Filamentous fungi, such as Neurospora crassa, are very efficient in deconstructing plant biomass by the secretion of an arsenal of plant cell wall-degrading enzymes, by remodeling metabolism to accommodate production of secreted enzymes, and by enabling transport and intracellular utilization of plant biomass components. Although a number of enzymes and transcriptional regulators involved in plant biomass utilization have been identified, how filamentous fungi sense and integrate nutritional information encoded in the plant cell wall into a regulatory hierarchy for optimal utilization of complex carbon sources is not understood. Here, we performed transcriptional profiling of N. crassa on 40 different carbon sources, including plant biomass, to provide data on how fungi sense simple to complex carbohydrates. From these data, we identified regulatory factors in N. crassa and characterized one (PDR-2) associated with pectin utilization and one with pectin/hemicellulose utilization (ARA-1). Using in vitro DNA affinity purification sequencing (DAP-seq), we identified direct targets of transcription factors involved in regulating genes encoding plant cell wall-degrading enzymes. In particular, our data clarified the role of the transcription factor VIB-1 in the regulation of genes encoding plant cell wall-degrading enzymes and nutrient scavenging and revealed a major role of the carbon catabolite repressor CRE-1 in regulating the expression of major facilitator transporter genes. These data contribute to a more complete understanding of cross talk between transcription factors and their target genes, which are involved in regulating nutrient sensing and plant biomass utilization on a global level.

Significance

Microorganisms have evolved signaling networks to identify and prioritize utilization of carbon sources. For fungi that degrade plant biomass, such as Neurospora crassa, signaling networks dictate the metabolic response to carbon sources present in plant cell walls, resulting in optimal utilization of nutrient sources. However, within a fungal colony, regulatory hierarchies associated with activation of transcription factors and temporal and spatial production of proteins for plant biomass utilization are unclear. Here, we perform expression profiling of N. crassa on simple sugars to complex carbohydrates to identify regulatory factors and direct targets of regulatory transcription factors using DNA affinity purification sequencing (DAP-seq). These findings will enable more precise tailoring of metabolic networks in filamentous fungi for the production of second-generation biofuels.

First published February 28, 2020.
Although biochemical activities of select PCWDEs have been investigated in a variety of filamentous fungi, how fungi sense complex carbohydrates in plant biomass and how that sensing is transduced intracellularly into a hierarchical metabolic response resulting in optimal production of PCWDEs and integration of cellular metabolism are unclear. The production of PCWDEs is dependent on transcription factors that modulate expression of these genes upon appropriate nutrient sensing. In *Neurospora crassa*, *Aspergillus nidulans*, *Aspergillus oryzae*, and *Penicillium oxalicium*, the transcription factor CLR-2 (ClrB/MAnR) is the major regulator of genes involved in the deconstruction of cellulose (5, 6), while in *Trichoderma reesei* and *Aspergillus niger*, the transcription factor Xyr1/XlnR regulates genes involved in both cellulose and hemicellulose degradation (7, 8). In species like *N. crassa* and *Fusarium graminearum*, XlnR homologs regulate genes involved in hemicellulose utilization (9, 10). Transcription factors associated with pectin deconstruction include RhaR/PDR-1 and GaaR. In *A. niger* and *N. crassa*, RhaR/PDR-1 is required for rhamnose utilization (11, 12), while in *Botrytis cinerea* and *A. niger*, GaaR is responsible for galacturonic acid utilization (13, 14). In *A. niger*, the AraR transcription factor modulates arabinose utilization, while a different transcription factor (Ara1) functions in an analogous manner in *Magnaporthe oryzae* and *T. reesei* (15, 16). Additional transcriptional regulators that affect expression of genes encoding PCWDEs include the carbon catabolite repressor protein CreA/CRE-1 in regulating the carbon catabolite repressor protein CreA/CRE-1 in regulating monosaccharides and disaccharides at 2 mM concentration; this concentration of cellubiose was previously shown to induce robust expression of cellulosytic genes in *N. crassa* (23) (Fig. S1 and Dataset S1). As predicted, *N. crassa* induced genes encoding cellulases in response to cellubiose, genes encoding starch-degrading enzymes in response to maltose, genes encoding hemicellulases in response to xylose and arabinose, and genes encoding pectin deconstruction enzymes upon exposure to rhamnose and galacturonic acid (Fig. L4 and Dataset S1). However, individual sugars were also capable of inducing expression of PCWDEs not responsible for degrading their parent polymer. For example, cellubiose induced expression of some genes encoding some xylanases and pectinases in addition to cellulases, and arabinose induced expression of some genes encoding some cellulases in addition to arabinases (Dataset S1). These data indicate metabolic cross talk between sugar-sensing pathways and/or overlap in regulatory networks. *N. crassa* also showed strong transcriptional responses to complex plant biomass substrates, such as corn stover (a monocotyledonous plant of the grass family) and wingnut (*Pterocarya*; a hardwood tree from the walnut family) (Fig. L4).

Monosaccharides, disaccharides, and oligosaccharides require transport into the cell for utilization and/or signaling for induction of genes encoding PCWDEs. Annotated sugar transporters belong to the major facilitator superfamily (MFS) and led us to hypothesize that uncharacterized sugar transporters would also come from this protein family. To test this hypothesis, we constructed a maximum-likelihood tree using protein sequences from all MFS transporters in the *N. crassa* genome (Fig. S1). The majority of predicted sugar transporters, with the exception of NCU05897 (fucose permease) and NCU12154 (maltose permease), fell into a single monophyletic clade corresponding to family 2.A.1.1 of the Transporter Classification Database (25). Of the predicted sugar transporters in this clade, five unannotated MFS transporters (NCU04537, NCU05350, NCU05585, NCU06384, and NCU07607) had increased expression on unique sugars and complex carbon sources, suggesting potential involvement in catabolism of those carbon sources (Fig. S1 and Dataset S1).

