Abstract

The probabilities of various elementary laser - photon - electron/positron interactions display in selected phase space and parameter regions typical non-perturbative dependencies such as $\propto P \exp\{-aE_{\text{crit}}/E\}$, where $P$ is a pre-exponential factor, $E_{\text{crit}}$ denotes the critical Sauter-Schwinger field strength, and $E$ characterizes the (laser) field strength. While the Schwinger process with $a = a_S \equiv \pi$ and the non-linear Breit-Wheeler process in the tunneling regime with $a = a_{ntBW} \equiv 4m/3\omega'$ (with $\omega'$ the probe photon energy and $m$ the electron/positron mass) are famous results, we point out here that also the non-linear Compton scattering exhibits a similar behavior when focusing on high harmonics. Using a suitable cut-off $c > 0$, the factor $a$ becomes $a = a_{ntC} \equiv 2cm/(p_0 + \sqrt{p_0^2 - m^2})$. This opens the avenue towards a new signature of the boiling point of the vacuum even for field strengths $E$ below $E_{\text{crit}}$ by employing a high electron beam-energy $p_0$ to counter balance the large ratio $E_{\text{crit}}/E$ by a small factor $a$ to achieve $E/a \to E_{\text{crit}}$. In the weak-field regime, the cut-off facilitates a threshold leading to multi-photon signatures showing up in the total cross section at sub-threshold energies.

Keywords: non-linear Compton scattering, strong-field QED, Breit-Wheeler pair production, Schwinger effect
I. INTRODUCTION

The Schwinger process signals the instability of the vacuum against particle (pair) creation in an external field. The pair \((e^+e^-)\) production rate \(\propto \exp\{-aE_{\text{crit}}/E\}\), \(a = \pi \left[1–3\right]\), in a spatio-temporally homogeneous electric field of strength \(E\) is exceedingly small due to the large value of the (critical) Sauter-Schwinger field strength \(E_{\text{crit}} = 1.3 \times 10^{18} \text{ V/m}\) and therefore escaped a direct experimental verification until now. Much hope was therefore put on the progressing laser technology which however delivers even at present and near-future ”ultrahigh intensities” far too low field strengths \[4, 5\]. Many efforts on the theory side attempted to find field configurations which enhance the Schwinger type pair production. To cite a few entries of the fairly extended literature, which documents the ongoing enormous interest in that topic, we mention dynamical assistance \[6–18\], double assistance effects \[19, 20\], multi-beam configurations \[21\] and their embedding into optimization procedures \[22, 23\]. In essence, these attempts envisage a reduction of the factor \(a\) in the above exponent, which is in general a complicated function of the external parameters. Despite such a ”practical goal”, these investigations aim at understanding the QED as a pillar of the Standard Model in the non-perturbative, high-intensity regime. Given the seminal meaning of the Schwinger process as paradigm for related processes, e.g. particle production in cosmology \[24\] and at black hole horizons as Hawking radiation \[25\], up to the disputed Unruh radiation \[26, 28\], various authors considered analog processes, e.g. in condensed matter physics \[29, 30\] and in wave guides \[31\] etc., which display also the monomomial, genuinely non-perturbative dependence on an external field parameter.

Still within QED, one can search for more easily accessible processes which have the prototypical non-perturbative dependence \(\propto \exp\{-aE_{\text{crit}}/E\}\). For instance, the LUXE collaboration \[32–34\] envisions to exploit the non-linear Breit-Wheeler process which is known to behave as \(\propto \exp\{-a_{\text{nlBW}}E_{\text{crit}}/E\}\) in the tunneling regime with \(a_{\text{nlBW}} = 4m/3\omega'\), where \(\omega'\) is the energy of a probe photon traversing a strong laser pulse. LUXE is planned as next-generation follow-up of the seminal SLAC experiment E-144 \[35\], which operated in the multi-photon regime, by ”Measuring the Boiling Point of the Vacuum of Quantum Electrodynamics” \[32\] via the non-linear Breit-Wheeler process since \(\omega' \gg m\) reduces the exponential suppression, i.e. it makes the above quantity \(a_{\text{nlBW}}\) small when using probe photon energies \(\omega'\) much larger than the electron mass \(m\), thus compensating the large
value of $E_{\text{crit}}/E$ at presently attainable facilities. Note furthermore that the trident process shows also an exponential behavior under certain conditions [36, 37], as originally elaborated in [38, 39].

Here, we point out that the non-linear Compton process has a similar non-perturbative exponential field strength dependence under certain side conditions. The key is the suppression of the low harmonics which facilitate the Thomson limit and display a polynomial dependence. What is then left is the otherwise exponentially suppressed contribution. The analogy to the non-linear Breit-Wheeler process is not surprising since it is the crossing channel of the non-linear Compton process in the Furry picture. The crucial difference is in the final-state phase spaces. This is most clearly evident in the perturbative, weak-field limit, where the Breit-Wheeler process is a threshold process, while the Compton process without side conditions has no threshold (see [40, 41] for the physical regions in the Mandelstam plane). We introduce here as side condition a cut-off which is related to exit channel kinematics. This in fact enforces the exponential behavior.

