Abstract

We propose an effective conformal field theory (CFT) description of steady state incompressible fluid turbulence at the inertial range of scales in any number of spatial dimensions. We derive a KPZ-type equation for the anomalous scaling of the longitudinal velocity structure functions and relate the intermittency parameter to the boundary Euler (A-type) conformal anomaly coefficient. The proposed theory consists of a mean field CFT that exhibits Kolmogorov linear scaling (K41 theory) coupled to a dilaton. The dilaton is a Nambu-Goldstone gapless mode that arises from a spontaneous breaking due to the energy flux of the separate scale and time symmetries of the inviscid Navier-Stokes equations to a K41 scaling with a dynamical exponent $z = \frac{2}{3}$. The dilaton acts as a random measure that dresses the K41 theory and introduces intermittency. We discuss the two, three and large number of space dimensions cases and how entanglement entropy can be used to characterize the intermittency strength.
I. INTRODUCTION

Fully developed incompressible fluid turbulence is largely considered as the most important unsolved problem of classical physics. One defines the inertial range to be the range of length scales $l \ll r \ll L$, where the scales $l$ and $L$ are determined by the viscosity and forcing, respectively. Experimental and numerical data suggest that turbulence at the inertial range of scales reaches a steady state that exhibits statistical homogeneity and isotropy and is characterized by universal scaling exponents that depend only on the number of space dimensions $d$.

In [1] we proposed an exact formula for the inertial range anomalous scalings $\xi_n$ of the longitudinal structure functions $S_n$:

$$S_n(r) = \langle (\delta v(r))^n \rangle \sim r^{\xi_n}, \quad (1)$$

where

$$\xi_n - \frac{n}{3} = G^2(d)\xi_n(1 - \xi_n), \quad (2)$$

and $G(d)$ is a numerical real parameter that depends on the number of space dimensions $d \geq 2$. It quantifies intermittency and the deviation from Kolomogorov linear scaling $\xi_n = \frac{n}{3}$. $\delta v(r)$ is the longitudinal velocity difference between points separated by a fixed distance $r = |\vec{r}|$, $\delta v(r) = (\vec{v}(\vec{r}, t) - \vec{v}(0, t)) \cdot \frac{\vec{r}}{r}$. By $\langle \rangle$ we mean both integration over space (normalized by the volume of space) and over the probability distribution function of a random force $F$, with $v^i = v^i(F)$. Note, that the dimensions $\xi_n$ in (2) are in units of length.

At leading order in the intermittency parameter $G$, (2) coincides with the Kolmogorov-Obukhov model [3, 4] :

$$\xi_n - \frac{n}{3} = G^2\frac{n}{3}(1 - \frac{n}{3}), \quad (3)$$

They differ at high intermittency and (2) may be viewed as a completion of the Kolmogorov-Obukhov formula to the strong intermittency regime. Unlike (3) which implies physically inconsistent supersonic velocities at large $n$ and a violation of the convexity inequality, its completion (2) is analytically and physically consistent [1]. Formula (2) predicts a generic behaviour at finite $d$ (finite intermittency) and large $n$: $\xi_n \sim \sqrt{n}$.

Formula (2) is consistent with the available numerical and experimental data [1], however, it is a conjecture for which we still lack an analytical derivation. It is KPZ (Knizhnik-Polyakov-Zamolodchikov)-type relation [5, 6] that arises when coupling a dynamical system...
to a random geometry. The inspiration for the proposal was the relation between fluids and geometry, and hence between the statistics of fluid flows and the statistics of geometries (for a brief review see [8]). By coupling to a random geometry one means changing the Euclidean measure $d\mu$ on $\mathbb{R}^d$ to a random measure

$$d\mu_{\gamma}(x) = e^{\gamma \phi(x) - \frac{\gamma^2}{2}} d\mu,$$

where the Gaussian random field $\phi(x)$ has covariance $\phi(x)\phi(y) \sim -\log |x-y|$ when $l \ll |x-y| \ll L$ is in the inertial range. The intermittency parameter $\mathcal{G}$ is related to $\gamma$. Intermittent features appear at short length scales, and this is when the effects of the random field $\phi$ are prominent.

The goal of this work is to propose an effective field theory framework of steady state incompressible fluid turbulence at the inertial range of scales, and derive (2). We will consider the energy cascade and work in the infinite Reynolds number limit. The basic questions that arise are what is the definition of the random field $\phi(x)$ in the turbulent fluid field theory, what is the field theory meaning of $\mathcal{G}(d)$ and how can we calculate it. We propose to identify the scalar field $\phi$ as a dilaton, the Nambu-Goldstone (NG) gapless mode that arises from a spontaneous breaking due to the energy flux of the separate scale and time symmetries of the inviscid Navier-Stokes (NS) equations to a K41 scaling with a dynamical exponent $z = \frac{2}{3}$.

We define the effective field theory on a $d$-dimensional closed ball in Euclidean space $\mathbb{R}^d$ with radius $L$, $B_d(L)$, whose boundary is the $(d-1)$-sphere $S^{d-1}$ of radius $L$. $L$ is the forcing IR scale when $d > 2$. The proposed effective field theory framework for the steady state dynamics of the turbulent fluid is conformally invariant. It consists of a mean field CFT that exhibits Kolmogorov linear scaling (K41 theory) coupled to the dilaton. The odd $n$ structure functions $S_n$ are non-vanishing in K41 theory hence it is not Gaussian. It is also non-local. The dilaton acts as a random measure that dresses the K41 theory and introduces intermittency that leads to (2). This is reminiscent of two-dimensional quantum gravity, where matter (our K41 fields) is coupled to a Liouville field (our dilaton). Here, however, both the K41 fields and the dilaton are made of the same hydrodynamic variables, the fluid velocity vector $v^i$ and the fluid pressure $p$. We express the intermittency

\footnote{The two-dimensional case is special since the energy cascade is inverse: the forcing scale is $l$ and the dissipation scale is $L$.}
parameter $G(d)$ in terms of the boundary Euler A-type conformal anomaly coefficient of the turbulent field theory and the number of space dimensions. We consider both odd and even number of space dimensions.

The paper is organized as follows. In section 2 we analyze the spontaneous symmetry breaking of the separate space and time scale symmetries of the inviscid NS equations due to the energy flux. The breaking leads to the K41 scaling theory with a dynamical exponent $z = \frac{2}{3}$ and a gapless NG dilaton mode. We construct the dilaton effective action which is scale invariant in the inertial range, and calculate the dimensions of scaling operators. In section 3 we propose the turbulent field theory and derive the KPZ scaling. We express the intermittency parameter as a function of the Euler boundary conformal anomaly and the number of space dimensions (Eq. (53),(55),(56),(65)). We propose the entanglement entropy as yet another tool to characterize the intermittency strength. In section 4 we consider the physical cases of two and three space dimensions and the large $d$ limit. Section 5 is devoted to a summary and outlook. In the appendix we specify the notations and discuss the GJMS operator, the $Q$-curvature and the structure of the higher-dimensional Liouville field theory.