To evaluate cross talk between regulatory pathways that coordinate expression of PCWDEs, we performed weighted gene coexpression network analysis (WGCNA) (26) across the transcriptional dataset and identified 28 modules of coexpressed genes (Fig. L1B and Dataset S2) that showed enrichment of specific functional classifications (SI Appendix, Fig. S2). The majority of PCWDE genes were found within three modules. Module 1 (red; *n* = 135) contained genes encoding PCWDEs that are up-regulated in response to cellulose and hemicellulose along with notable transcription factors *xdr-1*, *clr-1*, *clr-2*, *hac-1*, and *vib-1* (21, 27, 28). This module also contained 55 genes that encoded hypothetical proteins. Module 2 (yellow; *n* = 42) contained the majority of predicted pectin metabolic genes (28) and eight genes encoding hypothetical proteins. Module 3 (blue; *n* = 42) contained a number of predicted pentose catabolic genes along with some notable xylanases and xylose transporters and nine genes encoding hypothetical proteins (Dataset S2 and Fig. S2). An additional module (module 4; *n* = 142; midnight blue) clustered closely with modules 1 and 3. This module was significantly enriched for genes encoding endoplasmic reticulum (ER) and protein-processing proteins (Fig. S1 and Dataset S2) that showed enrichment of specific functional classifications (SI Appendix, Fig. S2). This module also included genes encoding 29 hypothetical proteins.

**Defining the PCWDE Transcriptional Network.** Prior studies in *N. crassa* identified conserved transcription factors that are positive regulators of cellulase and some hemicellulase genes (CLR1/CLR-2), xylanase and xylene utilization genes (XLR1-1), pectin-degrading genes (PDR-1), and starch catabolic genes (COL-26)
(10, 11, 19, 27). We hypothesized that it would be possible to identify additional regulators involved in plant cell wall degradation by looking for transcription factors with a similar expression profile to a specific class of genes encoding PCWDEs using hierarchical clustering. A systematic analysis of expression profiles of 336 proteins with predicted DNA-binding domains identified 34 additional transcription factors that were specifically induced on different plant biomass components (Dataset S3). We hypothesized that strains carrying a deletion of a transcription factor would display an altered transcriptional profile under the conditions where they were most highly expressed (Dataset S3). When the corresponding deletion strains were tested under the respective induction conditions, a majority of the 34 transcription factor deletion mutants did not display a clear expression phenotype compared to the parental strain, FGSC2489. However, deletion mutants for two transcription factors showed a consistent and obvious role in PCWDE expression, NCU04295 and NCU05414 (Dataset S4).

The expression of NCU04295 clustered with genes encoding pectin-degrading enzymes (Dataset S4) and a ΔNCU04295 mutant showed decreased expression levels of genes necessary for pectin utilization when grown in presence of pectin-rich citrus peel compared to WT cells on citrus peel (Fig. 2 A and B and Dataset S4). The genes with the largest decrease in expression level in ΔNCU04295 compared to WT included pectate lyases genes _ply_1 and _ply_2 (NCU06326 and NCU08176), the galacturonic acid transporter gene _gat_1 (NCU00988), the exopolgalacturonase gene _gh28_2 (NCU06961), and orthologs of _gaaA_1, _gaaB_ and _gaaC_ (NCU09533, NCU07064, and NCU09532, respectively), encoding enzymes for galacturonide catabolism (Fig. 2B and Dataset S4). The predicted protein sequence of NCU04295 showed similarity (~50% amino acid identity) to GaaR, which plays a role in galacturonic acid metabolism in _B. cinerea_ and _A. niger_ (13, 14). We therefore named NCU04295 _pdr_2 for pectin degradation regulator-2. Consistent with its predicted function, the Δpdr_2 mutant showed a severe growth defect in medium containing pectin or galacturonic acid as the sole carbon source and significantly reduced pectate lyase and endo-polgalacturonanase activity (Fig. 2 C and D). A second pectin degradation regulator previously identified in _N. crassa_, _pdr_1, also shows a severe growth defect on pectin (11). However, unlike Δpdr_1 cells, Δpdr_2 cells grew on l-rhamnose as the sole carbon source (SI Appendix, Fig. S3), suggesting distinct roles for PDR-2 and PDR-1 in regulating pectin degradation. A strain bearing both _pdr_1 and _pdr_2 deletions mimicked the phenotype of either a Δ_pdr_1 or a Δ_pdr_2 mutant (Fig. 2 C and D), but did not cause a complete abolition of growth with pectin as the sole carbon source (SI Appendix, Fig. S3).

NCU05414 displayed high expression on Miscanthus biomass (Dataset S1). When compared to WT cells exposed to 1% Miscanthus, a ΔNCU05414 mutant showed reduced expression of genes encoding several arabinosidasises (NCU09924, NCU9775), two β-xyladosidasises (NCU00709, NCU09923), the _L_-arabinose transporter _lat_1 (NCU02188), and _L_-arabinol dehydrogenase _adr_1 (NCU00643) (Fig. 2E and Dataset S4), suggesting that the ΔNCU05414 mutant would be defective for utilization of arabinin, arabinose, and galactose. As predicted, the ΔNCU05414 strain showed dramatically reduced growth on 2% arabinin, arabinose, and galactose, but was able to metabolize hemicellulose and pectin substrates (Fig. 2F). When NCU05414 was placed under the regulation of the strong constitutive promoter _gpd_1 (oxNCU05414), cells showed increased growth on arabinose relative to WT (SI Appendix, Fig. S3) and increased expression of _adr_1 (Fig. 2G), further supporting positive regulation of arabinose metabolic genes by NCU05414. The NCU05414 predicted protein showed significant similarity to the Ara1 protein in _T. reesei_ and _Magnaporthe oryzae_, where it plays a role in arabinose metabolism and arabinose and galactose catabolism, respectively (16, 29). We therefore named NCU05414 _ara_1.

Many PCWDEs involved in degradation of heterogeneous substrates like pectin and hemicellulose are under the control of multiple transcription factors. We constructed regulons of transcription factors CLR-1, CLR-2, XLR-1, PDR-1, PDR-2, and ARA-1 that are important for plant biomass deconstruction by identifying genes encoding PCWDE that were down-regulated during the starvation response, which indicated these transcription factors function positively. We also included data obtained under identical conditions as performed here from our previous studies for COL-26 and PDR-1 (11, 19). The regulons of CLR-1, CLR-2, XLR-1, PDR-1, PDR-2, and ARA-1 were similar to genes up-regulated during the starvation response, which indicated these transcription factors function positively.