Our brief note is organized as follows. In section II we outline the definition of a Lorentz invariant cut-off in the non-linear Compton scattering. In section III the restriction of the physically accessible regions in the Mandelstam plane is discussed. The cut-off facilitates a clear signature of multi-photon effects in the total cross section in the weak-field regime (section IV). The moderately strong-field regime is considered in section V where we compare the exact numerical results with some approximation formula to evidence the exponential dependence of the cross section. The discussion section VI contains a comparison with laser pulses and outlines of how the cut-off is realized by photon observables in the exit channel. We summarize in section VII.

II. NON-LINEAR COMPTON SCATTERING WITH CUT-OFF

We consider here a monochromatic laser field in plane wave approximation for circular polarization. The non-linear Compton (nℓC) cross section with cut-off $c$ reads

$$
\sigma = \frac{\alpha^2 \pi}{a_0^2} \frac{1}{k \cdot p} F(a_0, k \cdot p, c), \quad F(a_0, k \cdot p, c) = \sum_{n=1}^{\infty} \int_c^{y_n} dx \frac{1}{(1 + x)^2} F_n(z_n),
$$

where

$$
F_n(z_n) = -4J_n(z_n)^2 + \left(2 + \frac{x^2}{1 + x}\right) a_0^2 \left[ J_{n+1}(z_n)^2 + J_{n-1}(z_n)^2 - 2J_n(z_n)^2 \right]
$$
for $c \leq y_n$ and $F_n = 0$ elsewhere. The Lorentz and gauge invariant quantity $a_0$ is the classical non-linearity parameter characterizing solely the laser beam, and $\alpha$ stands for the fine-structure constant. The arguments of the Bessel functions $J_n$ read explicitly $z_n(x, y_n, a_0) = 2n a_0 \frac{1}{y_n} \sqrt{\frac{x(y_n - x)}{1 + a_0^2}}$, where the two invariants $x = k \cdot k'/k \cdot p'$ and $y_n = 2n \frac{k_p}{m^*_e}$ with $0 \leq x \leq y_n$ enter. For $c = 0$, one recovers the textbook formulas, e.g. in [40, 41], where the effective mass $m^*_e = m^2(1 + a_0^2)$ and the (quasi-)momentum balance as well as the relation to asymptotic four-momenta ($p/p'$ for $in/out$-electrons and $k/k'$ for $in/out$-photons) are discussed in detail.

The only but decisive difference is the introduction of the cut-off $c$ in (1) which pushes the lower limit of the $x$ integration to higher values, i.e. it is aimed at suppressing the lower harmonics.

### III. KINEMATICS IN THE MANDELSTAM PLANE

The meaning of the cut-off $c$ can be visualized in a covariant manner by inspecting the Mandelstam plane. Defining the invariants $s_n = (q + nk)^2$, $t_n = (k' - nk)^2$, $u_n = (q' - nk)^2$ for harmonics $n = 1, 2, 3 \cdots$, the physical regions I - III in scaled triangular coordinates $\hat{s} = s/m^2_e$, $\hat{t} = t/m^2_e$, $\hat{u} = u/m^2_e$ with $\hat{s} + \hat{t} + \hat{u} = 2$ refer to processes related by crossing symmetry on amplitude level: I (red area in Fig. [1]) for nCL process, $e^- + n\gamma \rightarrow e'^- + \gamma'$ or $q + nk = q' + k'$ with quasi-momenta $q$ and $q'$, II (upper gray area) for non-linear Breit-Wheeler (nLBW) pair production, $\gamma' + n\gamma \rightarrow e^+ + e^-$ or $k' + nk = q_e^+ + q_e^-$, and III (left gray area) as mirror of I, e.g. $e^+ + n\gamma \rightarrow e'^+ + \gamma'$. In I, the harmonics $\hat{s}_n = \text{const}$ are parallel lines (in blue in Fig. [1]), limited by $\hat{t} = 0$ (on-axis forward scattering, where $x = 0$) and by the hyperbola $\hat{s}\hat{u} = 1$ (on-axis backscattering), i.e. the physical interval of each harmonic is given by $0 \leq \hat{t} \leq 2 - \hat{s}_n - \hat{s}^{-1}_n$, which is another way of expressing the above quoted restriction $0 \leq x \leq y_n$. The scaled invariant-energy squared of the first harmonic is $\Delta \hat{s} = 1 + \Delta \hat{s}$ (measured from the bullet at the top of I in direction of the $\hat{s}$ coordinate, indicated by the arrow, as shown for the other coordinates too) and the spacing of adjacent harmonics is $\Delta \hat{s} = \hat{s}_{n+1} - \hat{s}_n = 2k \cdot p/m^2_e$. Considering an optical laser (we use the frequency $\omega = 1 \text{ eV}$ as representative value) colliding head-on with an electron beam, as available (i) in HZDR (40 MeV [12]) or planned (ii) at ELI (600 MeV [13]) and (iii) at LUXE (17.5 GeV [33]) for instance, one has (i) $\Delta \hat{s} \approx 6.5 \times 10^{-3}/(1 + a_0^2)$, (ii) $9.6 \times 10^{-2}/(1 + a_0^2)$ and (iii) $2.8 \times 10^{-1}/(1 + a_0^2)$ in the red region displayed in Fig. [1]. Instead of displaying so many
FIG. 1: (Color online) Mandelstam plane with physical regions of nℓC process (I, red area), nℓBW process (II, upper gray area) and the mirrored Compton I (III, left gray area). Arrows indicate the directions of positive variables \( \hat{s}, \hat{t} \) and \( \hat{u} \), and a few coordinate values are provided too. Bullets depict thresholds. Harmonics of nℓC are parallel to (and may coincide with) the blue lines in region I, which become restricted to the dark-red region (labeled by “\( x > 1 \)”) below the boundary \( x = 1 \) (in yellow) and above the hyperbola \( \hat{s}\hat{u} = 1 \) (in green) when imposing the cut-off \( c = 1 \) which facilitates the threshold at coordinates \( \hat{s} = 2, \hat{t} = -\frac{1}{2}, \hat{u} = \frac{1}{2} \). In region II, the harmonics of nℓBW are parallel to (and may coincide with) the horizontal green lines.

