Abstract

Background: The extent and the progression of vascular calcification (VC) are independent predictors of cardiovascular risk in the haemodialysis population. Vitamin K is essential for the activation of matrix gla protein (MGP), a powerful inhibitor of tissue calcification. Functional vitamin K deficiency may contribute to the high VC burden in haemodialysis patients. In addition, haemodialysis patients are frequently treated with vitamin K antagonists, mainly to prevent stroke in atrial fibrillation, potentially compounding the cardiovascular risk in these already vulnerable patients. New oral anticoagulants (NOACs) are valuable alternatives to vitamin K antagonists in the general population, but their use in dialysis has been encumbered by substantial renal clearance. However, a recent pharmacokinetic study provided information on how to use rivaroxaban in haemodialysis patients.

Methods: We conduct a randomized, prospective, multicentre, open-label interventional clinical trial that will include 117 chronic haemodialysis patients with non-valvular atrial fibrillation, treated with or candidates for treatment with vitamin K antagonists. Patients will be randomized to a vitamin K antagonist titrated weekly to an international normalized ratio between 2 and 3, a daily dose of rivaroxaban of 10 mg, or a daily dose of rivaroxaban 10 mg with a thrice weekly supplement of 2000 µg vitamin K2. Cardiac computed tomography, pulse wave velocity (PWV) measurements and MGP sampling will be performed at baseline, 6 months, 12 months and 18 months. Primary endpoints include progression of coronary artery and thoracic aorta calcification and changes in PWV. Secondary endpoints are progression of aortic and mitral valve calcification, all-cause mortality, major adverse cardiovascular events, stroke and bleeding. The ClinicalTrials.gov database was searched to retrieve related trials.

Results: Seven trials, three of which are performed in the haemodialysis population, evaluate whether pharmacological doses of vitamin K1 or K2 retard progression of VC. Five studies compare the effect of warfarin and NOACs on progression of VC, the present study being the only conducted in the dialysis population.

Conclusion: Vitamin K deficiency may be a modifiable cardiovascular risk factor in the haemodialysis population. Conversely, vitamin K antagonists may aggravate VC burden in haemodialysis patients. Several ongoing trials may provide an answer to these questions in the near future.

Key words: haemodialysis, rivaroxaban, vascular calcifications, vitamin K, vitamin K antagonists
Background and objectives

Patients on chronic haemodialysis suffer from extensive vascular calcifications (VC). The presence of VC is directly related to increased cardiovascular morbidity and mortality in the dialysis population [1]. Once progression of VC is established, it cannot be fully reversed [2]. Haemodialysis patients exhibit reduced vitamin K intake [3, 4], and urea interferes with vitamin K recycling [5]. Levels of dephosphorylated uncarboxylated MGP (dp-uc-MGP), the inactive form of MGP, increase with chronic kidney disease stage [6]. Haemodialysis patients thus represent a population with a very high overall vitamin K deficiency and vitamin K supplementation may be an attractive novel approach to attenuate progression of VC in haemodialysis patients. The optimal dose and form of vitamin K to achieve this goal is unknown. The group of K vitamins comprises phyloquinone (vitamin K1) and several menaquinones (vitamin K2). Menaquinones have side chains of varying length and are termed MK-n, in which n denotes the number of unsaturated isoprenoid residues. Vitamin K1 predominantly accumulates in the liver where it catalyses the carboxylation of the coagulation factors, whereas vitamin K2 is more readily transported to the extrahepatic tissues and is involved in the carboxylation of MGP and osteocalcin. Within the extrahepatic tissues, vitamin K1 may be converted to vitamin K2, mainly MK-4 [2]. Two-dose-finding studies in haemodialysis patients have shown an almost linear dose-response of dp-uc-MGP to the long-chain menaquinone MK-7, with doses ranging between 45 µg/day and 1080 µg trice weekly [4, 7]. A plateau phase was not obtained and even the highest dose of MK-7 did not normalize dp-uc-MGP, suggesting that the optimal dose of MK-7 supplementation in dialysis patients may be even higher. There is no documented toxicity for phyloquinone or menaquinones and the WHO has set no upper tolerance level for vitamin K intake [2]. An animal study reported no toxicity associated with synthetic MK-7 administered in a single oral dose up to 2000 mg/kg or for 90 days of oral administration of 10 mg/kg per day [8]. A theoretical consideration could be that excessive vitamin K results in an increased thrombosis risk. However, vitamin K-dependent proteins have a limited number of Glu residues capable of gamma-carboxylation per molecule, beyond which there can be no further gamma-carboxylation. Vitamin K supplementation had no adverse effects on thrombin generation [9]. Further, the anticoagulant proteins S and C are activated in parallel with the coagulation factors. No side events were recorded in a Japanese trial of 2185 postmenopausal osteoporotic women receiving 45 mg menatetrenone for 3 years [10]. Vitamin K intake was not associated with stroke risk in a prospective cohort of 35 476 healthy subjects [11]. Another potential problem relates to the vitamin K-dependent carboxylation of osteocalcin, also termed Bone Gla protein [12]. Besides its known role in bone health, osteocalcin may affect glucose homeostasis. So far, no clinical data suggest a potential adverse effect of vitamin K intake or supplements on diabetes control [12], but strict vigilance remains warranted.