II. SPONTANEOUS SYMMETRY BREAKING

A. Turbulent Flux States

The incompressible NS equations provide a universal description of fluid flows at low Mach number, that is $v \ll v_s$ where $v_s$ is the speed of sound. They read:

$$\partial_t v^i + v^j \partial_j v^i = -\partial_i p + \nu \partial_{jj} v^i + F^i, \quad \partial_i v^i = 0, \quad i = 1, \ldots, d,$$  \hspace{1cm} (5)

where $d$ is the number of space dimensions, $v^i, i = 1,\ldots,d$ is the fluid velocity vector, $p$ is the fluid pressure, $\nu$ is the kinematic viscosity and $F^i$ is an external random force.

Multiplying the first equation by $v^i$, summing over $i$, integrating over the ball $B_d(L)$ and using the second equation one gets

$$\partial_t \int_{B_d} d^d x \left( \frac{v^2}{2} \right) = \int_{B_d} d^d x \left( F^i v^i \right) - \frac{\nu}{2} \int_{B_d} d^d x \left( \partial_i v^i + \partial_j v^j \right)^2.$$  \hspace{1cm} (6)

The change in the kinetic energy of the fluid \cite{6} is dictated by the incoming energy flux due to the external force and by the energy dissipation due to viscosity. In deriving \cite{6} we need
to impose the boundary condition
\[ \int_{\partial B_d} \left( p + \frac{v^2}{2} \right) v^i d\Sigma_i = 0, \]  
(7)

where \( d\Sigma_i \) is the directed surface measure of the spherical boundary \( \partial B_d = S^{d-1} \). In a steady state we have the relation:
\[ \int_{B_d} d^d x \left( F^i v^i \right) = \frac{\nu}{2} \int_{B_d} d^d x \left( (\partial_i v^j + \partial_j v^i)^2 \right). \]  
(8)

At very large Reynolds number \( R_e = \frac{l c}{\nu} \), where \( l_c \) is a characteristic length scale and \( \nu \) the velocity difference at that scale, the viscosity term is very small compared to the nonlinear term \( v^j \partial_j v^i \) in the NS equation. However the local energy dissipation \( \epsilon(x) = \frac{\nu}{2} (\partial_i v^j + \partial_j v^i)^2 \) is nonvanishing even in the limit \( \nu \to 0 \) since the gradients of the velocity field are singular. This is called the dissipative anomaly \[9\]. The steady state of turbulence is far from equilibrium since there is always a flow of energy flux and cascade, hence the Gibbs measure is inappropriate for quantifying its statistics.

**B. Scale Symmetry Breaking**

In the absence of a viscosity term, the (inviscid) NS equations \[5\] exhibit two scale symmetries. These are independent scalings of space and time which we denote by \( R_x \times R_t \),
\[ R_x : x^i \to e^{\sigma_1} x^i, \quad R_t : t \to e^{\sigma_2} t, \]  
(9)

where an appropriate charge is assigned to the random force. We denote the charges of any object under the two symmetries by \( (r_x, r_t) \). The charges of \( v^i \) are \((1, -1)\), and the charges of the different term in the inviscid NS equations are \((1, -2)\). An alternative way of describing the two scale symmetries is
\[ x^i \to e^{\sigma} x^i, \quad t \to e^{z\sigma} t, \]  
(10)

where \( z \) is an arbitrary real parameter, and in relation to \[9\]: \( \sigma_1 = \sigma, \sigma_2 = z\sigma \). For any value of \( z \), one can define a total dimension of an object as
\[ \Delta_z = r_x + z r_t. \]  
(11)

The dimension of \( v^i \) is \( \Delta_z = 1 - z \) and the dimension of the different terms in the inviscid NS equations is \( \Delta_z = 1 - 2z \).
The symmetries (10) can be broken from arbitrary $z$ to a particular value $z = z^*$. We will denote this breaking by $R_x \times R_t \to R_{z^*}$. The flux $F^i v^i$ at the boundary of the theory breaks spontaneously the symmetries of the inviscid NS equations to $R_{z=\frac{2}{3}}$, as follows from the requirement that $\Delta_z(F^i v^i) = 2 - 3z = 0$. This is the Kolmogorov scaling $\Delta_{K41}[v^i] = \frac{1}{3}$. Thus, we interpret the turbulent flux state satisfying (8) as a state that spontaneously breaks (10) to $z = \frac{2}{3}$. One can instead consider the local energy dissipation $\epsilon(x)$ as the object whose expectation value breaks spontaneously the scale symmetry. Note, that the Kolmogorov scaling is the critical scaling above which there is no dissipative anomaly [10].

C. The Dilaton Effective Action

When a scale symmetry is spontaneously broken one expects a Nambu-Goldston gapless mode called the dilaton. We denote the expectation value that breaks $R_x \times R_t \to R_{\frac{2}{3}}$ by $\langle F^i v^i \rangle = \Lambda$, where by $\langle \rangle$ we mean both integration over space (normalized by the volume of space) and over the probability distribution function of $F^i v^i$. The dilaton $\tau$ is the fluctuation seen by replacing the VEV:

$$\Lambda \to \Lambda e^{\delta \tau},$$

where $\delta$ is a c-number, and it is charged under (9).

The dilaton effective action has to be invariant under Galilean boosts:

$$t \to t, \quad x^i \to x^i + v^i t, \quad \partial_i \to \partial_i, \quad \partial_t \to \partial_t - v^i \partial_i, \quad \tau \to \tau.$$  (13)

This forbids time derivative terms in the Lagrangian and allows only space derivative ones (see [11] for a similar situation). The dilaton effective action should also respect the symmetries (9) with a dilaton invariant under the unbroken scale symmetry $R_{z=\frac{2}{3}}$ [12]. We are interested in the steady state statistics and equal time correlation functions, hence we can average over time $\frac{1}{T} \int_0^T dt$.

We will separate the discussion to two cases: an even number of space dimensions and an odd one.
1. Even Number of Space Dimensions

The dilaton effective action on $B_d(L)$ can be written (with arbitrary dimensionless coefficients) as:

$$S_{\text{dilaton}} = S_0 + S_{\text{Euler}} + S_{\text{CF}} .$$  

(14)

$S_0$ reads:

$$S_0 = -\int_{B_d} \sqrt{g} d^d x \tau \Box^{\frac{d}{2}} \tau ,$$  

(15)

and it is the only local action in flat space that respects the symmetries (9) with a dilaton invariant under the unbroken scale symmetry [12]. It describes a log-correlated free scalar field that we will propose in the following to associate with the random scalar field in the random measure (4).

