One of the most primitive but elusive current-voltage (I-V) responses of a superconductor is when its supercurrent grows steadily after a voltage is first applied. The present work employed a measurement system that could simultaneously track and correlate \( I(t) \) and \( V(t) \) with sub-nanosecond timing accuracy, resulting in the first clear time-domain measurement of this transient phase where the quantum system displays a Newtonian like response. The technique opens doors for the controlled investigation of other time dependent transport phenomena in condensed-matter systems.

Keywords: ballistic, acceleration, kinetic inductance, supercurrent, superfluid, superconductor, superconductivity

The acceleration of a supercurrent density

\[
\frac{dj}{dt} \approx \frac{dj_s}{dt} = \frac{Ee^2n_s}{m^*} = \frac{E}{\mu_0 \lambda_k^2},
\]

where \( E \) is the local internal electric field, \( e \) is the electronic charge, \( m^* \) is the effective mass and \( n_s \) is the superfluid density (related to the number of electrons per volume participating in the condensate); the far right hand side of the equation relates \( n_s \) to the London magnetic-field penetration depth \( \lambda_L \); we can take \( j = j_s + j_n \approx j_s \) because the normal current density \( j_n \) is a negligible component of the total current density \( j \). This supercurrent acceleration phase lasts for the duration \( \Delta t \approx j_s \mu_0 \lambda^2_k / E \), where \( j_c \) is the critical current density that marks the onset of resistance. The inductance-like proportionality between \( dj/dt \) and \( E \) in Eq. 1 arising from the inertia of the superfluid, is referred to as the kinetic inductance \( L_k \).

In terms of the geometrical length \( l \) and cross sectional area \( A \), it is given by

\[
L_k = \frac{\mu_0 \lambda^2 l}{A},
\]

where \( \lambda \) is a more general penetration depth, which includes effects such as impurity scattering (\( \lambda \geq \lambda_L \)). Kinetic inductive effects are small except close to the transition temperature \( T_c \), where their signatures have been seen in the high-frequency ac response or as nonequilibrium inductive voltage spikes during abrupt current steps [3,11]. In the present work, timescales were chosen to be short enough to have a sufficient magnitude of \( V \) while long enough (compared to characteristic timescales such the gap-relaxation and electron-phonon scattering times) to avoid non-equilibrium effects. Variations in fields occurred at length scales that were long compared with both \( \lambda \) and the coherence length \( \xi \), so as to avoid non-local effects. Thus the conditions were optimum for observing the simplest limiting behavior of an accelerating condensate as predicted by the London equations, i.e., Eq. 1.

The samples used in this work were niobium films deposited on silicon substrates with DC magnetron sputtering. The films were patterned into long narrow meanders by electron-beam lithography using the lift-off technique. Sample A had a thickness of \( t = 70 \pm 8 \) nm, a width of \( w = 12.1 \pm 0.6 \) \( \mu \)m, and a length (between voltage probes) of \( l = 4.80 \pm 0.01 \) cm. Sample B had the dimensions \( t = 85 \pm 8 \) nm, \( w = 8.9 \pm 0.6 \) \( \mu \)m, and \( l = 4.53 \pm 0.01 \) cm. Their respective superconducting transition temperatures were \( T_c = 6.74 \) K and \( T_c = 7.23 \) K.

The measurements were carried out in a pulsed-tube closed-cycle refrigerator in zero applied magnetic field. The electrical measurements were conducted with a pulsed signal source and detection electronics, in combination with a digital storage oscilloscope. Parts of the signal-source and preamplifier circuitry in this setup were developed and built in-house. An active (buffered) ground arrangement was developed for improving the shielding between the fast changing high-voltage signal in the current leads from the low-voltage sample-signal
sensing leads. The entire signal chain up until the digital oscilloscope is analog. Using pulsed signals instead of continuous ac or dc excitations permits a wider range of currents without Joule heating of the sample and a flexible control over the waveform shape. The system performs simultaneous independent differential four-probe measurements of $I(t)$ and $V(t)$ with a relative timing accuracy of $\approx 100$ ps. The stray mutual inductive coupling between current and voltage leads has a (temperature independent) value of $\lesssim 1$ nH (the self inductances of the leads themselves are not sensed because of the four-probe configuration). The absolute accuracy of the inductance values measured in this system is about $\pm 5\%$. The voltage-measurement sensitivity is about $1 \mu$V. The time interval between digitized samples is $10^{-10}$ second (the single-shot digitizing sampling rate is 10 GS/s). The speed and accuracy with which both $I(t)$ and $V(t)$ were tracked and correlated in a superconductor in the present experiment are, to our knowledge, unprecedented.

Some tests and verifications of the measurement system are shown in Fig. 1. Panel (a) shows the voltage and current (scaled by a constant) for a purely resistive test sample and panel (b) shows the current derivative and voltage (scaled by a constant) for a purely inductive test sample. The time scales used in the actual experiment were longer than these test conditions of Fig. 1 so that the temporal tracking between the current and voltage sensing circuits was essentially perfect. Some additional information on the apparatus can be found in our previous review articles [12, 13].