Fig. 1. Hierarchical clustering and WGCNA of _N. crassa_ transcriptome across carbon sources. (A) Hierarchical clustering of the normalized counts (FPKM) of genes encoding PCWDEs in cells shifted to the indicated carbon sources. All disaccharides and monosaccharides are at 2 mM concentration, and complex carbohydrates are at 1% (wt/vol). The color bar represents the spectrum from lowest normalized count to highest normalized count for each gene centered on mean expression; each gene has a different range of FPKMs. (B) Coexpression network with nodes representing genes colored by modules and edges between genes with correlated expression profiles, shown using Cytoscape (79) (Dataset S2). Four modules enriched in genes encoding PCWDEs and polysaccharide metabolism are labeled. Module 1 (red): genes associated cellulose and hemicellulose utilization. Module 2 (yellow): genes associated with pectin deconstruction. Module 3 (blue): pentose catabolic and xylan utilization genes. Module 4 (midnight blue): genes encoding ER- and protein-processing proteins (Dataset S2). Total number of genes shown in the network is 3,282.
after a shift to Avicel, a 500-fold decrease in expression in Δxlr-1 cells after a shift to xylan, and a 7-fold decrease in expression in Δxlr-2 cells after a shift to citrus peel relative to WT cells (Dataset S4). Moreover, the cel-1 promoter was shown to be directly bound by both XLR-1 and CLR-2 by chromatin immunoprecipitation sequencing (ChIP-seq) (10).

**Utilizing DAP-Seq to Identify Direct Targets of *N. crassa* Transcription Factors.** The transcriptional regulators associated with plant biomass deconstruction identified above could be due to direct or indirect regulation of target genes by a particular transcription factor. To define the direct regulons of transcription factors involved in plant biomass deconstruction, we used DAP-seq, where in vitro-synthesized transcription factors are used for affinity purification of bound oligonucleotides in sheared genomic DNA, which are subsequently identified via DNA sequence analyses (30). To ensure that DAP-seq was an effective method for identifying direct binding sites of transcription factors involved in plant cell wall deconstruction in *N. crassa*, we confirmed the DNA binding sites of CLR-1 and XLR-1, for which ChIP-seq data were available (10).

We reanalyzed promoter regions of genes (defined as within 3 kb of the ATG start site) bound by XLR-1 identified via ChIP-seq (10) (Dataset S5) and bound promoter regions identified via DAP-seq where transcription was reduced by at least 21.5 (2.8)-fold via differential RNA-seq analysis of WT versus an Δxlr-1 mutant (Datasets S4 and S5). We identified 85 XLR-1 target genes using ChIP-seq data and 78 genes via DAP-seq, with 47 genes shared between the two datasets (SI Appendix, Fig. S4 A, C and F and Dataset S5). The binding site sequences from the 78 genes identified in the DAP-seq dataset were used to build an XLR-1 consensus binding motif, which was comparable to the one reported from ChIP-seq data analysis (10) (SI Appendix, Fig. S4G). Using the same methods to explore CLR-2, we identified 87 genes with CLR-2–bound promoters via DAP-seq and 65 genes with CLR-2–bound promoters via ChIP-seq; 48 genes were shared between datasets (SI Appendix, Fig. S4 D-F and Datasets S4 and S5). Slight differences were identified in the CLR-2 consensus binding sequence using DAP-seq versus that previously reported for ChIP-seq data (10) (SI Appendix, Fig. S4G).

Neither the ChIP-seq nor DAP-seq method reliably identified genes differentially expressed between WT and the transcription factor mutant under the conditions tested. For example, ChIP-seq performed on CLR-2 identified 158 genes with promoter regions bound, while DAP-seq identified 1,683; however, only 87 of the DAP-seq bound genes were differentially expressed in a Δclr-2 mutant relative to WT cells. For CLR-1, ChIP-seq identified 1,117 genes, while DAP-seq identified 531; 78 of these genes were differentially expressed in a Δclr-1 mutant relative to WT cells (Dataset S5). We assessed the relationship between DAP-seq peak intensity, expression values, and distance to translation start site in data for XLR-1 and CLR-2 target genes identified by DAP-seq/RNA-seq analyses (SI Appendix, Fig. S5). A trend toward DAP-seq peaks in/near the predicted promoter region of
DAP-Seq Suggests a Multitiered System of CRE-1–Mediated Carbon Catabolite Repression. CRE-1 is a major regulator of carbon catabolite repression, a process through which the expression of genes involved in the utilization of nonpreferred carbon sources is repressed in the presence of preferred carbon sources (32).

### Genes affecting carbon catabolite repression

Although many PCWDEs are known to be regulated by carbon catabolite repression, it was unclear whether this repression was directly or indirectly mediated by CRE-1. Using DAP-seq, we identified 329 CRE-1 binding sites in 318 promoter regions, with 11 promoters showing two peaks (Dataset S5). The 318 genes with promoters bound by CRE-1 were enriched for 30 functional categories \((P < 1 \times 10^{-5})\) involved in metabolic activities (Dataset S6). The top 17 functional categories were all involved in carbon metabolism, specifically cellulose, hemicellulose, pectin, and starch catabolism, representing ~50% of the total CRE-1 peaks and consistent with functions associated with CRE-1. We used the sequences from CRE-1–bound peaks to build a consensus core motif with the best-fit core motif being 5'-TSGGGS-3' \((E = 2.7 \times 10^{-22})\), similar to the 5'-SYGGGRG-3' motif described for CreA in *A. nidulans* (33) (*SI Appendix, Fig. S3C*).

If CRE-1 directly represses genes encoding PCWDEs, we would expect to see CRE-1 binding of PCWDE promoter regions. However, only 19 of 113 PCWDE genes had CRE-1 binding sites in the promoter (Dataset S5). According to the “double-lock” mechanism proposed for Cre1 in *Aspergillus nidulans* (34), indirect repression of PCWDE expression by CRE-1 could be due to either CRE-1 repression of transcription factors required for PCWDE gene activation or CRE-1 repression of genes necessary to activate those transcription factors. In our DAP-seq dataset, promoters for only two carbon transcription factors were bound by CRE-1, *clr-1* and *ara-1*. However, CRE-1 binding was highly biased for promoters of genes encoding MFS transporters (22 MFS genes), with 15 falling within the major sugar transporter clade (*SI Appendix, Fig. S1*), including one high-affinity glucose transporter, hgt-1 (NCU10021) (35) and additional uncharacterized transporters (NCU00809, NCU06522, NCU09287, NCU04537, NCU01494, NCU06384, and NCU05897).