$S_{\text{Euler}}$ reads:

$$S_{\text{Euler}} = -\int_{\partial B_d} \sqrt{g_b} d^{d-1} x \tau q_d ,$$  

(16)

where $\partial B_d = S^{d-1}$ is the spherical boundary of the ball, $g_b$ is the induced metric on the boundary and $q_d$ is a boundary Euler density term constructed from the boundary intrinsic and extrinsic curvatures [A.13]. The bulk Euler density $E_d$ is zero in (16) since we consider a ball in Euclidean space. The normalization of $q_d$ is fixed in (A.15).

$S_{\text{CF}}$ consists of non Weyl invariant terms that can be written on the $S^{d-1}$ boundary and take the general form:

$$S_{\text{CF}} = \int_{\partial B_d} \sqrt{g_b} d^{d-1} x H^{\mu_1 \mu_2 \cdots} \partial_{\mu_1} \tau \partial_{\mu_2} \tau \cdots ,$$  

(17)

where $H^{\mu_1 \mu_2 \cdots}$ are made of the intrinsic and extrinsic curvatures of the boundary. The terms in $S_{\text{CF}}$ are suppressed by inverse powers of $L$, and since we work in the inertial range of scales $r \ll L$ we will neglect them in the rest of the discussion.

Thus, the dilaton effective action consists of (15) and (16) with arbitrary dimensionless coefficients $\kappa, Q$:

$$S_{\text{dilaton}} = -\kappa \int_{B_d} \sqrt{g} d^d x \tau \Box^{\frac{d}{2}} \tau + Q \int_{\partial B_d} \sqrt{g_b} d^{d-1} x \tau q_d .$$  

(18)

The action (18) defines a higher derivative nonunitary (non reflection positive) scale invariant field theory. The Euler term in (18) leads to an ”anomalous” non-conservation of the current
\( J^\mu = 2 \partial^\mu \Box \frac{d-2}{2} \tau \). It has an interpretation of a background charge: If we shift \( \tau \rightarrow \tau + \sigma \) where \( \sigma \) is a constant we pick up a charge \( Q \) from \( e^{-S_{dilaton}} \), \( e^{Q \sigma} \) where
\[
Q = \alpha_d Q ,
\]

with
\[
\alpha_d = (4\pi)^{\frac{d}{2}} (\frac{d}{2})! ,
\]

and we used (A.15) and (A.9).

The background charge imposes a selection rule in correlation functions and affects the dimension of scaling operators as we will now calculate.

The two-point correlation function of \( \tau \) reads
\[
\langle \tau(\vec{x}_1) \tau(\vec{x}_2) \rangle = \frac{d}{2\alpha_d \kappa} \left( \log \frac{L}{|\vec{x}_{12}|} \right) + ... .
\]
\( \vec{x}_{12} = \vec{x}_1 - \vec{x}_2 \), \( L \) is the IR regulator and dots refer to a constant and additional terms in that vanish when \( L \rightarrow \infty \). \( \tau \) is not a scaling operator and one should consider operators that transform covariantly under scaling. Consider the correlation function of the operators \( e^{\beta_i \tau} \). The background charge imposes a selection rule:
\[
\sum_i \beta_i + Q = 0 .
\]

The two point function is :
\[
\langle \exp^{\beta \tau(\vec{x}_1)} \exp^{-(\beta + Q) \tau(\vec{x}_2)} \rangle = |\vec{x}_{12}|^{-2\Delta} ,
\]
where
\[
\Delta = -\frac{d}{4\alpha_d \kappa} \beta (\beta + Q) ,
\]
is the scaling dimension in units of \((\text{length})^{-1}\).

2. Odd Number of Space Dimensions

The case with odd number of space dimensions is more subtle. There are no local bulk action terms that respect the symmetries, and there is a fractional derivative in \( S_0 \) which makes the Lagrangian nonlocal in space. The Euler term takes the form:
\[
S_{\text{Euler}} = \int_{\partial B_d} \sqrt{g_0} d^{d-1} x \, \tau E_{d-1} ,
\]
where $E_{d-1}$ is the Euler density of the boundary $S^{d-1}$ sphere normalized as in (A.8). There is an additional local term that can be written on the boundary while neglecting terms suppressed by inverse powers of $L$:

$$S_{\text{Boundary}} = \int_{\partial B_d} \sqrt{g_b} d^{d-1}x \, \tau \Box^{\frac{d-1}{2}} \tau .$$

Thus, the dilation effective action includes the non-local term (15), the Euler term (25) and the additional local boundary term (26) with dimensionless couplings:

$$S_{\text{dilaton}} = -\kappa \int_{B_d} \sqrt{g} d^d x \, \tau \Box^\frac{d}{2} \tau - \tilde{\kappa} \int_{\partial B_d} \sqrt{g_b} d^{d-1}x \, \tau \Box^{\frac{d-1}{2}} \tau - Q \int_{\partial B_d} \sqrt{g_b} d^{d-1}x \, \tau E_{d-1} .$$

Matching the solution (21) at the boundary as dictated by the first and second terms in (27) implies:

$$\tilde{\kappa} = \frac{(d-1)\alpha_d}{\kappa} \kappa .$$

Formulas (22), (23) and (24) continue to hold with:

$$Q = 2\alpha_{d-1}Q ,$$

and we used (A.8) and (A.9).

3. Discussion

There are a couple of remarks in order. On the one hand, the fact that the dilaton carries charge under the time scaling symmetry $R_t$ (9) effectively forbids dilaton exponential terms $e^{\alpha \tau}$ in the steady state dilaton effective action. On the other hand we seem to allow operators of such structure and calculate their two-point function (23), which looks inconsistent. In fact, when we will construct the operators of the turbulence field theory in the next section the dilaton exponential terms will not stand by themselves. Rather, they will be used to dress the K41 field theory operators such that the whole operator should be invariant under $R_t$. In general, all the physical quantities that will appear later in calculations will be required to be invariant under $R_t$.

Physically, the K41 degrees of freedom and the dilaton are made of the same fluid variables: the velocity and the pressure. Separating the discussion to first constructing the dilaton effective action in this section and then dressing the K41 operators in the next section is in some sense artificial and simply reflects our ignorance of the detailed combined dynamics until steady state is reached.
In the odd-dimensional case we included a non-local term in the effective action. This opens up a pandora box since there is an infinite number of non-local terms that respect the symmetries and could have been included in the action. A proper physical justification for neglecting them will probably follow from an understanding of the combined K41 fields and dilaton dynamics. A mathematical explanation for neglecting them can come from a better understanding of conformally covariant pseudo-differential operators (see appendix A).

