\rangle = (|j\rangle \pm |7 - j\rangle)/\sqrt{2}$. That is, states of the form

$$|\phi\rangle = \sum_{j=1}^{8} \sqrt{\lambda_j} |\Psi^\pm_j\rangle,$$

(42)

with real coefficients $\{\sqrt{\lambda_j}\}$ such that $\sum_{j=1}^{8} \lambda_j = 1$.

The detection and characterization of entanglement in multipartite systems constitutes a hot research topic in QIT. However, no necessary and sufficient criterion is available to date that discriminates whether a given state of a multipartite system is entangled or not. Indeed, highly entangled multipartite states arouse enormous interest in quantum information processing and one-way universal quantum computing [45]. They are essential for several quantum error codes and communication protocols [46], as they are robust against decoherence.

In spite of the previous unbalanced present status between entanglement and nonlocality degree, the relation between both quantities for three qubits is seen in a new light when we study both resources for those states that attain the maximum possible nonlocality degree value given by expression (41). One way is to consider what class of particular states is maximally nonlocal for a given value of their degree of mixture, which is a tool employed to characterize mixed states. If we choose the participation ratio $R = 1/\text{Tr}(\rho^2)$, we can obtain what is the functional form of (41) in terms of $R$.

This procedure is virtually identical to the variational calculation performed for two-qubit mixed states. Following the exact treatment as in equation (13), and taking into account that $\text{Tr}[B_{\text{Mermin}}^2] = 32$, we obtain

$$\text{Mermin}^{\text{max}}(R) \propto \sqrt{8 - R/8R},$$

(43)

The constant in (43) is obtained by requiring Mermin$^{\text{max}}$ to be equal to 4 for pure states ($R = 1$). One class of states that possesses the previous optimal value is $\rho_{\text{diag}}^{\text{max}} = (1 - 7x, x, x, x, x, x, x, x)$, which is, interestingly enough, the generalized Werner state for three qubits

$$\rho_{\text{w}}^{\text{max}} = \tilde{x}|\text{GHZ}\rangle\langle\text{GHZ}| + \frac{1 - \tilde{x}}{8}I_8,$$

(44)

where $I_8$ is the $8 \times 8$ identity matrix and $\tilde{x} = 1 - 8x$. Note that this was not the case for the two-qubit instance.

This interesting feature enables us to discuss the different ranges for $R$ where to compare the nonlocality degree and the presence of genuine tripartite entanglement. On one hand, from (43) we obtain the nonlocality critical value $R_1 = 32/11 \approx 2.9$: no three-qubit states possess any nonlocality for participation ratios $R \geq R_1$. On the other hand, the special nature of generalized Werner states allows us to compute the separability threshold between entanglement and separability [47]. From [47], the contribution $\tilde{x}$ in (44) is such that $x \leq 1/5$ involves the absence of entanglement. Translated into $R$-language, it implies a second critical value $R_2 = 25/4 = 6.25$: no three-qubit states possess entanglement for participation ratios $R \geq R_1$. 

15
Therefore, the range of $R$-values splits into three regions: i) between 1 (pure states) and $R_1$, maximum amounts of nonlocality degree imply the presence of entanglement; ii) between $R_1$ and $R_2$, we have no violation of the Mermin inequality, yet entanglement exists; finally, iii) a region between $R_2$ and $R = 8$ (maximally mixed state) displays the absence of both magnitudes. Note, however, that in appearance there is some room left for LVM to hold in the second region, where no violation of the Mermin inequality occurs.

The exploration of nonlocality and entanglement for three-qubit states in a physical model can be revisited in the light of their applicability, such as the possible information-theoretic tasks limitations imposed by the former on the latter. There is one such case, which is the well-known infinite $XY$ model in a transverse magnetic field [39]. This instance was explored in detail in [38].

The $XY$ model is completely solvable, a fact that allows us to compute the reduced density matrix for three spins without the explicit construction of the global infinite state of the system. The reduced state of three spins reads as

$$\rho_{ijk}^{(a,b)} = \frac{1}{8} \left[ I + \sum_{u,v,w} T_{uvw}^{(a,b)} \sigma_u^i \otimes \sigma_v^j \otimes \sigma_w^k \right],$$  \hspace{1cm} (45)

where $i < j < k$ indicate the positions of the three spins and $a = j - i$, $b = k - j$ their relative distances. $\{u, v, w\}$ denote indices of the Pauli matrices $\{\sigma_0, \sigma_x, \sigma_y, \sigma_z\}$, and $T_{uvw}^{(a,b)} \equiv \langle \sigma_u^a \otimes \sigma_v^b \otimes \sigma_w^k \rangle_{ab}$. The calculation of the three-spin correlations $T_{uvw}^{(a,b)}$ was computed in [38] by using the Wick theorem in quantum field theory.

The most significant result is that, for any value of the anisotropy and external magnetic field, we have Mermin$_\text{max}$ to be less than or equal to

$$\sqrt{4(T_{zzz}^{(a,b)})^2 + 4(T_{zxx}^{(a,b)})^2 + 4(T_{xzx}^{(a,b)})^2 + 4(T_{xxz}^{(a,b)})^2},$$  \hspace{1cm} (46)

which is always $\leq 2$ for any configuration of the spins $(a, b)$ yet there is no null entanglement. This constitutes a clear sign that states (45) never violate the Mermin inequality, which entails an inherent limitation to the usefulness of entanglement itself. Furthermore, these states are shown to be distillable in most of the cases, which is a novel result: we have three-party distillable states in the $XY$ model with no violation of the Mermin inequality. The distillability issue constitutes the subject of the following section.