An uncharacterized sugar transporter bound by CRE-1, *sut-28* (NCU05897; annotated as a fucose permease; *SI Appendix, Fig. S1*), is a predicted ortholog of the *A. niger* 1-Rhamnose transporter RhtA (36). The *sut-28* mutant showed reduced growth on 1-Rhamnose and, to a lesser extent, poly-galacturonic acid (Fig. 4A), and uptake of 1-Rhamnose in the Δsut-28 cells was eliminated (Fig. 4B). Similar to a *dpdr-1* mutant, *sut-28* cells failed to activate expression of the rhamnose catabolite gene *1-rhamnose dehydratase* (NCU09034) (37) (Fig. 4C). The expression of *sut-28* was higher in Δcre-1 cells compared to WT when exposed to 1-Rhamnose or 1-Rhamnose and glucose (*SI Appendix, Fig. S3D*). These data supported the CRE-1 DAP-seq data indicating that CRE-1 negatively regulates the expression of *sut-28*.

CRE-1 also bound to the promoters of the cellobextrin transporters *cdt-1* (NCU00801), *cdt-2* (NCU08114), and *sut-12/cdt-1* (NCU05853) (37–40). Cells lacking both *cdt-1* and *cdt-2* are unable to activate cellulolytic gene transcription and do not grow on cellulose (41). The binding of CRE-1 to the promoter of *cdt-1* likely contributes to the repression of cellulolytic genes by CRE-1, as CLR-1 positively regulates *cdt-2*, the major regulator of cellulolytic genes in *N. crassa* (10, 27) (Dataset S5). Thus, our data suggested that cellulolytic gene expression is repressed by CRE-1 through a combination of direct binding to cellobextrin transporters, the transcription factor *clr-1*, and a few cellulolytic PCWDEs (Fig. 5).

For genes involved in hemicellulose deconstruction, CRE-1 binding sites were detected in the promoters of the arabino-transporter *lat-1* (NCU02188) (28), xylose transporters NCU00821 and NCU04527 (42), the xylodextrin transporter *cdt-2*, which is required for WT levels of growth on xylan (39), and pentose transporters *sut-1* (NCU01132) and *xyl-t* (NCU05627) (43) (Fig. 5). CRE-1 binding peaks were not detected in the promoter of the...
major transcriptional regulator of xylan utilization, \(xdr-1\), although CRE-1 binding sites were detected in the promoter of the arabino side utilization regulator, \(ana-1\); an \(ana-1\) mutant showed dramatically reduced growth on arabinoxylan, arabino side, and galactose (Fig. 2).

CRE-1 also directly bound to promoters of genes encoding xylanases, galactosidasases, and arabinanases, as well as genes necessary for arabino side metabolism (Dataset S5 and Fig. 5).

CRE-1 was not bound to the \(pdr-1\) or \(pdr-2\) promoters, which are responsible for regulating the majority of pectinase genes in \(N.\ crassa\) (ref. 12 and Fig. 2A). However, CRE-1 binding sites were identified in the promoter of a major exo-polygalacturonase (NCU09976; \(gh28-2\)) as well as predicted metabolic enzymes for galacturonic acid utilization (\(gauc\) ortholog NCU09533, \(gauB\) ortholog NCU07064, and \(gauC\) ortholog NCU09552) (Fig. 5 and Dataset S5).

Previous microarray data of a \(cre-1\) mutant relative to WT under minimal medium conditions with sucrose as the sole carbon source showed that 75 genes showed increased expression levels (greater than twofold) in the \(cre-1\) mutant (17), including seven genes encoding predicted MFS transporters (Dataset S5). Of these 75 genes, the promoters of 21 of them were bound by CRE-1 in the DAP-seq dataset (Dataset S5), a significant enrichment over expected value if random (3.5 genes). All seven of the predicted MFS transporters that showed increased expression in the \(cre-1\) mutant relative to WT were bound by CRE-1. These MFS sugar transporters included NCU04537 (monosaccharide transporter), NCU04963 (high-affinity glucose transporter), NCU06026 (quinate permease), NCU05897 (sucrose), NCU10021 (l-histidine), NCU00821 (sugar transporter), and NCU05627 (high-affinity glucose transporter ght-1). The remaining set of 21 genes included a number of carbon metabolic enzymes and 5 genes encoding proteins of unknown function (Dataset S5). Thus, an important component of CRE-1 function includes the repression of genes encoding transporters that play a role in the uptake of signaling molecules that act as inducers of transcription factors and genes associated with cellulose, hemicellulose, and pectin utilization (Fig. 5).

DAP-Seq of VIB-1 Reveals a Global Role in Regulating Carbon Metabolism. VIB-1 is a \(Zm\) transcription factor that first identified for its role in mediating self/nonself recognition and heterokaryon incompatibility in \(N.\ crassa\) (44, 45). The \(\Delta vib-1\) mutant also shows severely reduced growth on Avicel and a weak induction of \(cfr\)-2 (21), a phenotype also observed in \(T.\ reesei\) \(\Delta vib1\) strains (22). In addition to Avicel, the \(\Delta vib-1\) mutant also had a severe growth defect on pectin and a moderate growth defect on xylan (SI Appendix, Fig. S6A).

RNA-seq was previously performed on \(\Delta vib-1\) cells exposed to Avicel and carbon starvation conditions (21). Here, we performed additional RNA-seq experiments on the \(\Delta vib-1\) mutant exposed to 1% pectin or 1% xylan as the sole carbon source, 1% BSA as the sole carbon and nitrogen source, and 1% ground \(Miscanthus\) as the complete nutrient source (Dataset S7). RNA-seq data reflected the severity of growth phenotypes, as exposure to Avicel, pectin, and BSA displayed the greatest number of differentially expressed genes between WT and the \(\Delta vib-1\) mutant. Consistent with its phenotype, the \(\Delta vib-1\) mutant has a more similar expression profile to WT cells under xylan conditions.

Using DAP-seq, we identified VIB-1 binding sites within 1.5 kb upstream of the ATG start site of 1,742 genes (Dataset S5). The RNA-seq datasets were utilized to filter the DAP-seq data by limiting the set to genes with at least a 2.15 (2.8)-fold change in gene expression in any of our six conditions. In total, we identified 238 direct target genes of VIB-1 (Dataset S7). Hierarchical clustering of gene expression data of these direct targets showed that one cluster included the majority of genes that were down-regulated in the \(\Delta vib-1\) mutant in more than three conditions. We considered these genes to be the core regulon of VIB-1 (Fig. 6A). A consensus binding motif from VIB-1 peaks within the 1.5-kb promoter regions of core regulon genes showed conservation of three critical bases: T, A, and C (Fig. 6B).