III. TURBULENCE FIELD THEORY

We would like to construct a $d$-dimensional effective field theory for equal time correlation functions of steady state incompressible fluid turbulence. The number of space dimensions $d$ can be even or odd. The Kolomgorov linear scaling theory is a mean field theory (K41), and we will denote its set of degrees of freedom by $\varphi$. It is non-local and non-Gaussian field theory. We propose to define the complete theory as a dressing of the K41 theory by the dilaton $\tau$. The dilaton accounts for the fluctuations around the mean field $\varphi$ that result in the intermittency. This is reminiscent of two-dimensional quantum gravity [5, 6], where matter (our K41 fields) is coupled to a Liouville field (our dilaton). Here, however, both $\varphi$ and $\tau$ are made of the same hydrodynamic variables, the velocity vector $v^i$ and the pressure $p$. Also, unlike two-dimensional quantum gravity, here diffeomorphisms are not gauge symmetries and therefore there are no gauge fixing ghosts. The turbulence field theory is nonunitary since conserved quantities leak from the flux states [13].

As to symmetries, the field theory should exhibit $d$-dimensional translations and rotations and spatial scale invariance $R_x$. We propose that it posseses conformal invariance (suggested for two dimensions in [13]).

A. KPZ Scaling and Critical Exponents

We define the metric $\hat{g}_{ij}$ by dressing the background metric $g_{ij}$ with a dilaton factor:

$$\hat{g}_{ij} = e^{-2\gamma \tau} g_{ij}, \quad \sqrt{\hat{g}} = \sqrt{g} e^{-d\gamma \tau},$$

(30)

Note, that nonunitary scale invariant field theories are not necessarily conformal invariant. An example is the field theory of elasticity [14].
and require that the operator $e^{-d\gamma\tau}$ is a conformal operator of scaling dimension $d$. Using (24) we have
\[ d\gamma(-d\gamma + Q) = 1. \] (31)
Thus,
\[ Q = d\gamma + \frac{4\alpha_d\kappa}{d\gamma}, \] (32)
and
\[ \gamma_\pm = \frac{Q \pm (Q^2 - 16\alpha_d\kappa)^{1/2}}{2d}. \] (33)

We construct the operators of the turbulence field theory $\hat{O}$ by dressing the K41 field theory operators $O$ with a dilaton factor:
\[ \hat{O}(x) = e^{\beta\tau}O(x), \quad \beta = -d\gamma(1 - \Delta). \] (34)

As discussed in the previous section, we require that the $R_t$ charge of the dilaton exponential in (34) will be cancelled by the that of the K41 operator $O$ making $\hat{O}(x)$ $R_t$ invariant. Consider the dressed operator $O(x)$ (34), and let $d\Delta_0$ denote the undressed dimension of $O$. We require that the scaling dimension of $\hat{O}(x)$ is $d$, thus:
\[ -\frac{\beta(\beta + Q)}{4\alpha_d\kappa} + \Delta_0 = 1. \] (35)
Solving (35) we have the KPZ-type relation:
\[ \Delta - \Delta_0 = \frac{d^2\gamma^2}{4\alpha_d\kappa}\Delta(1 - \Delta). \] (36)
for the dressed dimension $\Delta$. The quantity:
\[ G^2 = \frac{d^2\gamma^2}{4\alpha_d\kappa} \] (37)
in (36) is the intermittency parameter $G^2(d)$ in (2).

Consider now the partition function of the turbulent field theory as a function of the volume $V$ of the ball $B_d(L)$:
\[ Z(V) = \int D\varphi D\tau e^{-S} \delta \left( \int \sqrt{g}e^{d\gamma\tau}d^dx - V \right), \] (38)
where $S$ is the turbulent field theory action that includes the K41 fields and the dilaton. Using a similar argument to that in [6], we shift $\tau \rightarrow \tau + \frac{\sigma}{d\gamma}$ where $\sigma$ is constant. This leads to the relation $Z(V) = e^{-\sigma(1 - \frac{Q}{d\gamma})}Z(e^{-\sigma}V)$, hence at large $L$
\[ Z(V) \sim V^{-1 + \frac{Q}{d\gamma}} \sim L^{-d + \frac{Q}{\gamma}} \sim L^{\frac{d}{G^2}}, \] (39)
where we used (32) and (37). The exponent:

$$
\gamma_s = \frac{d}{G^2} = \frac{\partial}{\partial \log L} \log Z(V) ,
$$

(40)
is reminiscent of the string susceptibility and it would be interesting to find a way to check this experimentally and numerically.

Consider next the expectation value of the one-point function:

$$
F_{O}(V) = Z(V)^{-1} \int D\varphi D\tau e^{-S} \delta \left( \int \sqrt{g} e^{d\gamma} \, d^d x - V \right) \int \sqrt{g} e^{d\gamma} e^{-d\gamma(1-\Delta)} O d^d x .
$$

(41)

Shifting by a constant as before we see that

$$
F_{O}(V) \sim L^{d\Delta} ,
$$

(42)

where $\Delta$ is the dressed dimension that satisfies the KPZ relation (36). Note, that with our dressing conventions the dimension $\Delta$ is of opposite sign compared to the standard CFT conventions (24) and is compatible with (2).

Note that the objects that appear in the calculations (38) and (42): the background metric $\sqrt{g} e^{d\gamma}$ and the dressed operators do not carry $R_t$ charges.

**B. Conformal Anomaly**

In the following we will use the requirement of conformal invariance to fix the intermittency parameter in terms of the boundary Euler anomaly coefficients of the K41 and the dilaton field theories.

1. **Even Number of Space Dimensions**

Conformally invariant relativistic field theories in even number of dimensions exhibit conformal anomalies [15]. This can be revealed in flat space correlation functions and via the one-point function of the trace of the stress-energy tensor in a bulk curved background or at the boundary. Since our bulk space is flat the one-point function bulk anomaly vanishes

$$
\langle T^\mu_\mu \rangle_{\text{bulk}} = 0 .
$$

(43)

We do have an anomaly localized at the boundary $r = L$. The boundary is conformally flat hence the relevant anomaly is the Euler A-type one:

$$
\langle T^\mu_\mu \rangle_{\text{boundary}} = (-)^{d/2} a q_d ,
$$

(44)
where $a$ is the boundary anomaly c-number coefficient.

We assume that under a Weyl transformation of the metric $g_{ab} \rightarrow e^{2\sigma}g_{ab}$ the K41 field theory action is invariant:

$$S_{K41}(e^{2\sigma}g, \varphi_\sigma) = S_{K41}(g, \varphi) ,$$

where by $\varphi_\sigma$ we denote the Weyl transformation of $\varphi$. $S_{K41}$ is a formal unknown expression that is expected to be non-local. There is a quantum anomaly due to the non-invariance of the measure of the form:

$$D_{e^{2\sigma}g} \varphi = e^{-a_{K41}S_{l}(\sigma)}D_{g} \varphi ,$$

where $S_l$ given by (A.10) (see [16–19])

$$S_l(\sigma) = \left[ \int_{B_d} \sqrt{g} d^{d}x \frac{d}{2} \Box_{d} \sigma - (-1)^{\frac{d}{2}} \int_{\partial B_d} \sqrt{g} d^{d-1}x \sigma q_{d} \right] ,$$

is the $d$-dimensional Liouville action, and we neglected the terms that are suppressed by inverse powers of $L$. $a_{K41}$ is the Euler anomaly coefficient of the K41 conformal field theory.