### 3.2. Distillability and nonlocality for three-qubit states

The distillability and the violation of Bell inequalities—nonlocality—constitute two manifestations of entanglement. While the former is related to the usefulness in quantum information processing tasks, due to the fact that most of them require pure-state entanglement as a key ingredient, the latter expresses the fact that a state cannot be simulated by classical correlations. In this vein, Gisin relates both resources when he points out in [48] the question of whether there exists any bound entangled state that violates some Bell inequality. By bound entangled state one implies a state that cannot be distilled by means of LOCC. In the bipartite case, it has been shown [49] that no bound state violates the CHSH inequality.

The separability criteria borrowed from the bipartite case, which employ positive partial transposition [50] for all parties, are all approximate. Nevertheless, this criterion based on the positivity of the ensuing partially transposed matrix $\rho^{T_j}$ has a very interesting application. Note that if a three-qubit state $\rho$ has positive $\rho^{T_j}$ for all $j = 1, 2, 3$, where $T_j$ represents partial transposition for the system $j$, then it is said that the state is GHZ distillable, that is, one can distill a GHZ state from many copies of $\rho$ by LOCC [51].
One of the questions that we want to address is whether there exists any nonlocal bound entangled state of three qubits. After applying a series of local transformations, one can convert any state into one belonging to the family $\rho_{\text{diag}}$ (40). For a state of three qubits to be non-distillable (bound entangled), any of the subsequent following inequalities must hold:

$$\rho_{T_1} > 0 \Rightarrow \begin{cases} \lambda_1^+ + \lambda_3^- > \lambda_2^+ - \lambda_1^- \\ \lambda_2^+ + \lambda_3^- > \lambda_0^+ - \lambda_0^- \\ \Rightarrow \lambda_1^+ + \lambda_3^- < \frac{1}{2} \end{cases}$$

$$\rho_{T_2} > 0 \Rightarrow \begin{cases} \lambda_1^+ + \lambda_3^- > \lambda_2^+ - \lambda_1^- \\ \lambda_2^+ + \lambda_3^- > \lambda_0^+ - \lambda_0^- \\ \Rightarrow \lambda_0^+ + \lambda_1^- < \frac{1}{2} \end{cases}$$

$$\rho_{T_3} > 0 \Rightarrow \begin{cases} \lambda_1^+ + \lambda_3^- > \lambda_3^+ - \lambda_2^- \\ \lambda_3^+ + \lambda_3^- > \lambda_1^+ - \lambda_2^- \\ \Rightarrow \lambda_3^+ + \lambda_3^- < \frac{1}{2} \end{cases}$$

where the last inequality in each case is a consequence of the sum of the previous two. None of the previous inequalities for the eigenvalues of states diagonal in the Mermin basis is compatible with (39) being greater than 2, which implies that no bound entangled state is present in Mermin-diagonal mixed states of three qubits that violates the Mermin inequality.

A complementary Monte Carlo numerical survey was performed over a set of $10^9$ sample states generated with a uniform distribution for the set $\{\lambda_i\}$ of the concomitant eigenvalues in order to further investigate the portion of the corresponding Hilbert space that violates the Mermin inequality. That is, we generate diagonal states in the Mermin basis and compute the quantity $\text{Mermin}^{\max}$. This exhaustive, random exploration confirms the previous result on bound entangled states and nonlocality. Figure 4 depicts the obtained probability (density) distribution for nonlocality-degree measure $\text{Mermin}^{\max}$ (39). Note the strong biased behavior toward no Mermin inequality violation, as well as the relative scarcity of those states with some nonlocality degree.

A previous work [52] also considered the connection between distillability and violation of the Mermin inequality for three qubits. It was concluded there that for a particular four-parameter three-qubit states, nonlocality implied Mermin distillability. With our analysis, which embraces a more general class of states, we find that this is not the case. In point of
fact, our numerical exploration obtains a probability 0.293 to find distillable states with no violation of the Mermin inequality, whereas the states being distillable and achieving some nonlocality nearly possess a zero measure (probability of 0.008). The vast majority of states are found, with probability 0.698, both bound entangled and with no violation of the Mermin inequality. In view of our results, it seems plausible to assume that mixed states of three qubits with high amounts of Mermin nonlocality degree, which are likely to be Mermin diagonal, possess no bound entanglement and are thus non-distillable.

