(March 30, 2022)

The interaction of two rectangular pulses in nonlinear Schrödinger model is studied by solving the appropriate Zakharov-Shabat system. It is shown that two real pulses may result in appearance of moving solitons. Different limiting cases, such as a single pulse with a phase jump, a single chirped pulse, in-phase and out-of-phase pulses, and pulses with frequency separation, are analyzed. The thresholds of creation of new solitons and multi-soliton states are found.

I. INTRODUCTION

The nonlinear Schrödinger (NLS) equation is an important model of the theory of modulational waves. It describes the propagation of pulses in optical fibers\textsuperscript{1,2}, the dynamics of laser beams in a Kerr media, or the nonlinear diffraction\textsuperscript{3}, waves in plasma\textsuperscript{4}, and the evolution of a Bose-Einstein condensate wave function\textsuperscript{5}. The NLS equation is written in dimensionless form as the following:

$$iu_z + u_{xx}/2 + |u|^2u = 0,$$

where $u(x,z)$ is a slowly varying wave envelope, $z$ is the evolutive variable, and $x$ is associated with the spatial variable.

An exact solution of the NLS equation has a form of a soliton:

$$u(x,z) = 2\eta \text{sech}(2\eta(x + 2\xi z - x_0)) \exp[-2i\xi x - 2i(\xi^2 - \eta^2)z + i\phi_0].$$

where $2\eta$ and $2\xi$ are amplitude, or the inverse width, and the velocity of the soliton, $x_0$ and $\phi_0$ are the initial position and phase, respectively. The soliton represents a basic mode and plays a fundamental role in nonlinear processes. The dynamics of NLS solitons and single pulses even in the presence of various perturbations is well understood (see e.g. Refs. \textsuperscript{1,2} and reference therein). However, the evolution of several pulses is not studied in details. In recent works\textsuperscript{6} (see also book\textsuperscript{2}) mostly an interaction of solitons and near-soliton pulses was considered. A study of near-soliton pulses, especially a use of the effective particle approach, often results in small variation of soliton parameters, including the soliton velocities and as a consequence weak repulsion or attraction of solitons. Such a study do not involve a possibility of appearance of additional solitons. However, for many applications it is necessary to consider the interaction of pulses with arbitrary amplitudes or pulses with different parameters. For example, in optical communication systems with the wavelength division multiplexing (WDM), the initial signal consist of several solitons with different frequencies. An estimation of the critical separation between pulses is important for determination of the repetition rate of a particular transmission scheme.

In present work the interaction of two pulses in the NLS model is studied both theoretically and numerically. We show the presence of different scenarios of the behaviour, depending on the initial parameters of the pulses, such as the pulse areas, the relative phase shift, the spatial and frequency separations. One of our main observation is a fact that a pure real initial condition of the NLS equation can result in additional moving solitons. As a consequence the number of solitons, emerging from two pulses separated by some distance, can be larger than the sum of the numbers of solitons, emerging from each pulse. Such properties were also found for the Manakov system\textsuperscript{7}, which is a vector generalization of the NLS equation. The scalar NLS equation was studied in\textsuperscript{7} as a particular case. Later similar results and approximation formulas for the soliton parameters were obtained in papers\textsuperscript{8,9} (see also\textsuperscript{10}). In works\textsuperscript{7–10}

\textsuperscript{*}Corresponding author: etsoy@physic.uzsci.net
mostly the interaction of real pulses was analyzed, while here we consider pulses with non-zero relative phase shift and frequency separation. A preliminary version of this study was presented in work\textsuperscript{11}.

The paper is organized as the following. The linear scattering problem associated with the NLS equation is considered in Section II. We also present the general solution of the problem for the case of two rectangular pulses. In Section III we study different particular cases, such as two in-phase pulses, two out-of-phase pulses, a single pulse with a phase jump, a single chirped pulse, and two pulses with the frequency separation. The results and conclusions are summarized in Section IV.

## II. DIRECT SCATTERING PROBLEM

In this paper we are interested only in an asymptotic state of the pulse interaction. In order to simplify the problem and to obtain exact results we consider the interaction of two rectangular pulses (“boxes”). Therefore we take the following initial conditions for Eq. (1):

\[
u(x, 0) \equiv U(x) = \begin{cases} Q_1 \exp[2iu_1 x], & \text{for } x_1 < x < x_2, \\ Q_2 \exp[2iu_2 x], & \text{for } x_3 < x < x_4, \\ 0, & \text{otherwise}, \end{cases}
\]

where \(Q_1\) and \(Q_2\) are the complex constant amplitudes, \(u_1 \equiv x_2 - x_1\) and \(u_2 \equiv x_4 - x_3\) are the pulse widths, and \(2u_1\) and \(2u_2\) are the detunings.