Under a Weyl transformation the dilaton field theory action (18) is not invariant:

$$S_{dilaton}(e^{2\sigma}g, \tau - \sigma) = S_{dilaton}(g, \tau) - S_{dilaton}(g, \sigma) ,$$

where to be consistent with the analysis below we used $Q = (-)^{\frac{d}{2}}\frac{2\kappa}{d}$. With this choice, the dilaton action is (up to the overall coefficient $\kappa$) the higher-dimensional Liouville action (47), and (48) follows from (A.4). There is a quantum anomaly due to the non-invariance of the measure:

$$D_{e^{2\sigma}g} \tau = e^{-a_{dilaton}S_{l}(\sigma)}D_{g} \tau ,$$

where $a_{dilaton}$ is the dilaton Euler anomaly coefficient. We will require conformal invariance of the turbulence field theory, and hence a cancellation of the conformal anomaly:

$$(a_{K41} + a_{dilaton})S_{l}(\sigma) - S_{dilaton}(\sigma) = 0 .$$

Denote:

$$a_+ = a_{K41} + a_{dilaton}, \quad \bar{a}_+ = \alpha_d a_+ ,$$

with $\alpha_d$ in (20). The condition for the cancellation of the conformal anomaly (50) gives:

$$\kappa = \frac{-d}{2} a_+, \quad Q = -(-)^{\frac{d}{2}} \bar{a}_+ .$$

13
Using (33) we get:

$$\gamma_{\pm} = \frac{(-1)^{\frac{d}{2}} \bar{a}_+ \pm \left( \bar{a}_+^2 + 8d\bar{a}_+ \right)^{\frac{1}{2}}}{2d}.$$  \hfill (53)

The requirement for real solution in (53) implies that

$$\bar{a}_+ = \bar{a}_{\text{critical}} \leq -8d.$$  \hfill (54)

The KPZ-type relation (36) reads:

$$\Delta - \Delta_0 = -\frac{d\gamma^2}{2\bar{a}_+} \Delta(1 - \Delta),$$  \hfill (55)

for the dressed dimension $\Delta$. The intermittency parameter (37) is expressed in (55) as a function of the number of space dimensions $d$ and the sum of the Euler anomaly coefficients of the K41 and dilaton field theories $a_+$:

$$G^2 = -\frac{d\gamma^2}{2\bar{a}_+}.$$  \hfill (56)

The condition (54) implies that $G^2 \geq 0$. We also have the relation:

$$\gamma_+\gamma_- = -\frac{2\bar{a}_+}{d},$$  \hfill (57)

or alternatively,

$$G_- G_+ = 1.$$  \hfill (58)

For a fixed number of space dimensions and a given $a_+$ there are two branches in (53). When $\frac{d}{2}$ is even: $(+) 1 \leq G^2_+$, where $G^2_+ (\bar{a}_{\text{critical}}) = 1$ and $G^2_+ (\bar{a}_+ \to \infty) = \infty$; $(-) 0 \leq G^2_- \leq 1$, where $G^2_-(\bar{a}_{\text{critical}}) = 1$ and $G^2_-(\bar{a}_+ \to \infty) = 0$, while when $\frac{d}{2}$ is odd they are exchanged: $G^2_+ \leftrightarrow G^2_-.$

2. Odd Number of Space Dimensions

In odd dimensions there is no bulk conformal anomaly but there is a boundary one [20]. In our case the boundary is the $(d - 1)$-sphere and relevant conformal anomaly is the boundary Euler anomaly:

$$\langle T^\mu_\mu \rangle_{\text{boundary}} = (-\frac{d+1}{2}) aE_{d-1},$$  \hfill (59)

where $a$ is the boundary anomaly coefficient. As in the even number of space dimensions case, we assume that under a Weyl transformation of the metric the K41 field theory action...
is invariant. There is a quantum boundary conformal anomaly due to the non-invariance of the measure of the form

\[ D_{e^{2\sigma\varphi}} = e^{-a_{K41}\mathcal{S}_{l,\text{boundary}}(\sigma)} D_g \varphi, \]

(60)

where \( \mathcal{S}_l \) is given by the boundary Liouville action \( \mathcal{A.10} \) (see e.g. [21]) is:

\[ \mathcal{S}_{l,\text{boundary}} = \int_{S_{d-1}} \sqrt{g} \, \varphi^{d-1} \left( \frac{d-1}{2} \sigma \Box \varphi + (-) \frac{d+1}{2} \sigma \mathcal{E}_{d-1} \right), \]

(61)

and we neglected the terms that are suppressed by inverse powers of \( L. \ a_{K41} \) is the Euler boundary anomaly coefficient of the K41 conformal field theory.

Under a Weyl transformation the dilaton field theory action is not invariant and one gets that its local part satisfies (18). There is also a quantum conformal boundary anomaly due to the non-invariance of the measure

\[ D_{e^{2\sigma\tau}} = e^{-a_{\text{dilaton}}\mathcal{S}_{l,\text{boundary}}(\sigma)} D_g \tau, \]

(62)

where \( a_{\text{dilaton}} \) is the dilaton Euler boundary anomaly. We will require conformal invariance of the turbulence field theory on \( B_d \), and hence a cancellation of the conformal anomaly (50). Using (27) (28) (29) and (61) we get

\[ \tilde{\kappa} = -\frac{d-1}{2} a_+, \quad \kappa = -\frac{d \tilde{a}_+}{2 a_d}, \quad Q = (-) \frac{d+1}{2} 2\tilde{a}_+, \]

(63)

where

\[ \tilde{a}_+ = a_{d-1} a_+. \]

(64)

Repeating the same steps as in the even-dimensional case we have:

\[ \gamma_{\pm} = \frac{(-) \frac{d+1}{2} \tilde{a}_+ \pm (a_+^2 + 2d\tilde{a}_+)\frac{1}{2}}{d}. \]

(65)

The requirement for real solution in (65) implies that

\[ \tilde{a}_+ = \tilde{a}_{\text{critical}} \leq -2d. \]

(66)

The KPZ-type equation (57) and (58) continue to hold with the definition (64). The analysis of the \((\pm)\) branches is similar except that one replaces the \( \frac{d}{2} \) odd and even cases by \( \frac{d+1}{2} \) odd and even cases, respectively.