4. Four qubits

The first Bell inequality for four qubits was derived by Mermin, Ardehali, Belinskii and Klyshko [53]. It constitutes four parties with two dichotomic outcomes, each being maximum for the generalized GHZ state \((|0000\rangle + |1111\rangle)/\sqrt{2}\). The Mermin–Ardehali–Belinskii–Klyshko (MABK) inequality reads as \(\text{Tr}(\rho B_{\text{MABK}}) \leq 4\), where \(B_{\text{MABK}}\) is the MABK operator

\[
B_{1111} - B_{1112} - B_{1121} - B_{2111} - B_{1122} - B_{1212} - B_{2112} - B_{2121} - B_{2211} + B_{2222} + B_{2221} + B_{2212} + B_{1222},
\]

with \(B_{\alpha\beta\gamma\delta} \equiv \alpha \cdot \sigma \otimes \beta \cdot \sigma \otimes \gamma \cdot \sigma \otimes \delta \cdot \sigma\) with \(\sigma = (\sigma_x, \sigma_y, \sigma_z)\) being the usual Pauli matrices. As in previous instances, we shall define the following quantity:

\[
\text{MABK}_{\text{max}} \equiv \max_{a_j, b_j} \text{Tr}(\rho B_{\text{MABK}})
\]

as a measure for the nonlocality-degree content for a given state \(\rho\) of four qubits. \(a_j\) and \(b_j\) are unit vectors in \(R^3\). MABK inequalities are such that they constitute extensions of previous inequalities with the requirement that generalized GHZ states must maximally violate them. New inequalities for four qubits have appeared recently (see [54]) that possess some other states required for optimal violation. In this study we limit our interest to the MABK inequality, although new ones could be incorporated in order to offer a broader perspective. However, with respect to entanglement, little is known for the quadripartite case, and thus little comparison can be done.

4.1. Nonlocality for four-qubit states: extension to generalized GHZ states

The maximization of the MABK inequality \(\text{Tr}(\rho B_{\text{MABK}}) \leq 4\) for four-qubits mixed states is done along similar lines as previously performed for bipartite and tripartite cases. Demanding maximum amount of nonlocality degree (49) is tantamount to computing their optimum values for those states that concentrate nonlocal correlations. In the case of four qubits, those maximally correlated states are the ones which are diagonal in the Bell4 basis defined by \(|\Psi_j^\pm\rangle = (|j\rangle \pm |15 - j\rangle)/\sqrt{2}\). Therefore we shall consider the following class of four-qubits mixed states:

\[
\rho_{\text{MABK}}^{(\text{diag})} = \sum_{j=0}^{7} (\lambda_j^+ |\Psi_j^+\rangle\langle \Psi_j^+| + \lambda_j^- |\Psi_j^-\rangle\langle \Psi_j^-|),
\]

with ordered eigenvalues \(\lambda_{j+1} \geq \lambda_j\).

Computation of one term \(B_{\alpha\beta\gamma\delta} \equiv \alpha \cdot \sigma \otimes \beta \cdot \sigma \otimes \gamma \cdot \sigma \otimes \delta \cdot \sigma\) of the MABK operator (48) for the Bell4 basis reads as
\begin{align*}
    \langle B_{a,b,y}\rangle_0^\pm &= \alpha \gamma \delta \pm \text{Re}[\alpha^+ \beta^+ \gamma^+ \delta^+], \\
    \langle B_{a,b,y}\rangle_1^\pm &= -\alpha \gamma \delta \pm \text{Re}[\alpha^+ \beta^+ \gamma^+ \delta^-], \\
    \langle B_{a,b,y}\rangle_2^\pm &= -\alpha \gamma \delta \pm \text{Re}[\alpha^+ \beta^+ \gamma^- \delta^+], \\
    \langle B_{a,b,y}\rangle_3^\pm &= \alpha \gamma \delta \pm \text{Re}[\alpha^+ \beta^+ \gamma^- \delta^-], \\
    \langle B_{a,b,y}\rangle_4^\pm &= -\alpha \gamma \delta \pm \text{Re}[\alpha^- \beta^+ \gamma^+ \delta^-], \\
    \langle B_{a,b,y}\rangle_5^\pm &= \alpha \gamma \delta \pm \text{Re}[\alpha^- \beta^+ \gamma^- \delta^-].
\end{align*}

Gathering all pure-state expectation values, \( \text{Tr}(\rho_{\text{diag}}^{(\text{MABK})} \mathcal{B}_{\text{MABK}}) \) is of the form

\[ \sum_{j=0}^{7} \pm f(\Pi_j^\pm)(\lambda_j^+ + \lambda_j^-) + g(\alpha, \beta, \gamma, \delta)(\lambda_j^+ + \lambda_j^-), \]  

with \( f(\cdot) \) being a real function of the product of all \( z \)-components of the four parties’ settings, and \( g(\cdot) \) represents a real function of several products of all parties’ components, all of them according to the special form of the MABK Bell inequality operator (48).

The maximum value of (52) is attained with \( f(\Pi_j^\pm) = 0 \), that is, no \( z \)-dependence. Similar to the calculations carried out in appendices A and B, the optimum value of the violation of the MABK inequality \( \text{Tr}(\rho \mathcal{B}_{\text{MABK}}) \leq 4 \) for mixed states (50) is of the form

\[ \max_{\Pi_j^\pm} \text{Tr}(\rho \mathcal{B}_{\text{MABK}}) \leq 4 \sqrt{\sum_{j=0}^{7}(\lambda_j^+ - \lambda_j^-)^2}. \]  

The exact form for (53), obtained by recourse to convex optimization, is extremely complicated (combination of rational functions of radicals involving integer powers of \( (\lambda_j^+ - \lambda_j^-) \)). As in the case of three qubits, the previous bound is an excellent one, and hence we can consider the equality in (53) as a close or exact measure of the amount of nonlocality degree present in a Bell diagonal mixed state of four qubits.