It is known that NLS equation is integrable by the inverse scattering transform method\textsuperscript{3}. As follows from this fact, initial conditions, which decreases sufficiently fast at \(x = \pm \infty\), results in a set of solitons and linear waves (so called, radiation). The number \(N\) and parameters of solitons emerging from an initial condition are found from the solution of the Zakharov-Shabat scattering problem:\textsuperscript{3}

\[
i \frac{\partial \psi_1}{\partial x} - iU(x) \psi_2 = \lambda \psi_1, \\ -i \frac{\partial \psi_2}{\partial x} - iU^*(x) \psi_1 = \lambda \psi_2
\]

with the following boundary conditions

\[
\Psi_{x \to -\infty} = \begin{pmatrix} 1 \\ 0 \end{pmatrix} e^{-i\lambda x}, \quad \Psi_{x \to \infty} = \begin{pmatrix} a(\lambda) e^{-i\lambda x} \\ b(\lambda) e^{i\lambda x} \end{pmatrix}.
\]

Here \(\Psi(x)\) is an eigenvector, \(\lambda\) is an eigenvalue, \(a(\lambda)\) and \(b(\lambda)\) are the scattering coefficients, and a star means a complex conjugate. The number \(N\) is equal to the number of poles \(\lambda_n = \xi_n + i\eta_n\), where \(n = 1, \ldots, N\), and \(\eta_n > 0\), of the transmission coefficient \(1/a(\lambda)\). Each \(\lambda_n\) is invariant on \(z\). If all \(\xi_n\) are different then \(u(x, z)\) at \(z \to \infty\) represents a set of solitons, each in the form of Eq. (2) with \(\eta = \eta_n\) and \(\xi = \xi_n\). If real parts of several \(\lambda_n\) are equal then a formation of a neutrally stable bound state of solitons is possible.

The solution of the Zakharov-Shabat problem (4) with the potential (3) is written as

\[
a(\lambda) = e^{i(\lambda + \nu_1)w_1} e^{i(\lambda + \nu_2)w_2} \\
\left\{ \begin{array}{l}
\cos(k_1 w_1) - i\left(\frac{\lambda + \nu_1}{k_1}\right) \sin(k_1 w_1) \\
\cos(k_2 w_2) - i\left(\frac{\lambda + \nu_2}{k_2}\right) \sin(k_2 w_2)
\end{array} \right\} \\
\frac{Q_1}{k_1} \frac{Q_2}{k_2} e^{-2i(\lambda + \nu_1)w_2} e^{2i(\lambda + \nu_2)w_2} \sin(k_1 w_1) \sin(k_2 w_2) \right\},
\]

\[
b(\lambda) = e^{i(\lambda + \nu_1)w_1} e^{-i(\lambda + \nu_2)w_2} \\
\left\{ \begin{array}{l}
-\frac{Q_1}{k_1} e^{-2i(\lambda + \nu_1)w_2} \sin(k_1 w_1) \\
\cos(k_2 w_2) + i\left(\frac{\lambda + \nu_2}{k_2}\right) \sin(k_2 w_2)
\end{array} \right\}.
\]
where \( k_j = \left[ (\lambda + \nu_j)^2 + |Q_j^2\right]^{1/2} \).

Since the linear operator in (4) is not Hermitian, complex eigenvalues are possible even for real \( u(x,0) \) (e. g. see Section III A). Though this is an obvious fact, "an interesting “folklore" property seems to have arisen in the literature over the last 25 years, namely, that only pure imaginary EVs (eigenvalues) can occur for symmetric real valued potentials". As demonstrated below, the statement [Theorem (III) in §2 of paper\(^1\)], that claims this result, is incorrect. An existence of eigenvalues with non-zero real parts for Zakharov-Shabat problem with pure real potential was first shown in paper\(^7\).

Equations (6,7) represent a general solution of the scattering problem (4,5) with initial condition (3). Applications of these equations to particular cases of the pulse interaction are considered in the next section.