The cancellation (50) is of the local terms and one remains with non-local terms that violate conformal invariance. As discussed in the appendix, it is plausible that there is an analog of the action \( \mathcal{A.3} \) for the bulk fractional derivative operator, which can be used to cancel the non-local terms. Another possibility is that these non-local violating terms should be cancelled by the K41 field theory. Clearly this issue needs further study.
3. Summary

We proposed to associate with \((\delta v(r))^n\) in a CFT operator \(\hat{O} = e^{-d\gamma(1-\Delta)\tau}O_{K41}\)
where the K41 field theory operator \(O_{K41}\) is dressed by the dilaton factor. The map between the fluid variables and the CFT variables is such that \(\Delta(O_{K41}) = d\Delta_0 = \frac{dn}{3}\) and \(\Delta = \xi_n\) is the anomalous scaling \(\langle\rangle\). More generally, we can consider not just the anomalous dimensions but also correlation functions \(\langle \hat{O}_1(r_1)...\hat{O}_N(r_N) \rangle\) that may be checked numerically or experimentally. Note, that the boundary anomaly coefficient \(a_+\) depends on the boundary condition of \(\varphi\) and \(\tau\) on \(\partial B_d\). This should probably be related to \((\tau)\) and the forcing.

As noted, for a fixed number of space dimensions and a given \(a_+\) there are two branches in \((\tau)\) and \((\mu)\). One may argue, that the "semi-classical" limit of large \(|a_+|\) corresponds to weak intermittency, and indicates the choice of the branch. This is compatible with the experimental and numerical data in three and four space dimensions where the intermittency parameter \(G^2\) is smaller than one \([1]\). However, it is not clear that the intermittency parameter cannot exceed one in general, which requires the other choice of branch.

C. The Conformal Anomaly Coefficients

The Euler conformal anomaly coefficient of the dilaton or K41 CFT can be obtained from its partition function \(Z_{B_d}\) on the ball \(B_d(L):\)

\[
a \sim \frac{\partial}{\partial \log L} \log Z_{B_d}(L) = - \int \sqrt{g} d^d x \langle T^\mu_\mu \rangle.
\]  

This calculation can be done for the dilaton field theory but not yet for the K41 CFT.

1. The Dilaton Theory

Consider an even number of space dimensions. The are two terms in the dilaton partition function that contribute to the anomaly coefficient: One contribution is from \(S_0\) \([15]\) and the second from the background charge term \([16]\) \(^3\). Denote this by \(a_{dilaton} = a_0 + a_{charge}\).

\(S_0\) \([15]\) can be coupled to gravity in a Weyl invariant way using the Weyl covariant GJMS operators \([22]\). On a constant curvature even-dimensional conformally flat manifold

\(^3\) I thank T. Levy for a discussion on this point.
of dimension $d$ the higher derivative GJMS operator factorizes as a product of Laplacians with masses. The conformal anomaly coefficient can be calculated and one gets in our notation [23]:

$$a_0 = -\frac{1}{d!\alpha_d} \int_0^d dt \int_0^{\frac{d}{2}-1} \prod_{i=0} (i^2 - t^2). \quad (68)$$

$a_0$ is positive when $\frac{d}{2}$ is odd and negative when it is even. Note, that if we integrate from zero to one in (68) we will get the anomaly coefficient of a free scalar in $d$ dimensions.

The contribution of the background charge to the partition function gives:

$$\log Z = -\frac{1}{2} \bar{a}_+ \log L, \quad (69)$$

where we used [21], [52] and [A.15]. The background charge contribution to the dilaton anomaly coefficient is:

$$a_{charge} = -\frac{(-)^d}{2} a_+. \quad (70)$$

As we will see, the value of $a_0$ is negligible compared to the value needed for $a_+$ when we match to the turbulence data, hence $a_{dilaton} \approx a_{charge}$. We are interested in the boundary anomaly and its precise value depends on the boundary conditions that will be imposed. However, this will not change significantly neither the values nor their large $d$ behaviour. The same calculation can be done for an odd-dimensional bulk with an even-dimensional boundary where $a_{charge} = -\frac{(-)^{d+1}}{2} a_+$ and the same conclusion holds.

2. $K41$ Effective Field Theory

The Kolmogorov linear scaling theory is a non-local theory, perhaps of vortices. It assumes that the mean viscous energy dissipation rate $\epsilon$ is constant in the limit of infinite Reynolds number, from which a linear scaling of the exponents follows. In K41 theory the random velocity field is self-similar which misses the intermittency of the turbulent flows. Although we know the spectrum of scaling dimensions, we need more information in order to construct the field theory and calculate the anomaly coefficient $a_{K41}$.

Let us first estimate the number of degrees of freedom of the K41 mean field theory following Landau’s argument. We assume that K41 is a theory of vortices of size $k_\nu^{-d}$, where $k_\nu \sim \left(\frac{\nu}{\nu_0}\right)^{\frac{1}{4}}$ is the viscous scale. The vortices fill a domain of size $L$, thus the number of degrees of freedom $N \sim (Lk_\nu)^d \sim R_e^{\frac{d}{3}},$ where $R_e$ is the Reynolds number $R_e \sim \frac{L^4}{\nu}$. 

17
We can try to estimate the anomaly coefficient $a_{K41}$ by multiplying the number of degrees of freedom by the anomaly coefficient $a_{\text{vortex}}$ of a free conformally invariant vortex field theory, e.g. a CFT of a two-form field in $d$ dimensions \[24\]. The calculation of $a_{\text{vortex}}$ can be done using the standard $\zeta$-function method and it is on general grounds an exponentially decreasing function of the number of space dimensions. By the Landau estimate $N$ is an exponentially increasing function of the number of space dimensions. It is hard at this point to draw a definite conclusion about the large $d$ behaviour of $|\bar{a}_{K41}|$ although the bounds \[54\] and \[66\] imply that it should grow at least linearly with $d$.

D. Entanglement Entropy

Taking a space derivative of the NS equation \[5\] and using the incompressibility condition one gets a relation between the fluid velocity and pressure

$$\nabla^2 p = -\partial_i v^j \partial_j v^i, \quad (71)$$

that is the pressure is non-locally related to the velocity.

The strength of intermittency is determined by a competition between the small scale cascade and the non-local pressure effect that couples different regions in space and tends to calm it \[25\]. The choice of the branch in \[53\] and \[65\] that is compatible with the data in three and for space dimensions suggests that in a fixed number of space dimensions the strength of the intermittency decreases with the increase of the Euler conformal anomaly coefficient $|a_+|$ of the effective conformal field theory of turbulence \[55\].

Entanglement entropy of quantum fields is a valuable tool to quantify the entanglement between degrees of freedom at different spatial regions. If we divide the space to two parts $A$ and $B$ and construct the reduced density matrix $\rho_A = Tr_B \rho$, the entanglement entropy is the von-Neumann entropy of $\rho_A$. The universal part of the entanglement entropy of a CFT is proportional to the conformal anomaly coefficient. For us :

$$S_A \sim |a_+| \log \frac{L}{l}, \quad (72)$$

where $L$ is the scale size of $A$ and $l$ is the UV cutoff, which is the viscosity scale. For large $|a_+|$ the entanglement entropy is large indicating a strong correlation between the different spatial region and hence weak intermittency. For small $|a_+|$ the entanglement entropy is
small indicating a weak correlation between the different spatial regions and hence strong intermittency. This is compatible with the predictions of the KPZ-like formula for the anomalous scaling (55) if we work in the branch $0 \leq G^2 \leq 1$, which is the branch appropriate for the data in three and four dimensions.