Figs. 2(a) and (b) show $V(t)$ (solid lines) across two niobium-meander samples in the superconducting state at one temperature. Panels (c) and (d) show the corresponding $I(t)$ functions, which are seen to accelerate steadily during the plateaus in $V(t)$. The dashed lines in panels (a) and (b) show $dI/dt$ (scaled by a constant $L=16.7$ and 16.9 nH for samples A and B respectively) and are seen to track $V(t)$ in instantaneous detail. Thus the response is purely inductive, with an inductance that is independent of $I$ and $dI/dt$.

The ratio between the $dI(t)/dt$ and $V(t)$ curves in the top panels of Fig. 2 gives the time and current dependent inductance: $L(t) = V(t)/(dI(t)/dt)$. Figs. 2(a) and (b) plot this $L(t)$ versus time for various values of $T$, for each of the samples. The plateau value of $L$ is seen to increase steadily with temperature as is expected because of the declining superfluid density and consequent rising $\lambda_L$. Another interesting trend is that the curves at highest temperatures show $L(t)$ functions that rise with time (i.e., current). This happens because the current suppresses the superfluid density through its pair-breaking action, a regime not seen before in any other kind of measurement. Note that continuous-ac probes of $n_s$ cannot endure high enough excitation levels to explore this regime because of Joule heating; and tunneling measurements reveal the spectral gap $\Omega_j$ rather than $n_s$. A systematic study of the suppression of $n_s$ by $j$ will be the subject of a future investigation, since the optimum sample geometry for studying this effect is almost opposite to the sample geometry required for the present experiment.

Figs. 2(c) and (d) plot $L$ (as measured above) versus
The third and fifth columns of Table I show, for comparison, theoretical estimates of $L_k(0)$ and $L_g$. For finding $L_k(0)$ we note that the effective penetration depth ($\lambda$) becomes lengthened with respect to its clean-limit value ($\lambda_L$) in the presence of scattering by static disorder. This effect of impurity scattering can be incorporated through the residual resistivity $\rho_o$ and expressed in terms of the order parameter $\Delta$ as

$$\lambda(0) = \sqrt{\frac{\hbar\rho_o}{\pi\mu_o\Delta(0)}}. \quad (4)$$

Taking the measured values of $\rho_o=0.347 \mu\Omega.m$ and 0.369 $\mu\Omega.m$, and obtaining $\Delta(0) \approx 2k_BT_c$ from our measured values of $T_c$, we get $\lambda=223$ nm and 222 nm, and $L_k=3.5$ nH and 3.7 nH for samples A and B respectively. There is an uncertainty in the values $\rho_o$ because of the uncertainty in sample dimensions and an uncertainty in $\Delta(0)$ because of an uncertainty in the absolute value of $T_c$ (this is roughly estimated to be around 200 mK). This gives rise to the error bars in the theoretical $L_k$ values that are stated in the table. The calculated values of $L_k$ are somewhat larger than the measured ones of but of comparable magnitude.

The theoretical geometrical inductances for the measured, tabulated in the last column of Table I were computed numerically by integrating the magnetic flux that links to the path between the voltage probes. The error bars in the theoretical $L_g$ arise from the uncertainties in the sample dimensions and the approximations inherent in the calculation. It can be seen that the theoretically estimated $L_g$ values are also in agreement with their measured counterparts.

In summary, this work has explored the initial acceleration phase during which a supercurrent builds up in response to an applied voltage. The voltage and current curves of Fig. 2 represent the first clear and direct time-domain demonstration of this primitive regime, where the quantum system shows a Newtonian like response. It is also the first time to observe the non-linear regime where the current suppresses the superfluid density, thereby increasing the kinetic inductance. The instrumentation developed for this experiment is unique and represents the first measurement of its kind where both $V(t)$ and $I(t)$ are tracked in a superconductor with sub-nanosecond timing accuracy. This technique can reveal more detailed information than just an impulse-response measurement, and it can be used to explore time-dependent and non-equilibrium phenomena in condensed-matter systems in a controlled way (some examples of such regimes in superconductors would be those related to phase slippage, 

| Sample | $L_k(0)$ in nH | $L_g$ in nH |
|--------|---------------|-------------|
| A      | 2.8±0.2       | 12.2±1      |
| B      | 2.8±0.2       | 12.9±1      |

glassy dynamics, and the nascent stage of a vortex right after its nucleation). The present work and its method should be distinguished from past experiments in which an abrupt supercritical current pulse was applied \cite{Frank1983, Jelila1998} and only the subsequent $V(t)$ response was measured without monitoring $I(t)$. In those experiments the superconductor recoils in a highly non-equilibrium manner to the supercritical stimulus. In the present study, the superconducting system is always maintained close to equilibrium by keeping the experimental timescales well in excess of the gap-relaxation and electron-phonon scattering times, while keeping the timescales short enough to observe the inertia of the superfluid.