III. RESULTS

A. Interaction of in-phase pulses with equal amplitudes

1. Properties of eigenvalues

Here we analyze a simple case of two real pulses, separated by a distance \( L \equiv x_3 - x_2 \), with zero detuning, i.e. \( Q_1 = Q_2 = Q_0 \), \( \nu_1 = \nu_2 = 0 \), where \( Q_0 \) is real. Then using Eq. (6), the equation for discrete spectrum is written as

\[
F(\lambda, Q_0, w) \pm \frac{Q_0}{k} e^{i\lambda L} \sin(kw) = 0 ,
\]

where \( F(\lambda, Q, w) \equiv \cos(kw) - i\lambda \sin(kw)/k \), and \( k = (\lambda^2 + Q^2)^{1/2} \). Note that \( F(\lambda, Q_0, w) = 0 \) determines the discrete spectrum for a single box with zero detuning\(^1\). Therefore the second term in Eq. (8) can be associated with the result of nonlinear interference. Recall also that for a single box with amplitude \( Q_0 \) and width \( w \), the number \( N_{SB} \) of emerging solitons is determined as\(^3 \) \( N_{SB} = \text{int}(Q_0w/\pi + 1/2) \), where \( \text{int}() \) means an integer part. Results for the two boxes are reduced to those for a single box in limiting cases \( L = 0 \) and \( L = \infty \).

As shown by Klaus and Shaw\(^8\), the Zakharov-Shabat problem with a “single-hump” real initial condition admits pure imaginary eigenvalues only, i.e. solitons with zero velocity. We show that the case of two pulses provides much richer dynamics.

Let us now compare the properties of eigenvalues at different \( S \equiv Q_0w \) (Fig. 1). In Fig. 1, as well as in subsequent figures of the paper, all variables are dimensionless. In the first two cases, \( S = 1.8 \) and \( S = 2.0 \), there is one soliton at \( L = 0 \) and there are two solitons at \( L = \infty \), while in the case \( S = 2.5 \) there are two solitons in both limits. The dependence of eigenvalues on \( L \) at \( S = 2.5 \) is obvious, while that at \( S = 1.8 \) and \( S = 2.0 \) looks unexpected. Firstly, the number of solitons at intermediate \( L \) is larger then that in the limits \( L = 0 \) and \( L = \infty \). Secondly, the two real boxes lead to eigenvalues with non-zero real part. Third, for \( S = 2.0 \) there is a “fork” bifurcation at \( L = L_F \approx 4.1 \), when two eigenvalues coincide. At larger \( L \) three pure imaginary eigenvalues constitute a three-soliton state, so that the limiting two-soliton case at \( L \to \infty \) is realized as a limit of a three-soliton solution with an amplitude of the third soliton tending to zero.

Results of numerical simulations of the NLS equation (1) agree with analysis of Eq. (8). For example, as shown in Fig. 2, in accordance with Fig. 1b there are one fixed and two moving solitons at \( S = 2.0 \) and \( L = 2 \), and there are a three-soliton state and two moving solitons at \( S = 2.0 \) and \( L = 5 \). Note that an appearance of moving solitons and multi-soliton states is not related to the rectangular form of initial pulses. For example, an initial condition \( u(x,0) = 0.7[\text{sech}(x + 2.5) + \text{sech}(x - 2.5)] \) also results in moving solitons.

Below we discuss in details the behaviour of the eigenvalues, namely we find a threshold of appearance of new roots, estimate a number of emerging solitons, and calculate a threshold for the “fork” bifurcation. It should be mentioned that eigenvalues with non-zero real part do not exist only at \( S = [3\pi/4, 3.3] \) and \( S = [7\pi/4, 5.51] \) (see Section III A 2), so that the dependence at \( S = 2.5 \) is rather an exception than a general rule. This results allows to understand why moving solitons are not observed in interaction of near-soliton pulses with area \( S \approx \pi \).
2. Appearance of new eigenvalues

Solving numerically Eq. (8), one can conclude that new eigenvalues penetrate to the upper half-plane of λ in pairs by crossing the real axis. Therefore, the bifurcation parameter can be found from Eq. (8), assuming that λ = β, where β is real:

\[ \cotan y = \pm \frac{\sqrt{2S^2 - y^2}}{y}, \]
\[ \beta = \pm Q_0 \sin(\beta L). \] (9)

Here \( y = \kappa w, \kappa = (\beta^2 + Q_0^2)^{1/2} \), and the signs are taken such that \( \tan(y) \tan(\beta L) < 0 \) is satisfied. As follows from the definition of \( y \) and Eq. (9), one has \( S \leq y < 2S \).