When comparing this last result for four qubits with those of two and three qubits, we see that all three cases involve the same functional form for the eigenvalues of the mixed multiparty state diagonal in the concomitant maximally correlated basis. This is not surprising since the Bell inequalities considered so far are multiparticle generalizations of the CHSH Bell inequality [53]. Therefore we can conjecture the form for the maximal violation of the \( n \)-party generalized MABK inequality \( \text{Tr}(\rho \mathcal{B}_{\text{MABK}}) \leq 4 \) for a mixed state diagonal in the corresponding maximally correlated basis.

**Conjecture.** The maximum amount of violation of \( n \)-party generalized MABK inequalities for diagonal \( n \)-qubit mixed states is equal to or less than

\[ 2^{\frac{N-1}{2}} \sqrt{\sum_{j=0}^{2^{N-1}-1}(\lambda_j^+ - \lambda_j^-)^2}. \]  

Generalized GHZ states are those states of \( N \) parties

\[ \sqrt{p}|0\rangle + \sqrt{1-p}|2^{N-1} - 1\rangle = \cos \alpha|0\rangle + \sin \alpha|2^{N-1} - 1\rangle \]  

which maximally violate the MABK inequality [53] \( \text{Tr}(\rho \mathcal{B}_{\text{MABK}_{\text{LVM}}}) \leq \mathcal{B}_{\text{LVM}}^{\text{MABK}_{\text{LVM}}}, \) where \( \mathcal{B}_{\text{LVM}}^{\text{MABK}_{\text{LVM}}} \) stands for the maximum violation allowed by a local variable model. We denote the quantal maximum violation [53] by \( \mathcal{B}_{\text{QM}}^{\text{MABK}_{\text{LVM}}} = 2^{\frac{N-1}{2}} \).
The maximum value for the corresponding MABK inequality for states (55) is obtained by exactly following the optimization procedures carried out in the appendices. In point of fact, GHZ states (55) are linear combinations of two pure states that can be written in the corresponding maximally correlated basis for that particular number of parties. That is, we can rewrite for convenience states (55) in the form

\[
\left( \frac{p}{2} + \sqrt{\frac{1-p}{2}} \right) |\Phi_0^+\rangle_N + \left( \frac{p}{2} - \sqrt{\frac{1-p}{2}} \right) |\Phi_0^-\rangle_N
\]

(56)

with \(\lambda_{1,2} = \frac{1}{2} \pm \sqrt{p(1-p)}\). This new form enables us to treat generalized GHZ as linear combinations of maximally correlated states in a similar fashion as performed for two-qubit states.

After some algebra, we obtain that the leading term in the violation goes as

\[2B_{QM}^{\text{CHSH}} \sqrt{p(1-p)}\] (symmetric around \(p = \frac{1}{2}\)), from which we re-obtain, after equating it to \(B_{LVM}^{\text{MABK}}\), the well-known result \([55]\) \(\sin 2\alpha \leq 1/\sqrt{2^{N-1}}\). Thus, by employing our optimization procedure, we not only recover the range where generalized GHZ states violate a Bell inequality, but also obtain its exact amount.

As far as entanglement for four qubits is concerned, we encounter a considerable discrepancy between maximum entanglement and nonlocality degree. First of all, it is well known that no proper entanglement measure is operational yet for states living in arbitrary Hilbert spaces. However, some measures (for pure states) based on partitions of the system have been advanced, such as the so-called global entanglement (GE), which describes the average entanglement of each qubit of the system with the remaining \(N-1\) qubits. The GE measure is widely regarded as a legitimate \(N\)-qubit entanglement measure [56–58]. Having a general mixed state implies that the previous measures do not apply as such. To overcome this fact we require the extension of these partition-based entanglement measures by recourse to the usual convex roof [59] defined over some given set of pure states. Given the extraordinary numerical effort that this procedure would imply, an alternative measure is given by the sum of the von Neumann entropy of all partitions of a state, the maximum is reached [61] for a particular (pure) state different from the generalized GHZ state for four qubits (which is not the case for two or three qubits). Therefore we encounter that maximum entanglement does not correspond to maximum nonlocality degree for four qubits already at the level of pure states. The analysis for mixed states—not performed here—would simply confirm this result.

5. Conclusions

In this work, we have studied how nonlocality is present in systems of two, three and four qubits. We have exhaustively explored several aspects that are shared by quantum entanglement and nonlocality degree—measured by the maximum violation of a Bell inequality—as well as pointed out those that differentiate these two magnitudes. By highlighting those issues that concern entanglement and nonlocality, we shed a new light on the connections that exist between these two concepts that play a paramount role in QIT and, in turn, in the foundations of quantum mechanics.

By means of a new optimization method, we have computed the maximum violation of the CHSH inequality for two-qubit systems and obtained the concomitant maximal states MNMS.
within the context defined by the degree of mixture, as measured by the participation ratio $R$ of the maximum eigenvalue $\lambda_{\text{max}}$ of the state $\rho$. The direct comparison with MEMS states illustrates an anomaly that appears between entanglement and nonlocality already for mixed states of two qubits, enhanced by the information-theoretic tasks limitations that appear in the study of bipartite states in the infinite $XY$ model. The study of nonlocality degree for linear combinations of pure states of two qubits allowed us to compare how both nonlocality degree and entanglement are distributed in the pure state superposition.