Information theory is a valuable framework for the analysis of quantum field theory properties. The above quantitative analysis suggests that perhaps such tools could prove useful also if applied to the statistical theory of incompressible fluid turbulence.

IV. TWO, THREE AND LARGE NUMBER OF DIMENSIONS

A. Two-dimensional Turbulence

In two-dimensional incompressible fluid turbulence the energy cascade is an inverse cascade, that is the energy flux flows to large length scales, and the numerical and experimental data are compatible with Kolmogorov linear scaling. Hence we expect that $G(d = 2) \sim 0$. In [26] the isovorticity lines of two-dimensional inverse cascade turbulence have been studied numerically and have been identified as $SLE_\kappa$ curves with $\kappa = 6$ (for an $SLE$ review see e.g. [27]). This result suggests that there is an underlying two-dimensional conformal structure in inverse cascade turbulence theory. The central charge of this theory can be read from $\kappa$ via

$$c = \frac{(8 - 3\kappa)(\kappa - 6)}{2\kappa},$$

and using $\kappa = 6$ we get $c = 0$. The two-dimensional relativistic Euler conformal anomaly coefficient $a$ is the central charge $c$ of the theory.

This can be compatible with our analysis if there is no NG dilaton in the two-dimensional inverse cascade where the IR scale is the viscous scale, and is perhaps analogous to non-existence of NG bosons in two-dimensional relativistic field theories. We associate with the two-dimensional turbulent field theory $a_{\text{dilaton}} = a_{K41} = 0$ and consistently Eq. (52) implies that the dilaton effective action vanishes. There is no dressing of the K41 operators, the bound (54) is not satisfied and we should not use the the KPZ relation (55). The intermittency parameter vanishes and we have the Kolmogorov linear scaling. This is reminiscent of two-dimensional quantum gravity [5, 6] in the case where the central charge of the matter $c_{\text{matter}} = -c_{\text{ghost}} = 26$ and the matter CFT decouples from gravity.
B. Three-dimensional Turbulence

The value of the conformal anomaly coefficient that is needed in order to explain the experimental and numerical data of three-dimensional turbulence is $\bar{a}_+ \sim -12.6$ and $a_+ \sim -1$ since $G^2 \sim 0.16$ [1], and we need to choose the $(-)$ branch. The main contribution to the dilaton anomaly comes from the background charge [70]: $a_{\text{dilaton}} \simeq a_{K41} \simeq \frac{a_+}{2}$. It is curious that we need such a large anomaly coefficient $a_+$ to account for the turbulence data: $|a_+| \sim 10^3 a_{\text{scalar}}$, where $a_{\text{scalar}}$ is the boundary Euler anomaly coefficient of a free scalar in three dimensions [21]. Although we cannot perform a precise calculation at this point, the estimate of $a_{K41}$ in a previous subsection can account for such a large number.

C. Large $d$ Turbulence

The analysis at large $d$ depends on the asymptotics of $a_+$. The numerical data in four space dimensions is compatible with $\bar{a}_+ \sim -47$ and $a_+ \sim -0.15$ since $G^2_+ \sim 0.278$ [1]. As above, $|a_+| \sim 10^3 a_{\text{scalar}}$ where now $a_{\text{scalar}}$ is the Euler anomaly coefficient of a free scalar in four dimensions. We have an indication that $\bar{a}_+$ increases while $a_+$ decreases as we increase $d$, which is also the behaviour of the critical values $\bar{a}_{\text{critical}}$ and $a_{\text{critical}}$. The large $d$ behaviour of the anomalous exponents depends on the detailed limit of $\bar{a}_+$. If it approaches $\bar{a}_{\text{critical}}$ we will have in the limit $G^2_+ = G^2_+ = 1$ and $\xi_n \sim \sqrt{n}$. However, it can increase to infinity faster than $\bar{a}_{\text{critical}}$ and depending on the branch we can get the suggestion of [28] that $\xi_n \rightarrow 1$ at large $d$, or $\xi_n \sim n$.

V. DISCUSSION AND OUTLOOK

We proposed an effective CFT description of steady state incompressible fluid turbulence at the inertial range of scales, which consists of a K41 mean field CFT coupled to a NG dilaton. The dilaton arises from a spontaneous breaking, due to the energy flux, of the separate scale and time symmetries of the inviscid Navier-Stokes equations to the K41 scaling. We proposed that it acts as a random measure that dresses the K41 theory and introduces intermittency. Using this framework we derived a KPZ-type equation for the anomalous scaling [55], and related the intermittency parameter to the boundary Euler A-type conformal anomaly coefficient in [53], [56] and [65]. We noted that field theory entanglement...
entropy can be used to characterize the intermittency strength. Finally, we considered the physical cases of two and three space dimensions and the large $d$ limit.

There are many open questions that are worth pursuing. The most important one is the construction of the K41 effective field theory and the calculation of the conformal anomaly coefficient and the intermittency parameter. In particular, an understanding of the physical two-dimensional and three-dimensional cases and the non-local structure of the odd-dimensional cases in general is required. A careful analysis of the boundary conditions is also needed since the value of the anomaly coefficient depends on that. Developing the OPE and bootstrap approach to the flux states can lead to a significant breakthrough in understanding the turbulence field theory (see [29]). Studying the consistency conditions on the KPZ scaling that follow from the NS equation as suggested in [30] is a valuable direction to follow. There is a mixture in the constraint equations that involve the longitudinal as well as the transversal structure functions [31], which in order to solve requires a proposal for the form of the transverse structure functions. The KPZ scaling [55] predicts that at large $n$ and finite $d$ the anomalous scalings $\xi_n \sim \sqrt{n}$. It would be of much importance to understand what type of fluid field configurations can lead to such a scaling.

There is a puzzle that needs to be addressed. If we try to use KPZ formula for the local energy dissipation $\epsilon(x)$, whose undressed K41 dimensions $\Delta_0[\epsilon(x)] = 0$, we get $\Delta[\epsilon(x)] = 1 - \frac{1}{G^2}$. But in order to match to experimental data in three space dimensions $\Delta \sim -0.1$, this means $G^2 \sim 1$. The data for the structure functions $S_n$ suggest $G^2 \sim 0.16$ [1]. It is possible that one cannot apply the KPZ-type formula to $\epsilon(x)$, but understanding why this is the case, and in general for which operators the KPZ formula can be applied is important.