narrow parallel lines representing the harmonics, we depict only a few representative proxies of them at \( \hat{s} = \frac{3}{2}, 2, \frac{5}{2}, 3 \) etc. as blue lines. In contrast to the perturbative, weak-field limits of the linear processes, \( n = 1, a_0 \to 0 \), the physical regions I - III of the non-linear processes are mapped out by the discrete harmonics \( n = 1 \cdots \infty \).

The cut-off \( c = 1 \) in (1) restricts the region I to the dark-red area, limited by a section of the hyperbola \( \hat{s}\hat{u} = 1 \) and the line \( x \equiv k \cdot k'/k \cdot p' = \hat{t}_n/(1 - \hat{s}_n - \hat{t}_n) \geq c \). This excludes the low harmonics \( \hat{s}_n < 2 \) and restricts the admissible \( \hat{t} \) intervals of the harmonics \( \hat{s}_n \geq 2 \) to \( \frac{1}{2}(1 - \hat{s}_n) \geq \hat{t} \geq 2 - \hat{s}_n - \hat{s}_n^{-1} \). For the above quoted numbers, harmonics with \( n > (1+a_0^2)/2p \cdot k \).
FIG. 2: (Color online) Scaled cross section of nℓC with cut-off values \( c = 1 \) (blue curves) and \( c = 2 \) (orange curves) for \( a_0 = 0.01 \) (left panel) and \( a_0 = 0.1 \) (right panel). The dashed curves depict separately the harmonic \( n = 2 \). Note the use of the variables \( \tilde{s} \equiv 2p \cdot \mathbf{k}/m^2 = (s_1 - m_n^2)/m^2 \) (bottom abscissa) or \( \chi = a_0 \tilde{s}/2 \) (top abscissa); accordingly, the harmonic thresholds are at \( \tilde{s} = c(1 + a_0^2)/n \).

For comparison, the Klein-Nishina cross section is depicted by a dotted curve, and the Thomson cross section is marked by a circle. Upon increasing the value of \( a_0 \), more and more harmonics are lifted, and at \( a_0 = 1 \) (not displayed) already a multitude of harmonics adds up to generate smooth distributions in the sub-threshold region, i.e. below \( \tilde{s} = 1 \) (2) for \( c = 1 \) (2). These distributions are discussed as functions of \( 1/\chi \), instead of \( \tilde{s} \) or \( \chi \), in section V below.

Imagine now that we keep the laser frequency \( \omega = |\mathbf{k}| \) but lower the electron energy \( p_0 \), i.e. the values of \( \tilde{s}_n \) would become gradually smaller. Then, a certain number of harmonics drop out the admissible area as they pass the threshold by moving to the left-above: less and less harmonics contribute to the nℓC process by (i) imposing a threshold by the cut-off \( c > 0 \) and/or (ii) diminishing \( \tilde{s}_1 \) (and all other \( \tilde{s}_n \)).

IV. MULTI-PHOTON REGIME, \( a_0 < 1 \)

To highlight this channel closing effect with invariant variables we exhibit in Fig. 2 the nℓC cross section as a function of \( \tilde{s} \equiv 2k \cdot p/m^2 \) for \( a_0 = 0.01 \) and 0.1 for two cut-off values, \( c = 1 \) and 2. The figure unravels clearly the multi-photon effects which look completely the
same as known from nℓBW, see figure 3 in [44] (complementary approaches to multi-photon effects are considered in [45]). Thus, the channel closing effect is exactly analog to sub-threshold nℓBW pair production in region II [46]. There, the threshold ̂t = 4 (depicted as bullet at bottom of the green top parabola ̂s ̂u = 1 in Fig. 1) limits the physically admissible region: only harmonics with ̂t_n ≥ 4 contribute. The notion ”sub-threshold” means ̂t_n = 1 < 4.

Similar to the nℓC process, we have displayed in Fig. 1 only two possible proxies (horizontal green lines) of two harmonics of nℓBW in the region II. Note that, in considering nℓBW pair production per se, one changes usually the coordinate names ̂t_n → ̂s_n etc. according to the crossing symmetry relations [41].