The extension to three-qubit states was done along similar lines, employing the maximal violation of the Mermin inequality as a nonlocality-degree measure. Analogous computations allowed us to obtain the expression for the nonlocality degree present in mixed states diagonal in the GHZ basis. We obtained that the generalized Werner states for three qubits possess maximum nonlocality degree for a given value of the degree of mixture, contrary to the two-qubit scenario. Also, we extend a previous result concerning distillability and nonlocality in the light of quantum entanglement.

The study of four-qubit systems was performed following the same steps as in the previous cases: by maximizing the MABK inequality for four qubits, we obtained the maximum violation of this nonlocality-degree measure for mixed states diagonal in the Bell$_4$ basis. As a consequence, a careful quantitative analysis is performed for generalized GHZ states as well. As far as entanglement is concerned, we observe the first discrepancy between maximum entangled and optimal nonlocality degree already for pure states of four qubits. Obviously, the MABK inequalities are not the only existing Bell inequalities for states of arbitrary number of qubits, but because it constitutes a simple generalization of the CHSH inequality (nevertheless, some authors introduce other inequalities that incorporate the MABK ones as special cases [62]), it has been enough to make use of this particular family of inequalities to illustrate the basic results of this work. Some further work will be required regarding different multipartite Bell inequalities.

Despite the fact that for small quantum systems we recognize a simple correlation between entanglement and nonlocality degree, the entire situation becomes more involved when the dimension of the Hilbert space of the system or subsystems augments. This fact is certainly transcendental for several information-theoretic tasks require the presence of either quantities. Physical situations such as the one encountered in the $XY$ model, were null nonlocality for two or three parties are compatible with non-zero entanglement, do not contribute to unify the ultimate quantum correlations that define the state of a quantum system. Rather, we are tempted to regard nonlocality and entanglement as different quantum resources in view of the undefined limits between them.

On the whole, however, many aspects that also concern nonlocality and entanglement have not been considered here. One such example could be the so-called monogamy of entanglement, a fundamental property stating that if two quantum systems are maximally correlated (maximum entanglement), then they cannot be correlated with a third party. This is, for instance, the basis for secure quantum key distribution based on entanglement [7]. The fact that this trade-off also occurs for nonlocality [63] in the multipartite case constitutes an issue that surely deserves future study.

Appendix A

The goal of this appendix is to derive the maximum violation of the CHSH inequality (4) for two-qubit systems. Such an endeavor might render somewhat difficult the study of the general instance, but this is not the case for there is no need to explore the whole space of mixed states of two qubits. Since we require \( \text{Tr}(\rho B_{\text{CHSH}}) \), which is a convex function of the two-qubit state \( \rho \), to be maximum, it suffices to consider those states that concentrate all quantum correlations after the action of a depolarizing channel [29]. This class of states is, as expected, the Bell diagonal states.

The optimization is taken over the two observers’ settings \([a_j, b_j]\), which are real unit vectors in \( R^3 \). We choose them to be of the form \((\sin \theta_1 \cos \phi_1, \sin \theta_1 \sin \phi_1, \cos \theta_1)\). With this parameterization, the problem consists in finding the supremum of \( \text{Tr}(\rho B_{\text{CHSH}}) \) over the \( |k = 1 \cdots 8| \) angles of \([a_1, b_1, a_2, b_2]\) that appear in (5).

The general form entering the Bell operator (5) for one single entry is of the kind \( \alpha \cdot \sigma \otimes \beta \cdot \sigma \). Written in the computational basis \([0], [1]\), we have

\[
\begin{pmatrix}
\alpha \beta_z & \alpha \beta_z & \alpha \beta_z & \alpha \beta_z \\
\alpha \beta_z & \alpha \beta_z & -\alpha \beta_z & -\alpha \beta_z \\
\alpha \beta_z & -\alpha \beta_z & \alpha \beta_z & -\alpha \beta_z \\
\alpha \beta_z & -\alpha \beta_z & -\alpha \beta_z & \alpha \beta_z
\end{pmatrix},
\tag{A.1}
\]

with \( \alpha^\pm = \alpha_x \pm i \alpha_y \) and \( \beta^\pm = \beta_x \pm i \beta_y \). The evaluation of (A.1) for all states in the Bell basis reads as

\[
\begin{align}
\langle \alpha \cdot \sigma \otimes \beta \cdot \sigma \rangle_{\Phi^+} &= \alpha_x \beta_z \pm \text{Re}[\alpha^+ \beta^+], \\
\langle \alpha \cdot \sigma \otimes \beta \cdot \sigma \rangle_{\Phi^-} &= -\alpha_x \beta_z \pm \text{Re}[\alpha^+ \beta^-].
\end{align}
\tag{A.2}
\]

The expression for \( \text{Tr}(\rho_{\text{Bell}}^{(\text{diag})} B_{\text{CHSH}}) \), with eigenvalues \( \lambda_1 \geq \lambda_2 \geq \lambda_3 \geq \lambda_4 \), can be cast as

\[
\begin{align}
&\left( (\lambda_1 - \lambda_4) - (\lambda_2 - \lambda_3) \right)[a_1^2(b_1^2 + b_2^2) + a_2^2(b_1^2 - b_2^2)] \\
&\quad + \left( (\lambda_2 + \lambda_3) - (\lambda_1 + \lambda_4) \right)[a_1^2(b_2^2 + b_1^2) + a_2^2(b_2^2 - b_1^2)] \\
&\quad + \left( (\lambda_1 - \lambda_4) + (\lambda_2 - \lambda_3) \right)[a_1^2(b_1^2 + b_2^2) + a_2^2(b_1^2 - b_2^2)].
\end{align}
\tag{A.3}
\]