The 56 gene VIB-1 core regulon included genes involved in heterokaryon incompatibility (\(tol,\ pin-c,\) and \(het-6\)) and a number of uncharacterized genes encoding proteins with predicted roles in heterokaryon incompatibility (\(HET\) domain proteins and genes with polymorphic alleles in wild populations; NCU05533, NCU05840, NCU07335, and NCU04453) (Dataset S7). Most of the other annotated genes in the VIB-1 core regulon were associated with metabolism, including three arabinofuranosidases (NCU09170 NCU09975 and NCU02343), a \(\beta\)-xylosidase (NCU09923), three cellulase polysaccharide monoxygenases (NCU02240, NCU09764, and NCU02344), a starch-active polysaccharide monoxygenase (NCU08746), a galacturonic acid transporter (\(gat-1\); NCU00988), an exogalacturonase (NCU06961), rhmogalacturanan acetylesterase (NCU09976), a secreted phospholipase (NCU06650), and acid phosphatase (\(pho-3\); NCU08643) (Dataset S7) (Fig. 6C). Three genes encoding LaeA-like methyltransferase domains (NCU05841, NCU05832, and NCU05501) were in the core VIB-1 regulon and four additional LaeA-like genes were direct targets of VIB-1 (NCU04909, NCU04717, NCU04707, and NCU01148) (Dataset S7). LaeA is a regulator of secondary metabolism in ascomyceete fungi first described in \(A.\ nidulans\) (47).

The \(cfr\)-2 and \(pdr-2\) genes were the only ones encoding transcription factors that were direct targets of VIB-1 (Fig. 6C). In the \(\Delta vib-1\) mutant, expression of \(cfr\)-2 was reduced 5.2-fold relative to WT during exposure to Avicel, and expression of \(pdr-2\) was reduced 3.4-fold relative to WT during exposure to pectin. In addition to \(cfr\)-2 and \(pdr-2\), a number of PCWDE-encoding genes were bound and regulated by VIB-1, including genes encoding enzymes in the core VIB-1 regulon (above), cellulases (\(gh6-3,\) NCU07190; \(gh45-1,\) NCU05121, NCU05751), arabinosidase (NCU05965), rhmogalacturanan acetylesterase (NCU09976), a pectinesterase (NCU10045), etc.
were both required for full activation of cellulase genes in cells was not as high as WT cells, indicating that CLR-1 and VIB-1 interactions, we measured cellulase production in a 

\[ \text{CLR-3} \]

strain showed higher cellulase activity than 

\[ \text{clr-1} \]

eliminates regulation of gene expression in the absence of VIB-1 (48), and in a \( \Delta \text{vib-1} \) mutant, which eliminates regulation of \( \text{clr-1} \) by CRE-1. Both double-mutant strains showed higher cellulase activity than \( \Delta \text{vib-1} \) cells (\( P \)-adj < 0.01), indicating that when relieved from either CLR-3– or CRE-1–mediated repression, CLR-1 was capable of activating cellulolytic enzyme expression in the absence of VIB-1 (SI Appendix, Fig. 6B). However, the cellulase activity of \( \Delta \text{vib-1} \Delta \text{clr-3} \) or \( \Delta \text{vib-1} \Delta \text{cre-1} \) cells was not as high as WT cells, indicating that CLR-1 and VIB-1 were both required for full activation of cellulase genes in \( N. \ crassa \) (\( P \)-adj < 0.01) (SI Appendix, Fig. 6B).

In addition to defects in growth on cellulose and pectin, \( N. \ crassa \) and \( A. \ nidulans \) vib-1 sprG mutants show reduced growth when BSA is the sole carbon or nitrogen source (44, 49). However, analyses of the VIB-1 regulon on BSA did not reveal a clear reason for this growth deficit. The expression of only three genes encoding predicted proteases/peptidases was significantly reduced in the \( \Delta \text{vib-1} \) mutant compared to wild-type cells, including a metalloprotease (mpr-8; NCU07200), a carboxypeptidase (mpr-14; NCU07536), and a proteinase T (spr-7; NCU07159). An additional set of vitamin B6 synthesis genes also showed decreased expression in the \( \Delta \text{vib-1} \) mutant specifically on BSA, including pdx-1 (NCU06550) and pdx-2 (NCU06549) that encode proteins that form the enzyme complex pyridoxal 5-phosphate synthase or vitamin B\( \delta \) synthase (Dataset S7). Pyridoxal 5-phosphate is a cofactor for many enzymes involved in amino acid metabolism and other protein metabolic processes (50).

**Discussion**

In nature, the primary source of nutrients for \( N. \ crassa \) is plant biomass. In this study, we determined expression patterns of the laboratory strain of \( N. \ crassa \) during exposure to different types of carbon sources, including monosaccharides, disaccharides, oligosaccharides, and plant biomass. These results showed that \( N. \ crassa \) responds specifically to the constituents of plant biomass in a largely specific manner (e.g., genes encoding cellulases were induced upon exposure of \( N. \ crassa \) to cellulobiose) but also revealed cross-regulation of genes encoding enzymes not found in the substrate (e.g., genes encoding some xylanases were induced upon exposure of \( N. \ crassa \) to cellulobiose). Induction of PCWDEs by constituents of the plant cell wall, particularly cellulobiose and xylene, have also been shown for other basidiomycete and ascomycete fungi (51–53). These data indicate that filamentous fungi respond specifically to the presence of the individual nutrient sources available but also that the cells anticipate the presence of additional nutrient sources. This anticipation is likely due to the fact that individual components of the plant cell wall are unlikely to be found alone in nature, and therefore expression profiles of fungi deconstructing plant biomass are shaped by the structure and composition of the plant cell wall.

Analyses of a large dataset of microarray transcriptomics data of \( A. \ niger \) exposed to different conditions and performed by multiple laboratories were used to generate coexpression networks (54). Here, WGCNA on \( N. \ crassa \) datasets from exposure Xylanases (NCU02855, NCU04997), feruloyl esterase B (NCU09491), and acetyl xylan esterases (NCU08785, NCU04494) (Fig. 6C). Additional genes encoding PCWDEs that were down-regulated in the \( \Delta \text{vib-1} \) mutant but did not have VIB-1 binding sites in their promoters, could be explained by reduced expression of \( \text{clr-2} \) or \( \text{pdr-2} \) (Fig. 6C), consistent with the severe growth defect on cellulose and pectin substrates in the \( \Delta \text{vib-1} \) mutant.