V. NON-PERTURBATIVE REGIME, a_0 ≥ 1

After enforcing a non-trivial threshold in nℓC process by the cut-off c > 0, one expects a further similarity to the nℓBW in the region a_0 > 1 despite different phase spaces. As shown originally in [47–49], in the tunneling regime a_0 ≲ 1/√κ ≫ 1, the nℓBW pair creation rate scales as ∝ κ exp{−8/3κ}, where κ = a_0 k · k'/m^2 (here, k and k' are the in four-momenta of the laser and probe photons). In head-on collisions, κ = 2ω' E/E_{crit} since a_0 = m ω E_{crit}. That yields the Schwinger type dependence ∝ exp{−a_{nℓBW} E_{crit}/E} with a_{nℓBW} = 4m/3ω'. The large ratio E_{crit}/E can be compensated by a small ratio m/ω', thus making the pair creation rate accessible in present day experiments by using hard probe photons with ω' ≫ m, in contrast to the plain Schwinger rate, even with assistance effects. As emphasized in [32], such a Schwinger type rate of nℓBW is found numerically already for a_0 ≥ 1 and κ ≲ 1.

Quite in contrast to nℓBW, the nℓC cross section without cut-off displays a polynomial dependence on the invariant Ritus variable\(^1\) \(\chi ≡ a_0 k · p/m^2 = a_0 (s_1 - m^2)/2m^2\). However, imposing the cut-off c > 0, thus suppressing the low harmonics in (1) by a threshold, turns the behavior to an exponential one. In fact, evaluating (1) numerically, one obtains the solid curves in Fig. 3 for c = 1 (left panel) and 2 (right panel). Since at 1/\(χ \) < 1 the curves display an a_0 dependence, we have employed scaling factors. Without the latter ones, the curves at 1/\(χ \) > 1 are nearly perfectly on top of each other, i.e. independent of a_0. To quantify the

\(^1\) The Ritus variable \(\chi\) is a measure of the field strength \(E/E_{crit}\) in the rest frame of the electron; \(\chi\) encodes the energy of the laser + electron beams as well as the laser intensity. The high-energy limit and the high-intensity limit do not commute albeit they yield both a high-\(\chi\) asymptotic [50, 51].
FIG. 3: (Color online) Normalized cross section $m^2\sigma(\chi)/\chi$ of nC from (1) as a function of $1/\chi$ (solid curves) with cut-off values $c = 1$ (left panel) and $c = 2$ (right panel). The dashed (dotted) curves exhibit the approximation (3) with erfc (exp). For $a_0 = 1, 2$ and 4 from top to bottom with scaling factors as indicated. The red bullets mark results of QED calculations with bandwidth and ponderomotive effects for $a_0 = 1$ (see sub-section VI C). Fits of these data by $m^2\sigma(\chi) \propto \exp(-2c c_{\text{fit}}/3\chi)$ within the interval $1/\chi = (1, 5]$ deliver $c_{\text{fit}} = 1.27$ and $c_{\text{fit}} = 2.59$.

One avenue to (3) is to start with (1) in the limit $a_0 \to \infty$ with side condition
\[
(1 - \frac{z^2}{n^2}) a_0^2 = \text{const}
\]
and then to convert the sum via the Euler-Maclaurin formula into an integral
\[
F_{\infty}(\chi, c) = \int_{-\infty}^{\infty} dx f(x) \exp\left\{\frac{-2c}{3} z^3(x)\right\}
\]
where $f(x) = (5 + 7c + 5c^2)/(1 + c)^3$ and "erfc" stands for the complementary error function.

Under the condition $c \gg \chi$, the derivative of the Airy function, $A_i'(z)$, can be replaced by its asymptotic representation and the integral can be executed upon a shift of the variable $x$ and a suitable Taylor expansion.

Surprisingly, the small-$\chi$ leading-order term $\propto \exp(-2c c_{\text{fit}}/3\chi)$ in (3) numerically approximates (1) fairly well in the non-asymptotic region, $a_0 \gtrsim 1$ and $\chi < 1$, irrespectively of the assumptions made in the sketched derivation. As a consequence, the nC cross section also displays a Schwinger type dependence $\sigma(c > 0) \propto \exp(-a n_{\ell} \epsilon_{\text{crit}}/E)$ for suitable values of the cut-off $c > 0$, in general with $a = c(a_0, s)$. That is, the paradigmatic transmonomial dependence we depict for a comparison the dashed (dotted) curves based on...
Compton scattering on the level of “total” cross section, which actually means integration over a fraction of the out-phase space.