Eigencoefficients in the first and second terms of (A.3) are strictly positive, whereas in the second one it is undefined. By rearranging terms in (A.3), we obtain

\[
\begin{align}
&\left( (\lambda_1 - \lambda_4) \right)[a_1^2(b_1^2 + b_2^2) + a_2^2(b_1^2 - b_2^2)] \quad + (\lambda_2 \lambda_3) \left( a_1^2(b_1^2 + b_2^2) + a_2^2(b_1^2 - b_2^2) - (a_1^2(b_1^2 + b_2^2) + a_2^2(b_1^2 - b_2^2)) \right) \\
&\quad + \Delta \left[ a_1^2(b_1^2 + b_2^2) + a_2^2(b_1^2 - b_2^2) \right],
\end{align}
\tag{A.4}
\]

with \( \Delta \equiv (\lambda_2 + \lambda_3) - (\lambda_1 + \lambda_4) \) possessing no clear sign, which would imply some further insight. However, on the contrary, this fact points out that no y-dependence makes (A.4) even greater. Also, the symmetry in (A.4) allows us to choose the alignment of one of the settings. From inspection of (A.4), we therefore optimize it by choosing \([a_1 = (1, 0, 0), a_2 = (0, 0, -1), b_1 = (b_1^1, 0, -b_1^2), b_2 = (b_2^1, 0, b_2^2)]\).

The final concomitant result amounts to

\[
\begin{align}
\max_{a_i, b_i} \text{Tr}(\rho B_{\text{CHSH}}) &= \max_{b_1^1, b_1^2} 2(\lambda_1 - \lambda_4)[b_2^1 + b_1^1] + 2(\lambda_2 - \lambda_3)[b_2^2 - b_1^1] \\
&= \max_{\Theta} [2\sqrt{2}(\lambda_1 - \lambda_4) \cos(\Theta) + 2\sqrt{2}(\lambda_2 - \lambda_3) \sin(\Theta)] \\
&= 2\sqrt{2}\sqrt{(\lambda_1 - \lambda_4)^2 + (\lambda_2 - \lambda_3)^2}.
\end{align}
\tag{A.5}
\]
In the case where nonlocality degree is to be found in linear combinations of pure states of two qubits, we shall perform a similar analysis. Our starting point is the matrix of expectation values of elements \( \alpha \cdot \sigma \otimes \beta \cdot \sigma \) (A.1) in the Bell basis \( \{|\Phi^+\rangle, |\Phi^-\rangle, |\Psi^+\rangle, |\Psi^-\rangle\} \)

\[
\begin{pmatrix}
\alpha \beta_2 + \text{Re}[\alpha^+ \beta^+] & i \text{Im}[\alpha^+ \beta^+] & i \text{Im}[\alpha^- \beta_2 + \alpha \beta^-] & \text{Re}[\alpha \beta^+ - \alpha^+ \beta_2] \\
-i \text{Im}[\alpha^+ \beta^+] & \alpha \beta_2 - \text{Re}[\alpha^+ \beta^+] & \text{Re}[\alpha \beta^+ + \alpha^+ \beta_2] & i \text{Im}[\alpha \beta^- + \alpha^+ \beta_2] \\
-i \text{Im}[\alpha^- \beta_2 + \alpha \beta^-] & \text{Re}[\alpha \beta^+ + \alpha^+ \beta_2] & -\alpha \beta_2 + \text{Re}[\alpha^+ \beta^-] & i \text{Im}[\alpha \beta^-] \\
\text{Re}[\alpha \beta^+ - \alpha^+ \beta_2] & -i \text{Im}[\alpha \beta^+ + \alpha^+ \beta_2] & -i \text{Im}[\alpha^- \beta_2] & -\alpha \beta_2 - \text{Re}[\alpha^+ \beta^-]
\end{pmatrix}
\]

(A.6)

Let us consider a general pure state of the form

\[
|\phi\rangle = \sqrt{\lambda_1}|\Phi^+\rangle + \sqrt{\lambda_2}|\Phi^-\rangle + \sqrt{\lambda_3}|\Psi^+\rangle + \sqrt{\lambda_4}|\Psi^-\rangle,
\]

with real coefficients \( \{\sqrt{\lambda_i}\} \) such that \( \lambda_1 + \lambda_2 + \lambda_3 + \lambda_4 = 1 \). We will demand the latter to be sorted in decreasing value though, as we shall see, this is not mandatory. The general case with complex coefficients is somewhat more involved. However, for most practical purposes, it will suffice to consider real states of the form (A.7).