Our DAP-seq data suggest that VIB-1 acts through \( \text{clr-2} \) to promote cellulase gene expression. However, ChIP-seq identified \( \text{vib-1} \) as a target of the cellulase regulator, CLR-1 (10). CLR-1 also binds to the promoter and is required for the expression of \( \text{clr-2} \) (10). These observations suggest an interplay in the regulation of \( \text{clr-2} \) by CLR-1 and VIB-1. To investigate these interactions, we measured cellulase production in a \( \Delta \text{vib-1} \) \( \Delta \text{clr-3} \) strain, where repression of CLR-1 activation in the absence of cellulose is relieved (48), and in a \( \Delta \text{vib-1} \) \( \Delta \text{cre-1} \) mutant, which eliminates regulation of \( \text{clr-1} \) by CRE-1. Both double-mutant strains showed higher cellulase activity than \( \Delta \text{vib-1} \) cells (\( P \)-adj < 0.01), indicating that when relieved from either CLR-3– or CRE-1–mediated repression, CLR-1 was capable of activating cellulolytic enzyme expression in the absence of VIB-1 (SI Appendix, Fig. 6B).

However, the cellulase activity of \( \Delta \text{vib-1} \) \( \Delta \text{clr-3} \) or \( \Delta \text{vib-1} \) \( \Delta \text{cre-1} \) cells was not as high as WT cells, indicating that CLR-1 and VIB-1 were both required for full activation of cellulase genes in \( N. \ crassa \) (\( P \)-adj < 0.01) (SI Appendix, Fig. 6B).

In addition to defects in growth on cellulose and pectin, \( N. \ crassa \) and \( A. \ nidulans \) vib-1 sprG mutants show reduced growth when BSA is the sole carbon or nitrogen source (44, 49). However, analyses of the VIB-1 regulon on BSA did not reveal a clear reason for this growth deficit. The expression of only three genes encoding predicted proteases/peptidases was significantly reduced in the \( \Delta \text{vib-1} \) mutant compared to wild-type cells, including a metalloprotease (mpr-8; NCU07200), a carboxypeptidase (mpr-14; NCU07536), and a proteinase T (spr-7; NCU07159). An additional set of vitamin B6 synthesis genes also showed decreased expression in the \( \Delta \text{vib-1} \) mutant specifically on BSA, including pdx-1 (NCU06550) and pdx-2 (NCU06549) that encode proteins that form the enzyme complex pyridoxal 5-phosphate synthase or vitamin B\( \delta \) synthase (Dataset S7). Pyridoxal 5-phosphate is a cofactor for many enzymes involved in amino acid metabolism and other protein metabolic processes (50).

**Discussion**

In nature, the primary source of nutrients for \( N. \ crassa \) is plant biomass. In this study, we determined expression patterns of the laboratory strain of \( N. \ crassa \) during exposure to different types of carbon sources, including monosaccharides, disaccharides, oligosaccharides, and plant biomass. These results showed that \( N. \ crassa \) responds specifically to the constituents of plant biomass in a largely specific manner (e.g., genes encoding cellulases were induced upon exposure of \( N. \ crassa \) to cellulobiose) but also revealed cross-regulation of genes encoding enzymes not found in the substrate (e.g., genes encoding some xylanases were induced upon exposure of \( N. \ crassa \) to cellulobiose). Induction of PCWDEs by constituents of the plant cell wall, particularly cellulobiose and xylene, have also been shown for other basidiomycete and ascomycete fungi (51–53). These data indicate that filamentous fungi respond specifically to the presence of the individual nutrient sources available but also that the cells anticipate the presence of additional nutrient sources. This anticipation is likely due to the fact that individual components of the plant cell wall are unlikely to be found alone in nature, and therefore expression profiles of fungi deconstructing plant biomass are shaped by the structure and composition of the plant cell wall.

Analyses of a large dataset of microarray transcriptomics data of \( A. \ niger \) exposed to different conditions and performed by multiple laboratories were used to generate coexpression networks (54). Here, WGCNA on \( N. \ crassa \) datasets from exposure...
to different carbon sources under carefully controlled conditions identified 28 clusters of coregulated genes (Dataset S2). We were particularly interested in defining new transcription factors and regulons associated with plant biomass deconstruction and identified 34 transcription factors whose expression level varied across our panel. Of these, two transcription factor mutants, \( \Delta ara-1 \) and \( \Delta pdr-2 \), showed a significantly different response to \( \text{Miscanthus} \) and pectin, respectively, compared to WT cells (Fig. 2) and a deficiency in the utilization of arabino/galactose (\( \Delta ara-1 \)) and galacturonic acid and pectin (\( \Delta pdr-2 \)). Our transcriptional analyses showed that the expression of the \( \text{lat-1 transporter gene} \) and the \( \text{ard-1 gene} \) were significantly down-regulated in the \( \Delta ara-1 \) mutant. Loss of \( \text{LAT-1} \) prevents arabino transport (29), while \( \text{ard-1 encodes L-arabinitol-4-dehydrogenase} \), which catalyzes the second reaction of arabino catabolism (55) as well as the third step of the oxidoreductive galactose catabolism (56). PDR-2 is involved in the regulation of genes encoding homogalacturunan backbone-degrading enzymes and galacturonic acid catabolic enzymes, similar to GaaR in \( \text{A. niger} \) and \( \text{B. cinerea} \) (13, 14). Activation of a number of pectinase genes, such as the endo-PGase \( gh28-1 \), were dependent on the presence of both PDR-1 and PDR-2 (Fig. 2 B and D). Further characterization of transcription factors associated with plant biomass deconstruction, including those identified in this study, will lead to a better understanding of metabolic cross talk and reveal direct and/or indirect influence on each other in a synergistic regulatory network important for temporal and spatial deconstruction of plant biomass.