Analysis of Eqs. (9,10) results in the following conclusions:

(i) As follows from Eq. (9), the number \( N_{P_+} \) of the penetration points depends only on \( S \) and is determined from:

\[ N_{P_+} = 4(m - n + 1) - 2\theta \left[ \left( S - \left( \frac{n + \frac{1}{4}}{1} \right) \pi \right) - 2\theta \left[ S - \left( \frac{n + \frac{3}{4}}{4} \right) \pi \right] - 4\theta(S_m - S) \right] \]
\[ \text{for } S \geq \frac{3\pi}{4}, \] (11)

where \( m = \text{int}\left(\sqrt{2} \frac{S}{\pi}\right), \) \( n = \text{int}(S/\pi), \) \( \theta(x) \) is the Heavyside function, and \( S_m \) is a root of

\[ \tan(\sqrt{2S^2 - 1}) = \sqrt{2S^2 - 1}, \] (12)

which satisfies \( m\pi \leq (2S_m^2 - 1)^{1/2} < (m + 1)\pi. \) It is easy to find that \( N_{P_+} = 0 \) for \( S < \pi/4 \) and \( N_{P_+} = 2 \) for \( \pi/4 < S < 3\pi/4. \) Equation (12) defines such values of \( S = S_m \), when the right hand side of Eq. (9) with plus sign touches cotany curve. All penetration points \( \beta_j \), where \( j = 1, \ldots, N_{P_+} \), are symmetrically situated with respect to \( \beta = 0. \)

(ii) All roots \( |\beta_j| \leq Q_0 \), which follows from \( 2S^2 - y^2 \geq 0. \)

(iii) For every \( \beta_j \), Eq. (10) defines the separation distance \( L = L_C \), when eigenvalues cross the real axis.

(iv) As follows from Eq. (10) there is an infinite number of thresholds \( L_C \) for a given \( \beta_j. \) However, the total number of eigenvalues in the upper half-plane of \( \lambda \) is, most probably, finite, because for some \( L_C \) eigenvalues pass to the upper half-plane, and for other \( L_C \) eigenvalues go to the lower half-plane. The direction of eigenvalue motion is defined by the derivative \( d\lambda/dL \) at \( \lambda = \beta_j. \)

The positions of penetration points, \( \beta_j \), as a function of \( S \) is shown in Fig. 3a, where only positive \( \beta_j \) are presented. As follows from Eq. (9) the number \( N_{P_+} \) decreases by two, when \( S \) passes \( (2l + 1)\pi/4, \) where \( l = 1, 2, \ldots, \) and \( N_{P_+} \) increases by four, when \( S \) exceeds \( S_m \) [see Eq. (12)]. Therefore one can obtain that Eq. (9) has no roots only at \( S = [3\pi/4, S_2] \) and at \( S = [7\pi/4, S_3], \) where \( S_2 \approx 3.26 \) and \( S_3 \approx 5.51 \) are found from Eq. (12). This property is clearly seen in Fig. 3. The dependence of \( L_C \) on \( S \) is presented in Fig. 3b. Only the thresholds, such that \( \beta_jL = [0, 2\pi], \) are shown for each \( \beta_j. \)

3. Thresholds of “fork” bifurcation

Here we analyze a bifurcation, when a pair of complex eigenvalues becomes pure imaginary, e.g. \( L_F \approx 4.1 \) in Fig. 1b. The equation which determine pure imaginary eigenvalues can be obtained from Eq. (6) with \( \text{Re}[\lambda] = 0, \) i.e. \( \lambda = i\gamma: \)

\[ \cotan y = \frac{-\sqrt{S^2 - y^2} \pm S \exp[-\sqrt{S^2 - y^2} L/w]}{y}, \] (13)

Here \( y = \kappa w, \kappa = (-\gamma^2 + Q_0^2)^{1/2}. \) It is easy to show that \( \kappa^2 \) should be positive (there is no real solution for \( \kappa^2 < 0). \)

As a consequence, all pure imaginary eigenvalues satisfy \( \gamma_j \leq Q_0. \)

The value of \( L = L_F, \) when new pure imaginary root of Eq. (13) appears, corresponds to the “fork” bifurcation. The bifurcation threshold \( L_F \) can be found from the condition that the functions, corresponding to the right-hand side of Eq. (13), touch the cotany curve.