The fact of having real coefficients in (A.7) greatly simplifies the expectation value \( \langle \phi| B_{\text{CHSH}} |\phi\rangle \). Its general term term \( \langle \phi| \alpha \cdot \sigma \otimes \beta \cdot \sigma |\phi\rangle \) (A.1) is of the form

\[
\lambda_1(\alpha \beta_2 + \text{Re}[\alpha^+ \beta^+] + \lambda_2(\alpha \beta_2 - \text{Re}[\alpha^+ \beta^+]))
\]

\[
\lambda_3(-\alpha \beta_2 + \text{Re}[\alpha^- \beta^-]) + \lambda_4(-\alpha \beta_2 - \text{Re}[\alpha^+ \beta^-])
\]

\[
+ \sqrt{\lambda_2 \lambda_3}2 \text{Re}[\alpha \beta^+ + \alpha^+ \beta_2] + \sqrt{\lambda_1 \lambda_4}2 \text{Re}[\alpha \beta^+ - \alpha^+ \beta_2].
\]

Note that, in view of (A.8), that the optimization of the CHSH inequality for linear combinations of pure states in the Bell basis is almost identical to the corresponding mixed state case (differing in the last two terms of (A.8)).

Proceeding as before, optimization of \( \langle \phi| B_{\text{CHSH}} |\phi\rangle \) returns the value

\[
2\sqrt{2} \sqrt{(\lambda_1 - \lambda_4)^2 + (\lambda_2 - \lambda_3)^2 + 4[\sqrt{\lambda_1 \lambda_4}]^2 + 4[\sqrt{\lambda_2 \lambda_3}]^2}
\]

\[
= 2\sqrt{2} \sqrt{(\lambda_1 + \lambda_4)^2 + (\lambda_2 + \lambda_3)^2}.
\]

(A.9)

Appendix B

In this appendix, we shall derive the explicit form for the maximum amount (39) of violation of the Mermin inequality for a three-qubit state. As expected, since \( \text{Tr}(\rho B_{\text{Mermin}}) \) is a convex function of the quantum state \( \rho \), its maximum is obtained only for pure states, namely, the whole class of states forming the Mermin-basis \( |\Psi^+\rangle = (|j\rangle \pm |7 - j\rangle)/\sqrt{2} \). In view of this observation, we shall consider instead what is the maximum violation attained for mixed states diagonal in this basis, that is, states of the class \( \rho^{(\text{diag})}_{\text{Mermin}} \) (40). Another argument for studying these states is that any initial state \( \rho \) can be converted into one in the class by means of LOCC.

Optimization of Mermin\( ^{\text{max}} \) (39) for states \( \rho^{(\text{diag})}_{\text{Mermin}} \) (40) is carried out in the same fashion as the previous bipartite case. Once the observers’ settings \( \{\mathbf{a}_j, \mathbf{b}_j\} \), which are real unit vectors in \( \mathbb{R}^3 \), are parameterized in spherical coordinates (\( \sin \theta \ cos \phi, \ sin \theta \ sin \phi, \ cos \theta \), the problem consists in finding the supremum of (39) over the set of \( \{k = 1 \cdots 12\} \) possible angles for \( \{\mathbf{a}_1, \mathbf{b}_1, \mathbf{a}_2, \mathbf{b}_2, \mathbf{a}_3, \mathbf{b}_3\} \) in (38).
To start with, let us write a generic element of the Mermin operator \((38)\) of the form
\[B_{\alpha \beta \gamma} \equiv \alpha \cdot \sigma \otimes \beta \cdot \sigma \otimes \gamma \cdot \sigma\] in the computational basis \([0], [1]\) defined by the z-projections of \(\sigma = (\sigma_x, \sigma_y, \sigma_z)\). \(B_{\alpha \beta \gamma}\) reads as
\[
\begin{pmatrix}
\alpha_\beta\zeta \\
\alpha_\beta^+ \\alpha_\beta^- \\
\alpha_\beta^+ \ \alpha_\beta^- \\
\alpha_\beta^+ \ \alpha_\beta^- \\
\end{pmatrix}
\otimes
\begin{pmatrix}
\gamma_\zeta \\
\gamma_+ \\
\gamma_+ \\
\gamma_+ \\
\end{pmatrix},
\]
with \(\alpha^\pm = \alpha_x \pm i\alpha_y\), \(\beta^\pm = \beta_x \pm i\beta_y\), and \(\gamma^\pm = \gamma_x \pm i\gamma_y\) being ‘raising’ and ‘lowering’ terms in the \(x\)-\(y\) plane. Nonlocality-degree measure \((39)\) for diagonal states \((40)\) is computed by recourse to four \(B_{\alpha \beta \gamma}\) in \((B.1)\) for different configurations of vectors.

The evaluation of \((39)\) for diagonal states \((40)\) amounts to computing the expectation value \(\langle \Psi^+_1 | B_{\alpha \beta \gamma} | \Psi^+_1 \rangle \equiv \langle \alpha \beta \gamma \rangle^+_1\) for all states \([\Psi^+_1]\) in the Mermin basis and several vector configurations. The positions in \(\langle \alpha \beta \gamma \rangle^+_1\) are such that \(\alpha, \beta, \gamma\) correspond to the first, second and third observer, respectively. This computation returns
\[
\langle \alpha \beta \gamma \rangle^+_1 = \pm \text{Re}[\alpha^+ \beta^+ \gamma^+]\] (B.2)

As we can observe, the observers settings can be two dimensional (there is no \(z\)-dependence).