To define the direct regulons of transcription factors involved in plant biomass deconstruction, we utilized DAP-seq, developed to assess the direct targets of predicted transcription factors in \( \text{Arabidopsis thaliana} \) (30). Unlike other methods of identifying DNA binding sites, DAP-seq has the advantage that chromatin structure and growth conditions do not play a role in determining transcription factor binding sites. However, transcription factors that require chromatin structure or other cofactors to bind to their DNA target site will not be identified by DAP-seq. Our comparison of ChIP-seq and DAP-seq data for CLR-2 and XLR-1 showed a strong overlap in these two datasets. Analyses of both datasets were helped substantially by the availability of RNA-seq data of the deletion mutants exposed to relevant carbon sources. Although we identified 34 transcription factors whose expression varied across our transcriptional profiling dataset, mutants in a majority of these transcription factors did not show an obvious expression profile difference compared to WT when shifted to conditions where their expression increased (Dataset S1). This result could be due to redundancy of transcription factor function in nutrient regulation, a role of the transcription factor at a different time point than what was assessed in this study, or a role in cross-regulation that was not obvious from the RNA-seq dataset. We predict that these transcription factors do play a role in nutrient regulation in \( \text{N. crassa} \) and that a combination of DAP-seq to help identify conditions and timing for RNA-seq and expression profiling may help to illuminate their function. We may also have missed direct targets of transcription factors using either DAP-seq/RNA-seq or ChIP-seq/RNA-seq methods due to our stringent differential expression requirements (at least \( 2^{1.5} \)-fold) from expression analyses taken at a single time point.

Our DAP-seq data indicated that CRE-1–mediated carbon catabolite repression acts not only through regulation of PCWDEs and their positive transcription factor regulators, but also through key sugar catabolic genes and sugar transporters. Repression of transporter gene expression by CRE-1 may reduce entry of signal-transducing sugars into the cell, thus limiting induction of genes encoding PCWDEs. In \( \text{A. niger} \), low concentrations of galacturonic acid were required to induce gene expression of galacturonic acid utilization genes, including a galacturonic acid transporter, which was repressed by glucose in a CreA-dependent manner (57). Thus, CRE-1 may be regulating carbon catabolite repression through more than four levels of control or a “quadruple-lock” mechanism: 1) regulating expression of

---

**Fig. 6.** VIB-1 regulon. (A) Hierarchical clustering of log2 fold change values from differential expression analysis of FGSCA489 versus \( \Delta vib-1 \) strains shifted to the indicated carbon conditions. Only genes with greater than \( 2^{1.5} \)-fold change in at least one of the indicated conditions and with promoters bound by VIB-1 via DAP-seq are included. The VIB-1 core regulon is a cluster of genes that were differentially expressed across multiple conditions (Dataset S7). (B) VIB-1 binding motif built using MEME v4.12.0 using DAP binding peak sequences of VIB-1 core regulon. \( \text{E value} = 1.8^{-49} \). (C) Plot built with Circos, version 0.69 (80), to display positive regulation of a catabolic CAZymes by VIB-1 and the transcription factors CLR-1 and PDR-2, which are bound and directly regulated by VIB-1. The thickness of the line corresponds to degree of fold change between WT and transcription factor mutant (Datasets S4 and S7), with thicker lines indicating a higher fold change.
sugar transporters; 2) regulating expression of sugar catabolic genes; 3) regulating expression of transcription factors important for expression of genes encoding PCWDEs; and 4) regulating the expression of genes encoding PCWDEs (Fig. 5). This quadruple-lock mechanism may be important in nutrient sensing, in production of specific PCWDEs based on nutrient source, and for integration of different nutrient signals for optimal metabolic regulation during plant biomass deconstruction. Our DAP-seq data on CRE-1 provide a framework for investigating the variety of conditions where CRE-1 plays a role in regulating metabolism (Dataset S6), particularly in conjunction with transcription factors that control condition-specific responses.

The transcription factor VIB-1 belongs to the p53 superfamily, which in mammalian cells regulates the cell cycle, DNA repair, and apoptosis (58). In Saccharomyces cerevisiae, the p53 homolog, Ndt80, regulates entry into meiosis upon nitrogen starvation (59). The genome of N. crassa has three p53 homologs, vib-1, fst-1, and NCU04729, none of which is required for meiosis, although both fst-1 and vib-1 mutants affect female reproductive structure development, which is regulated by nutritional status (60). In filamentous fungi, vib-1 homologs have been shown to regulate protease production, production of extracellular hydrolysates and PCWDEs, N-acetyl glucosamine catabolism, and secondary metabolism (61). Additionally, a vib-1 homolog in the human pathogen Candida albicans controls genes virulence (62). These observations suggest a general role for VIB-1 orthologs in sensing and responding to the availability of nutrients in their environment. In N. crassa, upon starvation, VIB-1 is required for an increase in the expression of a number of secreted proteins associated with polysaccharase and protein degradation (VIB-1 core regulon). These “scout” enzymes release mono/di/oligosaccharides from the insoluble carbohydrates in the plant cell wall, which are transported into the cell, resulting in the full activation of genes and secretion of enzymes associated with the utilization of a particular plant biomass component. This model is consistent with VIB-1 functioning as a general starvation response transcription factor, or a transcription factor important for basal expression of nutrient acquisition genes. In cells lacking VIB-1, this positive-feedback loop is not fully initiated, and full expression of the PCWDE genes necessary for optimal utilization of plant biomass is not achieved. Also consistent with this model, is that the PCWDE genes necessary for optimal utilization of plant biomass are not achieved. Also consistent with this model, is that the PCWDE genes necessary for optimal utilization of plant biomass are not achieved.

Previously, it was hypothesized that VIB-1 functions upstream of CRE-1 and COL-26, as the introduction of vib-1 mutant suppressed the inability of the Δvib-1 mutant to utilize cellulose (21). Our DAP-seq and RNA-seq data support an alternative hypothesis. We predict that the deletion of cre-1 and col-26 allows sufficient expression of clr-2, and, thus, downstream enzymes and transporters necessary for cellulose degradation, to restore growth of the Δvib-1 mutant on cellulose (partly due to a lack of repression of the celldextrin transporters by CRE-1) in a manner similar to how deletion of the three β-glucosidase genes restored cellulase production in the Δvib-1 mutant on cellulobiase (48). Under carbon-limiting conditions, VIB-1 promotes expression of clr-2 and padr-2 along with a small set of PCWDEs. These secreted enzymes cleave plant biomass and signaling sugars are transported into the cell. For cellulose utilization, cellulose (or a modified version of cellulobiase) results in inactivation of the repressor CLR-3 (48), allowing activation of CLR-1. CLR-1 promotes expression of clr-2 and cellulobiase and, together with VIB-1, results in full expression of clr-2 and induction of a positive-feedback loop. As the glucose concentration increases inside the cell, CRE-1–mediated carbon catabolite repression is activated, reducing expression of clr-1 and celldextrin transporters cdt-1, cdt-2, and cht-1, thus negatively regulating expression of PCWDEs both by limiting the expression of clr-1 and the cleaving and import of sugar signaling molecules (Fig. 5). Our data support the cooperative regulation of PCWDEs by negative regulation of transporters by CRE-1 and positive regulation of enzyme scours that regulate signaling processes via VIB-1.