VI. DISCUSSION

A. Imposing the cut-off: kinematics

The cut-off \( c > 0 \) in (1) looks quite innocent, but in practice it may become challenging. To illustrate that feature let us employ laboratory observables: \( \nu \equiv \omega / m \left( = 2 \times 10^{-6} \right. \) for optical lasers), \( p_0 / m = \cosh \zeta \) the Lorentz factor of the in-electron, \( \nu' \equiv \omega' / m \) for the normalized energy of the out-photon in direction \( \Theta' \) such that \( \Theta' = 0 \) and \( \Theta' = \pi \) mean on-axis forward scattering and on-axis backscattering, respectively. Adopting the notation in [40] we recall the relation

\[
x = \frac{(1 - \cos \Theta')\nu'}{e^\zeta - (1 - \cos \Theta')\nu'}.
\]

The admissible intervals for a harmonic \( n \) are for head-on collisions \( 0 \leq x \leq y_n \equiv 2n\nu e^\zeta / (1 + a_0^2) \), \( n
\nu \leq \nu'_n \leq n\nu / (1 + 2\kappa_n e^{-\zeta}) \) for \( 2\kappa_n \equiv 2\nu - e^\zeta + (1 + a_0^2) e^{-\zeta} < 0 \) or \( n\nu / (1 + 2\kappa_n e^{-\zeta}) \leq \nu'_n \leq n\nu \) for \( \kappa_n > 0 \), and \( 0 \leq \Theta' \leq \pi \). One has also to recall the well known n\ell C kinematic relation \( \nu'(n, \Theta'; a_0, \nu, \zeta) = n\nu / [1 + \kappa_n e^{-\zeta}(1 - \cos \Theta')] \), e.g. in relating the \( x \) and \( \Theta' \) coordinates: a point at \( x = \xi y_n \) corresponds to \( (\pi - \Theta')^2 \approx 4(1 - \xi)(1 + a_0^2) e^{-2\zeta} \), independent of the harmonic number. This highlights the preference of backscattering in the relativistic regime, since a significant fraction of events with \( x \rightarrow y_n \) is seen at \( \Theta' \rightarrow \pi \).

These relations evidence that one has to reject events with too low values of \( \nu' \) or select sufficiently high harmonics to realize the request \( x \geq c \), see left panel of Fig. 4 for on-axis backscattering. The meaning of these curves is that the realization of \( x \geq c \) requires in general \( \nu'(n, \Theta'; a_0, \nu, \zeta) \geq \nu'(x, \Theta'; \zeta) \) either as a function of \( n \) (left panel, for \( \Theta' = \pi \)) or as a function of \( \Theta' \) (right panel, for selected harmonics), where (4) determines the \( \nu \) independent function \( \nu'(x, \Theta'; \zeta) \). These relations are exhibited also in the right panel of Fig. 4, where the light-blue region depicts the range wherein \( x \geq c = 1 \) is fulfilled. In the preferred backward direction \( \Theta' \rightarrow \pi \), the curves \( \nu'(x, \Theta'; \zeta) \) (black dashed) are nearly horizontal, with the benefit that only an energy-resolved measurement is necessary to select the wanted range \( x \geq c \) by imposing a veto for all events with \( e^{2\zeta(1 - \cos(\pi - \Theta'))} > 20 \), for instance. At smaller angles \( \Theta' \), i.e. going further to the right – beyond the region displayed in the right
FIG. 4: (Color online) Left panel: The scaled out-photon energy $\nu'$ as a function of the harmonic number $n$ for three kinematic situations referring to the entrance channels at LUXE (left, in blue), ELI (middle, in green), and HZDR (right, in red). For $a_0 = 0.01$ (dashed), 1 (solid) and 2 (dotted) and on-axis backscattering. The curves connect smoothly the values of $\nu'$ at the discrete harmonic numbers $n$. Selecting the out-channel with $x \geq c$ means accepting only events in the light-blue region if $c = 1$ is chosen. Right panel: The scaled out-photon energy as a function of the angle $\Theta'$ for the harmonics $n = 7$, (black thin), 10 (blue dotted), 20 (red solid), 50 (green dashed) and 100 (black thin) (LUXE parameters). Note the relation $1 - \cos(\pi - \theta') \approx \frac{1}{2} \vartheta'^2$ for backscattering, where $\vartheta' = \pi - \theta'$ measures the angle of the out-photon relative to the in-electron direction. The seemingly horizontal dashed lines $e^{-\zeta \nu'} = \frac{x}{1 + x} \frac{1}{1 - \cos \vartheta'}$ are depicted for three values of the invariant quantity $x = 0.1, 1$ and $\infty$, and the light-blue region is again for admissible events if $c = 1$ is chosen. The harmonic $n = 7$ does never enter the light-blue region.