Low bound of the number of the pure imaginary eigenvalues is found as \( N_{LB} = \text{int}(2S/\pi + 1/2). \) This number is an actual number of the pure imaginary eigenvalues for all \( S, \) except of the regions where
\[ \frac{\pi}{2} + \pi l < S < \frac{3\pi}{4} + \pi l, \quad l = 0, 1, \ldots \] (14)

If $S$ satisfies Eq. (14) then the number of pure imaginary eigenvalues can be either $N_{LB}$ or $N_{LB} + 2$, depending on whether $L < L_F(S)$ or $L > L_F(S)$, respectively. Therefore the appearance of new pure imaginary eigenvalues, in other words, the fork bifurcation, is possible only if $S$ satisfies Eq. (14). Figure 4 represents the dependence of $L_F$ on $S$, where only one interval, corresponding to $l = 1$ in Eq. (14), is shown; the behaviour for $l > 1$ is similar. One can calculate that $L_F(S = 1.8) = 10.4$, that is why the fork bifurcation is not seen in Fig. 1a.

**B. Two out-of-phase pulses with equal amplitudes**

In this section we study the influence of constant phase shift on the pulse interaction, i.e. we consider $Q_1 = Q_0 \exp(-i \alpha)$, $Q_2 = Q_0 \exp(i \alpha)$, where $Q_0$ and $\alpha$ are real, $w_1 = w_2 = w$, and $\nu_1 = \nu_2 = 0$. The non-zero relative phase shift, $2\alpha$, changes greatly the properties of the eigenvalues, so that the behaviour presented in Section III A is hard to realize in experiments, because it is difficult to prepare two pulses exactly in phase. The phase shift breaks the *simultaneous* appearance of a pair of solitons at $\lambda = \pm \beta_j$, and affects to the “fork” bifurcation.

For $\alpha \neq 0$, the equations for eigenvalues and for penetration points can be obtained from Eq. (8) and Eqs. (9,10) by changing $\lambda L \to \lambda L + \alpha$ and $\beta L \to \beta L + \alpha$ in the exponent and sinus functions, respectively. Therefore the number and positions of the penetration points are the same as for the case $\alpha = 0$. As for the threshold $L_C$, it is shifted on the value $\alpha/\beta_j$, so that $L_C(\alpha) = L_C(\alpha = 0) + \alpha/\beta_j$, where only $L_C \geq 0$ should be taken into account.

The influence of the phase shift on the distribution of eigenvalues is shown in Fig. 5. As seen, now new eigenvalues appear one by one, not in pairs, and, as a consequence, the “fork” bifurcation disappears. Further, the real parts of the roots do not vanish at finite $L$, but decreases smoothly. This means that the presence of the phase shift breaks up a multi-soliton state, which is known to be neutrally stable to perturbations.

At $L = 0$, the phase shift corresponds to the phase jump of a single pulse. Such a phase jump can result in an appearance of additional solitons as shown in Fig. 5b. The threshold of the phase shift $\alpha_{th}$, when the first new soliton appear, can be found from the condition $\alpha_{th} = |\beta_1|L_C(\alpha = 0)$, where $\beta_1$ is the position of the penetration point nearest to zero.

**C. Two pulses with frequency separation**

In this section we analyze the initial condition (3) with the following parameters $Q_1 = Q_2 = Q_0$, $w_1 = w_2 = w$, $-\nu_1 = \nu_2 = \nu$, where $Q_0$ is a real constant. This case models the wavelength division multiplexing in optical fibers, the case when an input signal consists of two or more pulses with different frequencies. Actually, since $Q_0$ can be taken sufficiently large we consider the interaction of multi-soliton states. The detailed analysis of the interaction of sech-pulses at different frequencies is presented in papers\textsuperscript{14} and in review\textsuperscript{15}. In particular, the authors of papers\textsuperscript{14,15} consider the evolution of a superposition of $N$ solitons with the same position of the centers, but with different frequencies. As shown in these works there is a critical frequency separation, above which $N$ solitons with almost equal amplitudes emerge. Below this critical value the number of emerging solitons can be not equal $N$ and their amplitudes can appreciably differ from each other. It was also demonstrated that an introduction of a time shift between pulses results in decrease of the frequency separation threshold. The geometry described by Eq. (3) corresponds to the combination of WDM and time-division multiplexing schemes, therefore our study can give some insight to such a behaviour of the threshold. Moreover, the authors of works\textsuperscript{14,15} mostly used the perturbation technique and numerical simulations, while in the present paper we deal with an exact solution of the Zakharov-Shabat problem.