In one space dimension one describes (compressible) fluid flows by the Burgers equation. The steady state statistics is characterized by the anomalous scaling exponents $\xi_n = 1$. It would be interesting to see whether a one-dimensional CFT on a line interval provides a field theory description of Burgers turbulence that requires an infinite intermittency parameter. Another interesting direction to follow is the anomalous scalings of relativistic turbulence [32, 33] and the construction of an effective field theory framework to calculate them.

The AdS/CFT correspondence is a powerful framework to analyze strongly coupled CFTs [34] and perhaps can be used to study our proposal for an effective field theory of turbulence.

Finally, the field theory structure that has been discussed in this work is worth studying irrespective of whether it provides the correct description of incompressible fluid turbulence.
In particular, the higher-dimensional generalization of the Liouville action (A.3) and (A.18) is both an interesting CFT and may be an important ingredient in studying a summation over manifolds as part of a study of higher-dimensional random geometry and gravity [38].

ACKNOWLEDGEMENTS

I would like to thank I. Arav, C. Bachas, C. Eling, I. Hason, B. Keren-Zur, T. Levy, V. Mukhanov and A. Polyakov for discussions. Appendix: Notations and Higher-Dimensional Liouville Field Theory

Let $M$ be an even-dimensional manifold of dimension $d$ and metric $g_{ab}$. Under a Weyl transformation of the metric $g_{ab} \rightarrow e^{2\sigma} g_{ab}$ the conformally covariant GJMS operator $P \equiv \Box^d_d + \text{lower order}$ transforms as:

$$P_{e^{2\sigma}g} = e^{-d\sigma} P_g ,$$

and the $Q$-curvature [35], $Q = -\frac{1}{2(d-1)} \Box^{d-1}_d R + \ldots$ as:

$$Q_{e^{2\sigma}g} = e^{-d\sigma} (Q_g + P_g \sigma) .$$

Define the higher-dimensional Liouville action by:

$$S(g, \tau) = \int_M \sqrt{g} d^d x (\tau P \tau + 2\tau Q_g) .$$

Under the Weyl transformation $g_{ab} \rightarrow e^{2\sigma} g_{ab}, \tau \rightarrow \tau - \sigma$ we have:

$$S(e^{2\sigma}g, \tau - \sigma) = S(g, \tau) - S(g, \sigma) .$$

We can relate the $Q$-curvature and the Euler density $E_d$ on a constant curvature conformally flat manifold $M$. Using:

$$\int_M Q_g = \frac{(-1)^d}{d} (4\pi)^{\frac{d}{2}} (\frac{d}{2})! \chi(M) ,$$

and

$$\int_M E_d = (4\pi)^{\frac{d}{2}} (\frac{d}{2})! \chi(M) ,$$
where $\chi(M)$ is the Euler characteristic of $M$ and $E_d$ is the Euler density, we obtain on a constant curvature conformally flat manifold the relation:

$$E_d = (-1)^{\frac{d}{2}} d Q_g .$$  \tag{A.7}$$

Since $\chi(S^d) = 2$ we get from (A.6)

$$\int_{S^d} E_d = \Omega_d d! , \tag{A.8}$$

where

$$\Omega_d = \frac{2(\pi)^{\frac{d+1}{2}}}{\Gamma\left[\frac{d+1}{2}\right]} \frac{2(4\pi)^{\frac{d}{2}}(\frac{d}{4})!}{d!} , \tag{A.9}$$

is the surface volume of the $d$-sphere.

Using (A.3) and (A.7) we define:

$$S_{\text{Liouville}}(g, \tau) = \int_M \sqrt{g} d^d x \left( \frac{d}{2} \tau \Box d \tau + (-1)^{\frac{d}{2}} \tau E_d \right) , \tag{A.10}$$

Using (A.4) we have under Weyl transformation to order $O(\sigma^2)$:

$$\delta_\sigma S_{\text{Liouville}}(g, \tau) = \int_M \sqrt{g} d^d x \sigma T^\mu_\mu = \int_M \sqrt{g} d^d x \sigma \left( -(-1)^{\frac{d}{2}} E_d \right) . \tag{A.11}$$

Hence, the anomaly action $a S_{\text{Liouville}}$ where $a$ is the anomaly coefficient gives:

$$\langle T^\mu_\mu \rangle = -(-1)^{\frac{d}{2}} a E_d . \tag{A.12}$$

Note that in $d > 2$ there are addition terms in the WZ anomaly action compared to (A.10), which in our work were surpressed since we worked in the inertial range of scales $r \ll L$, where $L$ is the size of the ball and the boundary sphere. (A.12) follows from solving the Wess-Zumino consistency conditions and is independent of whether the CFT is unitary.

The Euler characteristic of an even-dimensional manifold of dimension $d$ with a boundary reads:

$$\chi(M) = \frac{2}{\Omega_d d!} \left( \int_M E_d - \int_{\partial M} q_d \right) , \tag{A.13}$$

where $\partial M$ is the boundary of $M$ and $q_d$ is a boundary Euler class term constructed from the boundary intrinsic and extrinsic curvatures. When $M = B_d$ is the $d$-dimensional ball in Euclidean space, whose boundary is the $d$-sphere $\partial M = S^{d-1}$, the bulk Euler term $E_d$ is zero in (A.13). The ball $B_d$ is contractible, hence its Euler characteristic is that of the point $\chi(B_d) = 1$,

$$\chi(S^{d-1}) = (1 + (-1)^{d-1}) \chi(B_d) , \tag{A.14}$$
which fixes the normalization of \( q_d \) as:
\[
- \int_{\partial B_d} q_d = \frac{1}{2} \Omega_d d! = \alpha_d .
\]
(A.15)

The Liouville action (A.10) and its conformal transformation (A.11) in the presence of the boundary are defined in the same way.

In general, one can also define a boundary \( P^b \equiv P_{d-1}^2 \) that transforms as [36] :
\[
P^b_{e^{2\sigma}g} = e^{-(d-1)\sigma} P^b_g ,
\]
(A.16)
and a boundary \( Q \)-curvature such that :
\[
Q^b_{e^{2\sigma}g} = e^{-(d-1)\sigma} (Q^b_g + P^b_g) .
\]
(A.17)

When \( M \) is an odd-dimensional manifold of dimension \( d \) one can define a pseudo-differential conformally covariant GJMS operator \( P_d = \Box_{d/2} + \text{lower order} \), which transforms under Weyl transformation as in (A.1) (see e.g. [37]). It is plausible that one can define the analog of the \( Q \)-curvature and the action (A.3) in this case. We are not aware, however, of such a construction.

Finally, note that we can add a ”cosmological constant” term to the Liouville action (A.3) of the form :
\[
S_{\text{cosmo}}(g, \tau) = \int_M \sqrt{gd^d x} e^{d\tau} ,
\]
(A.18)
which we did not use in this work, but will be valuable in the study of the higher-dimensional Liouville theory.