In addition to this purely kinematic relations one has to account for the dynamics, in particular the dead cone effect which is special for circularly polarized lasers according to [1]: Ignoring for the moment being the cut-off, the harmonics $n > 1$ are (multiply) peaked within the interval $0 < x < y_n$ and drop smoothly towards zero at the boundaries $x \to 0$
FIG. 5: (Color online) Left panel: Angular differential cross sections $m^2 d\sigma_n / d \cos \Theta' = \alpha_0^2 \pi m^2 n \nu' \nu (1-\cos \Theta')^2 (1+x)^2 F_n(z_n)$ with $x$ and $z_n$ to be viewed as functions of $\Theta'$ (cf. [40]) for the harmonics $n = 1 \cdots 20$ (in steps of 1) and $20 \cdots 100$ (in steps of 10). The harmonics $n = 10$ (blue dotted), 20 (read solid) and 50 (green dashed) are depicted in color code and line style as in Fig. 4-right; the other harmonics (black solid) are partially labeled. The black dashed curve – to be continued by the harmonic $n = 8$ – limits the admissible range (in light-blue) where $x \geq c = 1$ is fulfilled. Right panel: Angular differential cross sections $m^2 d\sigma_n / d \cos \Theta'$ (see color code on r.h.s.) over the scaled $\nu' - \Theta'$ plane. Low-order harmonics are clearly separated for monochromatic lasers (but are smeared out for pulses, see below). The gray lines connect points of equal values (given by the numbers in the boxes) of $m^2 d\sigma_n / d \cos \Theta'$ on adjacent harmonics. Contributions smaller than $10^{-15}$ are not displayed. Both panels are for the LUXE kinematics with $\nu = 2 \times 10^{-6}$, $e^\xi = 7 \times 10^4$ and $a_0 = 1$.

and $x \to y_n$. Transforming to the laboratory frame, the angular differential cross sections $d\sigma_n / d \cos \Theta'$ of selected harmonics $n > 1$ are peaked as exhibited in Fig. 5-left. Only the $n = 1$ harmonic remains non-zero for $\Theta' \to \pi$. The dropping of $d\sigma_n / d \cos \Theta' |_{n>1}$ at the left side is the dead cone effect. The dropping at the right side refers to the suppression of forward scattering, i.e. at $\Theta' \to 0$. The black dashed curve connects the points of intersections of the curves $\nu'(n, \Theta'; a_0, \nu, \xi)$ and $\nu'(x = 1, \Theta'; \xi)$, which can be read off in Fig. 4-right for $n = 10, 20, 50$ and 100. For $n < 8$, there are no such intersections and, as a consequence, the harmonic $n = 8$ – left-beyond the dashed curve – limits the admissible region $x \geq c = 1$ which is highlighted in light-blue, as in Fig. 4.

As advertised above, the contributions of the high harmonics at $e^{2\xi} (1-\cos(\pi-\Theta')) > 20$
FIG. 6: (Color online) Same as in Fig. 2 but for laser pulses with envelope shape $g(\phi) = 1/\cosh(\phi/N\pi)$. $N = 1$ (red curves) represents ultra-short pulses and $N = 10$ (green curves marked by dots) is among currently available short pulses. Blue curves are as in Fig. 2 for the monochromatic case. For the cut-off value $c = 1$ and $a_0 = 0.01$ (left panel) and 0.1 (right panel).

are exceedingly small, thus substantiating our claim that imposing a frequency threshold is enough for a measurement of $\sigma(c = 1)$, at least for the here employed LUXE kinematics. This is evidenced in Fig. 5-right, where some proxy of a contour plot (gray lines) of the angular differential cross sections $m^2d\sigma_n/d\cos\Theta'$ is exhibited over the scaled $\nu'-\Theta'$ plane. [The harmonics $n$ have only support on the curves $\nu'(n, \Theta'; a_0, \nu, \zeta)$ (see Fig. 4-right for several values of $n$), and the colored pixels encode the values of $m^2d\sigma_n/d\cos\Theta'$. The gray lines connect points of equal strengths on adjacent harmonics, thus serving as contour lines despite the discrete occupancy in $\nu'$ direction.] The experimental challenge is therefore the precise setting of a frequency threshold to select $x \geq c$ events out of a large background.

C. Bandwidth effects and ponderomotive broadening

While $[1]$ is for monochromatic laser beams with the four-potential $\vec{A}(\phi) = g(\phi) [\vec{a}_1 \cos \phi + \vec{a}_2 \sin \phi]$ of the e.m. field with invariant phase $\phi$ and obeying $g(\phi) = 1$, $\vec{a}_1 \cdot \vec{a}_2 = 0$, $\vec{a}_1^2 = \vec{a}_2^2$, one has to check whether laser pulses$^2$ are well approximated when