From previous definitions, we now write \(\text{Tr}(\rho^{(\text{diag})}_{\text{Mermin}} B_{\text{Mermin}})\) as
\[
(\lambda^+_0 - \lambda^-_0) \left[ (\text{aaa}\rangle^+_1 - \langle \text{abb}\rangle^+_1 - \langle \text{bab}\rangle^+_1 - \langle \text{bba}\rangle^+_1 \right] \\
+ (\lambda^+_1 - \lambda^-_1) \left[ (\text{aaa}\rangle^+_1 - \langle \text{abb}\rangle^+_1 - \langle \text{bab}\rangle^+_1 - \langle \text{bba}\rangle^+_1 \right] \\
+ (\lambda^+_2 - \lambda^-_2) \left[ (\text{aaa}\rangle^+_1 - \langle \text{abb}\rangle^+_1 - \langle \text{bab}\rangle^+_1 - \langle \text{bba}\rangle^+_1 \right] \\
+ (\lambda^+_3 - \lambda^-_3) \left[ (\text{aaa}\rangle^+_1 - \langle \text{abb}\rangle^+_1 - \langle \text{bab}\rangle^+_1 - \langle \text{bba}\rangle^+_1 \right].
\]
(B.3)

The explicit evaluation of the previous quantity can be cast as
\[
(\lambda^+_0 - \lambda^-_0) \left[ (\text{aaa}\rangle^+_1 - \langle \text{abb}\rangle^+_1 - \langle \text{bab}\rangle^+_1 - \langle \text{bba}\rangle^+_1 \right] \\
- \left[ (\text{aaa}\rangle^+_1 - \langle \text{abb}\rangle^+_1 - \langle \text{bab}\rangle^+_1 - \langle \text{bba}\rangle^+_1 \right] \\
- \left[ (\text{aaa}\rangle^+_1 - \langle \text{abb}\rangle^+_1 - \langle \text{bab}\rangle^+_1 - \langle \text{bba}\rangle^+_1 \right] \\
+ \left[ (\text{aaa}\rangle^+_1 - \langle \text{abb}\rangle^+_1 - \langle \text{bab}\rangle^+_1 - \langle \text{bba}\rangle^+_1 \right].
\]
(B.4)

Since the Mermin inequality settings are such that it must posses rotationally invariance (\(x\)-\(y\) plane), we are free to fix one of them. In view of \((B.4)\), we choose \(a_2 = (-1, 0, 0)\). Also, differences in each term of \((B.4)\) must be maximum in absolute value, which is compatible with fixing \(b_2 = (0, 1, 0)\). Further calculations imply a configuration of the type \(a_1 = (a_1^+, a_1^-), a_3 = (a_3^+, a_3^-), b_1 = (-a_1^+, a_1^-), b_3 = (a_3^+, -a_3^-)\). Expected value \(\text{Tr}(\rho^{(\text{diag})}_{\text{Mermin}} B_{\text{Mermin}})\) greatly simplifies from \((B.4)\) into
\[
(\lambda^+_0 - \lambda^-_0) \left[ 2|a_1^+a_3^+| + 2|a_1^-a_3^-| \pm 2|a_1^+a_3^-| \pm 2|a_1^-a_3^+| \right] \\
+ (\lambda^+_2 - \lambda^-_2) \left[ 2|a_1^+a_3^+| - 2|a_1^-a_3^-| \pm 2|a_1^+a_3^-| \pm 2|a_1^-a_3^+| \right].
\]
(B.5)
Note that we have reduced our optimization problem to one which entails only two real quantities. By introducing explicit angles \((\phi, \psi)\), and after some algebra, we obtain

\[
\max_{a_j, b_j} \text{Tr}(\rho B_{\text{Mermin}}) = \max_{\phi, \psi} (\lambda^+_0 - \lambda^-_0) 4 \sin \phi \sin \psi \\
+ (\lambda^+_1 - \lambda^-_1) 4 \sin \phi \cos \psi \\
+ (\lambda^+_2 - \lambda^-_2) 4 \cos \phi \cos \psi \\
+ (\lambda^+_3 - \lambda^-_3) 4 \cos \phi \sin \psi. 
\]

We do not worry about the signs in each term of \((B.4)\) since we have chosen, without loss of generality, the eigenvalues \(\{\lambda^\pm_j\}\) to be sorted in decreasing value. The solution of \((B.6)\) is obtained by recourse to the use of convex optimization techniques [64], although it can also be found by direct computation. The function of equation \((B.6)\) has a negative and nonsingular Hessian locally. But since it is concave for the relevant range of values of \((\phi, \psi)\), therefore the function has a unique global maximum. The maximum occurs when the concomitant partial derivatives are zero, returning the set of equations

\[
\tan \phi = \frac{4(\lambda^+_0 - \lambda^-_0) \tan \psi + 4(\lambda^+_1 - \lambda^-_1)}{4(\lambda^+_2 - \lambda^-_2) + 4(\lambda^+_3 - \lambda^-_3) \tan \psi}, \\
\tan \psi = \frac{4(\lambda^+_0 - \lambda^-_0) \tan \phi + 4(\lambda^+_1 - \lambda^-_1)}{4(\lambda^+_2 - \lambda^-_2) + 4(\lambda^+_3 - \lambda^-_3) \tan \phi}. 
\]

By solving \((B.7)\) we finally obtain the desired evaluation of \((39)\) for diagonal states \((40)\). Though the final result is rather cumbersome, we nevertheless derive an excellent bound. In view of the coefficients in \((B.6)\) (the sum of their squared values equals one), we provide the final result \((41)\).