First let us consider the case $L = 0$ that correspond to the case of a single *chirped* pulse of width $2w$. The dependence of the eigenvalues on $\nu$, which plays here the role of a chirp parameter, is shown in Fig. 6. At small $\nu$ the interaction of the pulse components is strong, so that there is one pure imaginary eigenvalue, or a single soliton with zero velocity. At larger $\nu$ the frequency difference of the pulse components results in a repulsion of the components, or a pulse splitting. At sufficiently large $\nu$ the velocities of emerging solitons tends, as expected, to $\pm 2\nu$.

There is also a narrow region of $\nu$, e.g. $\nu = [0.98, 0.99]$ on Fig. 6, where three solitons, one fixed and two moving solitons, exist. This region separate two different types of the evolution of a chirped pulse. The left boundary, which corresponds to the appearance of new eigenvalues, of the region is found from the condition similar to that considered in Section III A 2. The right boundary is found from $a(\lambda = 0) = 0$, which defines the values of $\nu$ as a function of the other parameters, when the pure imaginary root disappears.

The dependence of the spectrum on $L$ is presented in Fig. 7. At small $\nu$ (Fig. 7a) we see again an appearance of additional solitons similar to the case $\nu = 0$ (Fig. 1). At larger $\nu$ (Fig. 7b) the repulsion is so strong that it suppresses
the appearance of small-amplitude solitons. Therefore there is a threshold of the frequency separation above which the interaction of two pulses is negligible. This result is in agreement with the conclusions of the paper\textsuperscript{15}.

IV. CONCLUSION

The interaction of two pulses in the NLS model is studied by means of the solution of the associated scattering problem. The strong dependence of the dynamics on the parameters of the initial pulses is shown. For intermediate separation distances $L$ the existence of additional moving solitons is possible even in the case of two in-phase pulses with the same frequencies. These additional solitons can be considered as a result of nonlinear interference of pulses. The phase shift of two pulses removes a degeneracy in the behaviour, namely it affects to the symmetry of the parameters of emerging solitons and results in a break-up of multi-soliton states peculiar to the in-phase case. It is also shown that the strong frequency separation suppress the appearance of additional solitons. The results obtained in the present paper can be useful for analysis of the transmission capacity of communication systems and for interpretation of experiments on the interaction of two laser beams in nonlinear media. Recently, the generation of up to ten solitons has been observed experimentally in quasi-1D Bose-Einstein condensate of \textsuperscript{7}Li with attractive interaction\textsuperscript{16}. Our study can be also helpful for interpretation of this experiment.

FIG. 1. In-phase pulses: The dependence of real (dashed lines) and imaginary (solid lines) parts of $\lambda_n$ on the separation distance, $w = 1$. Numbers near lines corresponds to $n$. (a) $Q_0 = 1.8$, (b) $Q_0 = 2.0$, (c) $Q_0 = 2.5$.

FIG. 2. Evolution of two rectangular pulses, $Q_0 = 2, w = 1$. (a) One fixed soliton and two moving solitons at $L = 2$. (b) Three-soliton state at $L = 5$. 
FIG. 3. (a) The dependence of $\beta_j$ on $S$. (b) Threshold $L_C$, when eigenvalues cross the real axis of $\lambda$-plane, as a function of $S$.

FIG. 4. Threshold $L_F$ of the fork bifurcation as a function of $S$.

FIG. 5. Out-of-phase pulses: The dependence of real (dashed lines) and imaginary (solid lines) parts of $\lambda_n$ on $L$ for $Q_0 = 2, w = 1$. Numbers near lines corresponds to $n$. (a) $\alpha = \pi/8$, (b) $\alpha = \pi/4$. 
FIG. 6. Single chirped pulse: The dependence of real (dashed lines) and imaginary (solid lines) of $\lambda_n$ on $\nu$ for $Q_0 = 2, w = 1, L = 0$. Numbers near lines corresponds to $n$.

FIG. 7. Pulses with frequency separation: The dependence of real (dashed lines) and imaginary (solid lines) of $\lambda_n$ on $L$ for $Q_0 = 2, w = 1$. Numbers near lines corresponds to $n$. (a) $\nu = 0.5$; (b) $\nu = 1.25$.