$^2$ The Fourier-zero mode of the non-linear phase can not be longer absorbed in a redefinition of the electron momentum as quasi-momentum $[53]$, which is a key quantity in the monochromatic laser beam model $[1]$, but an expansion into harmonics is still possible for smooth, long pulses $[53, 54]$ (cf. $[55]$ for a discussion of these issues and a compendium of one- and two-photon emission off electrons in laser pulses).
focusing on total cross sections. In Fig. 6, the cross section as a function of $\tilde{s}$ is exhibited, for $a_0 = 0.01$ and 0.1 as in Fig. 2, however, for short and ultra-short pulses. The QED calculations are based on equations (40, 42) in [45] (version v1) with $u \geq c$ to impose the cut-off. The pulse shape envelope is here especially $g(\phi) = 1 / \cosh(\phi/N\pi)$, where $N$ characterizes the number of oscillations of the field. This envelope $g(\phi)$ does have neither an extended flat-top section nor narrow ramping sections. The former property makes it quite different to a near-monochromatic beam with broad flat-top envelope and may be considered as representing a “worst case” in that respect. The related bandwidth effects and longitudinal ponderomotive broadening are fully included in the QED calculation of one-photon emission in [45]. For short pulses, these effects smoothen the step like shape of the total cross sections, as known from nℓBW [44]. In particular, for the ultra-short pulse with $N = 1$ (red curves), the combined strong bandwidth effect and ponderomotive broadening overwrite completely the multi-photon effects; the cross section is stark enhanced in the sub-threshold region. However, for sufficiently long pulses with $N \geq 10$, i.e. a pulse duration of $> 30$ fs for optical laser pulses, even without pronounced temporal flat-top profile, the essential dependencies of the cross section model with cut-off [1] are recovered, see green curves marked by dots in Fig. 6 for $a_0 = 0.01$ and 0.1 and red curves marked by bullets in Fig. 3 for $a_0 = 1$. Since the normalization of cross sections in pulses is special (cf. [45, 56]), let us focus on slopes at $a_0 = 1$. As noted in the caption of Fig. 3, the slope parameters $c_{fi}$ of the pulse model with $N = 10$ are about 25% larger than the ones of the monochromatic model [1]. Despite these differences, the ratio is still 1 : 2. Such a cut-off dependence can be experimentally tested in the analysis of a given data set after data taking, e.g. at a suitable value of $\chi$. (A comprehensive theoretical study of the $a_0 > 1$ dependence must be postponed because our present numerical implementation restricts us to $a_0 \leq 1$.)

Turning to details of differential observables, the model [1] is in general a less useful guide. In fact, keeping the above pulse shape parameterization by $g(\phi) = 1 / \cosh(\phi/N\pi)$, the differential cross section $d\sigma/d\omega'|\Theta'$, e.g. for $e^{2\xi}(1 - \cos(\pi - \Theta')) = 3$ (that is for $\Theta'$ at about the maximum of the angular differential cross section in Fig. 5-left), does hardly recover the harmonic structures which can be deduced from the right panels of Figs. 4 and 5, even for longer pulses, see left panel in Fig. 7. Instead of clearly recognizable peaks at $\omega' = m\nu'(n, \Theta'; a_0, \nu, \zeta)$, the spectrum in Fig. 7-left displays some complexity which is further obscured by increasing gradually the parameter $N$. This feature is known since some
time, cf.\cite{53,56,57} for instance. Bandwidth effects and ponderomotive broadening have been identified as responsible, together with interferences.

To highlight the impact of the former ones it is instructive to cast the above nℓC kinematic relation $\nu'(n, \Theta'; a_0, \nu, \zeta)$ in the form

$$2e^{-\zeta\nu'} = \frac{1}{1 + \frac{e^{-\zeta}}{2n\nu} (1 + a_0^2(\phi)) + e^{2\zeta}(1 - \cos(\pi - \Theta')) \frac{e^{-\zeta}}{4n\nu} \left[ 1 - \frac{2n\nu}{e^\zeta} - e^{-2\zeta}(1 + a_0^2(\phi)) \right]}, \quad (5)$$

where $a_0(\phi)$ puts emphasis on the longitudinal ponderomotive broadening by the variation of the intensity in the course of a pulse, $0 < a_0(\phi) \leq a_0$, and $\mu \neq 1$ accounts for the bandwidth effects, i.e. there is a distribution of laser frequencies around the central frequency $\nu$. These effects are seen best in very backward kinematics, where $e^{2\zeta}(1 - \cos(\pi - \Theta')) \to 0$: The support of harmonic $n$ is in the interval $\left( \frac{1 + e^{-\zeta}}{2n\nu} (1 + a_0^2) \right)^{-1} \leq 2e^{-\zeta}\nu' \leq \left( 1 + \frac{e^{-\zeta}}{2n\nu} \right)^{-1}$ and depends additionally on the frequency spread parameterized by $\mu$. The net effect is blowing up the curves $\nu'(n, \Theta')$ in the right panels of Figs. 4 and 5 to overlapping bands (not displayed), already either for $a_0 \geq 1$ or $0.5 < \mu < 2$ separately. Both effects, $a_0(\phi)$ and $\mu \neq 1$, can be separated only in certain asymptotic regions \cite{56}. Besides rich sub-structures within the broadened and overlapping harmonic support regions, QED calculations for laser pulses exhibit complicated interference patterns over the $\omega'-\Theta'$ plane depending on the actual pulse envelope shape $g(\phi)$ and its parameters, see figure 1 in \cite{58} for an example.

Nevertheless, the model \cite{1} can provide a useful guide for the gross shape of the locally averaged spectrum. Averaging the differential cross section, exhibited in Fig. 7-left by the blue curve, over the intervals $\omega'((\ell - 0.5, \Theta') \cdots \omega'(\ell + 0.5, \Theta')$ for $\ell = 1, 2, 3 \cdots 3$ leads to the spectral shape displayed by blue bullets in the right panel of Fig. 7. Within a factor of two, both spectral shapes – the one based on the monochromatic model \cite{1} and the one with $1/\cosh$ pulse envelope – agree over six orders of magnitude. The displacement of pair-wise related red crosses and blue bullets in the right panel of Fig. 7 can be attributed to the frequency difference in \cite{5} for $\nu'(a_0)$ and $\nu'(a_0 = 0)$ at the same value of $n$ when ignoring the bandwidth effect.