VIB-1 regulation of HET domain genes may also play a role in nutrient acquisition. HET domain genes allow fungi to distinguish between self and nonself, and initiate programmed cell death upon fusion between nonself colonies (63). Starvation increases vegetative cell fusion frequency in a number of ascomycete fungi, including N. crassa (64–66). We hypothesize that VIB-1 increases expression of these HET domain genes to ensure viable fusion is prevented between nonself cells. Potentially, this activity may also be related to the regulation of secondary metabolism by VIB-1–like proteins. The promoters of LaeA-like methyltransferase domain-containing proteins were abundant in the direct target gene set of VIB-1. LaeA and LaeA-like methyltransferase orthologs are negative regulators of secondary metabolite production in fungi (47, 48, 67). The modulation of the expression of these methyltransferases by VIB-1 may have downstream gene-regulatory consequences that may affect competition among microbes and nutrient acquisition during plant biomass deconstruction and utilization.

Materials and Methods

Comprehensive List of PCWDE Genes in the N. crassa Genome. A comprehensive list of predicted N. crassa genes encoding PCWDE was compiled by examining all CAZymes from the Carbohydrate Active Enzymes Database (http://www.cazy.org) (69) (SI Appendix, Table S2).

Strains, Growth Conditions, RNA Extraction, and RNA-Seq. Strains are listed in SI Appendix, Table S3 (see SI Appendix, Supplemental Materials and Methods for strain construction). For DAP-seq experiments, induction of 2 mM monosaccharides and disaccharides was used (23); for complex sugars pectin or 0.5% D-glucose and transferred to either 0.5% pectin or 0.5% pectin plus 2D-glucose and transferred to either 0.5% pectin or 0.5% pectin plus 2D-glucose. RNA isolation and RNA-seq methods are described in SI Appendix, Supplemental Materials and Methods. Filtered reads were mapped against the N. crassa OR74A genome (v12) using TopHat 2.0.4 (70) and transcript abundance was estimated with Cufflinks 2.0.2 (71) in fragments per kilobase of transcript per million mapped reads (FPKM) using up to 3% normalization. Differential expression analysis was performed on raw counts with DEseq2, version 3.3 (72), using data from biological triplicates.

WGCNA and FUNCAT Analyses. The gene coexpression network was calculated across expression profiles for the WT strain exposed to carbon sources listed in Dataset S1 using the R package WGCNA (26) and a custom catalog (11) based on MIPS Functional Catalogue Database (FunCatDB) (73) with expanded categories for cell wall degradation-related genes for enrichment analysis.

Enzyme Activity and Transport Assays. WT and Δcre-1 strains were induced in 0.5% pectin or 0.5% pectin plus 2% glucose and transferred to either 100 μM L-rhamnose or 100 μM L-rhamnose plus 100 μM glucose as uptake solution. WT and ausr-28 strains were transferred to uptake solutions containing either 100 μM L-rhamnose, 90 μM α-fucose (VWR; A16789), 90 μM α-galactose, or 90 μM β-galactose (Sigma-Aldrich; G7050). Monosaccharide concentration of sample supernatants was quantified by high pH anion exchange chromatography–pulsed amperometric detection on an ICS-3000 instrument (Thermo Scientific). A 25-μL sample was injected onto a Dionex CarboPac PA20 column (3 × 30-mm guard and 3 × 150-mm analytical) and eluted using an isocratic mobile phase of 10 mM NaOH at 0.4 mL/min and 30 °C over 12 min. Cellulase activity assays were modified from Coradetti et al. (27) (SI Appendix, Supplemental Materials and Methods).

DAP-Seq. Predicted open reading frames for each transcription factor were amplified from cDNA generated using RNA to cDNA EcoDry premix (Clontech). Amplified transcription factor sequences were inserted into an expression vector containing T7 and SP6 promoters upstream of HALO tag as previously described (30). In vitro transcription and translation of transcription factors were performed using Promega T7 T7 Rabbit Reticulocyte Quick Coupled Transcription/Translation System by incubating 1 μg of plasmid DNA with 60 μL of TnT Master Mix and 1.5 μL of 1 mM methionine overnight at room temperature. Expression was verified using Western blot analysis with Promega.
Anti-HaloTag monoclonal antibody. Single DAP-seq libraries were generated once for each transcription factor, tested, and sequenced once with Illumina MiSeq 2 × 150-bp runs.

Filtered reads were aligned to the N. crassa OR74A genome (v12) using Bowtie2 v2.3.2 (70). Peak calling was performed using MACS2 v2.1.1 (74) with P value cutoff at 0.001 and utilizing negative control library alignments. Peaks within 3,000 bp upstream of translation start sites were selected for and annotated using a custom Python script. The same Python script was used for reanalysis of CHIP-seq peaks data from Craig et al. (10) for DAP-seq/CHIP-seq comparisons.

Data Availability. The RNA-seq data reported in this paper have been deposited in the Joint Genome Institute Genome Portal (75), in the National Center for Biotechnology Information (NCBI) Sequence Read Archive (ID SRP133337), and in the NCBI BioProject database (76). Data are also provided for processed RNA-seq experiments in Datasets S1, S4, S5, and S7 (75 SRP133337), and in the NCBI BioProject database (76). Data are also provided for DAP-seq/ChIP-seq comparisons.

The same Python script was used for reanalysis of ChIP-seq peaks dataset from Craig et al. (10) and for reanalysis of ChIP-seq peak dataset from Malloy et al. (39). A list of DAP-seq data reported in this paper have been deposited in the NCBI Sequence Read Archive (ID SRP133627). Standard Neurospora methods information is available from the Fungal Genetics Stock Center (FGSC) at http://www.fgsc.net/Neurospora/NeurosporaProtocolGuide.htm. A list of DAP-seq deletion strains and strains constructed for this study are available in SI Appendix, Table S3. Strains in this table are available from the FGSC (http://www.fgsc.net/Hcrasala).