If one wishes to recover the clear harmonic structures exhibited in Fig. 5-right, one has to employ suitable laser pulse shapes, e.g. with extended flat-top profiles (see figure 6 in \cite{57}).

\footnote{The continuous variable $\ell$ is an internal auxiliary quantity which replaces the harmonic number $n$ in the case of a pulse with smoothly varying envelope (cf. equations (16, 17) in \cite{50}).}
FIG. 7: (Color online) Left panel: The differential spectrum $d\sigma/d\omega'\rvert_{\Theta}$ as a function of $\omega'$ at polar angle $\Theta'$ determined by $e^{2c(1 - \cos(\pi - \Theta'))} = 3$ for the $1/cosh(\phi/N\pi)$ pulse envelope with $N = 10$ (blue curve). The corresponding QED calculation is as in figure 5 of [56] but for the LUXE kinematic parameters used in Fig. [5] Red pluses mark the peak positions in the monochromatic model (IPA). Right panel: The same as in the left panel but with locally averaged cross section (blue bullets) over the intervals $\omega'((\ell - 0.5)\cdots\omega'((\ell + 0.5)$ for the internal auxiliary variable $\ell = 1, 2, 3\cdots$ (cf. equation (16) in [56]). The legends adopt the nomenclature in [56]: IPA stands for the monochromatic laser beam and FPA denotes the laser pulse model.

or frequency chirping [59] etc. Nevertheless, we argue that these details, which shape the differential spectra, have a sub-leading impact on the phase space integrated cross section, and the prediction in Fig. 3 is essentially robust within the range uncovered by our pulsed QED calculations (red curves marked by bullets) and the model (IPA) (red solid curves).

In addition to such effects, there is transverse broadening w.r.t. to multiple photon emission: The incoming electron may suffer a (or many) transverse kick(s) due to soft-photon emission prior to hard-photon emission, thus not being longer subject of a head-on collision. Since for the above LUXE kinematics our focus is on the hard-photon tail, e.g. with $\omega' > \frac{1}{2}p_0$ for $c = 1$, we do not expect a significant impact of the leakage of low harmonics into this region and multiple photon emission and radiation reaction as well. For a proper quantitative account, the simulation tools developed in view of the recent experiments [60, 61] should be employed in dedicated analyses and compared with analog QED calculations.
VII. SUMMARY

In summary we point out that the non-linear Compton process obeys a field strength dependence $\propto P \exp\{-a_{nlc} E_{crit}/E\}$, similar to the Schwinger process of “vacuum breakdown”, when imposing a suitable cut-off $c$ which suppresses the low harmonics. We focus on the slope coefficient $a_{nlc} = \frac{2}{3} \text{cm}/(p_0 + \sqrt{p_0^2 - m^2})$ by a comparison with some approximation formula which displays a dependence $\propto \exp\{-2c/3\chi\}$ already in the non-asymptotic region. Albeit the Compton process does not have such an obvious tunneling regime as the pair production processes, its formal similarity with the non-linear Breit-Wheeler process provides evidence \cite{48, 62} for selected differential contributions with an exponential field dependence. The here introduced cut-off acts as a threshold and enforces a large gap between in- and out-Zel’dovich levels (which suffer some broadening in laser pulses) or, equivalently, a large light-cone momentum-transfer from the in-electron to the out-photon; it makes the otherwise hidden exponential contributions visible in the “total” cross section, which actually refers to a fraction of the out-phase space. This opens another avenue towards a measurement of the boiling point of the vacuum, complementary to plans of the LUXE collaboration by utilizing the non-linear Breit-Wheeler pair production \cite{32}. While for the latter one a high-energy photon beam is vital, our approach requires either a moderately high-energy $(p_0)$ electron beam and the selection of very high harmonics or a high-energy electron beam and the selection of moderately high harmonics. The experimental challenge is anyway the isolation of the high harmonics region characterized by the out-photon kinematics.

The present considerations apply primarily to a plane-wave, monochromatic laser beam, i.e. a long flat-top pulse duration, with circular polarization. Selected examples of one-photon emission in laser pulses, based on Furry picture QED calculations of the cross section, support such a clear-cut approach. Nevertheless, necessary obvious extensions should take into account general laser polarizations as well as further bandwidth effects, ponderomotive broadening and multiple photon emissions in finite-duration pulses and their detailed temporal structures together with a larger range of the laser intensity parameter $a_0$. Planned follow-up work is devoted to energy- and angular-differential spectra and suitable realizations of the crucial cut-off implementation in non-perfect head-on collisions.

Acknowledgments: The authors gratefully acknowledge the collaboration with D. Seipt, T. Nousch, T. Heinzl, and useful discussions with A. Ilderton, K. Krajewska, M. Mark-
lund, C. Müller, S. Rykovanov, R. Schützhold and G. Torgrimsson. A. Ringwald is thanked for explanations w.r.t. LUXE. The work is supported by R. Sauerbrey and T. E. Cowan w.r.t. the study of fundamental QED processes for HIBEF.