Vitamin K antagonists are frequently used in chronic haemodialysis patients, mainly for the prevention of stroke and systemic embolism in atrial fibrillation, a condition that is highly prevalent in this population [13]. Vitamin K antagonists are increasingly implicated in the development of VC [14–16], precisely because they block not only the gamma-carboxylation of coagulation factors, but also prevent the activation of MGP. The use of anticoagulants alternative to warfarin has been problematic in the dialysis population for lack of data, given their substantial renal clearance. Rivaroxaban is a factor Xa inhibitor, shown to be effective and safe in a large trial on the prevention of stroke and systemic embolism in non-valvular atrial fibrillation [17]. Rivaroxaban is partially eliminated via the kidneys, resulting in a decreased clearance in subjects with renal failure and its use is officially contraindicated in patients with a creatinine clearance <15 mL/min. A recent pharmacokinetic study in patients on chronic haemodialysis demonstrated that a daily dose of 10 mg rivaroxaban in dialysis patients provides an anticoagulant effect that is comparable to that of 20 mg in healthy volunteers [18]. Dialysis had no significant effect on the plasma levels of rivaroxaban [18].

The present study targets dialysis patients with non-valvular atrial fibrillation that are candidates for treatment with vitamin K antagonists according to the most recent guidelines [19]. It addresses the question of whether replacement of the vitamin K antagonist by rivaroxaban is able to slow progression of VC. The second research question is whether addition of vitamin K2 to rivaroxaban can further beneficially affect the progression of VC. Two non-invasive methods are used to evaluate the impact of the interventions on the progression of VC: i.e. coronary artery calcification (CAC) and pulse wave velocity (PWV) measurements. Although controversial as treatment target, the detection of CAC is a frequently used surrogate marker and is predictive of future cardiovascular events in haemodialysis patients [20]. Stiffening of the central elastic-type arteries is an independent predictor of cardiovascular morbidity and mortality in haemodialysis patients [21].

Trial design

This study is a randomized, prospective, multicentre and open-label interventional clinical trial. The study is performed in accordance with the ethical standards of the responsible institutional committee on human experimentation and with the Helsinki Declaration of 1975 (and as revised in 1983). The study is registered on ClinicalTrials.gov (Identifier NCT02610933).

The study has a three-arm parallel group design with a 1:1:1 allocation ratio. Patients will be screened in order to randomize 117 patients (Figure 1). The total expected trial duration is 3 years. Each patient will have a follow-up of at least 18 months.

Participants

The study population are adults on chronic haemodialysis with non-valvular atrial fibrillation, who have a CHA2DS2–VASc Score of ≥2 and therefore are candidates for anticoagulation [19] or already receive vitamin K antagonists, and are able to provide informed consent.

Exclusion criteria are:

- known intestinal malabsorption or inability to take oral medication
- inability to stop co-medication that causes major interactions with rivaroxaban (e.g. ketoconazole, itraconazole, voriconazole, posaconazole, ritonavir, rifampicin, phenytoin, carbamazepine, phenobarbital or St John’s wort)
- investigator’s assessment that the subject’s life expectancy is <1 year
- prosthetic mechanical heart valve
- contraindication for anticoagulation
- liver dysfunction Child-Pugh grade B–C
- pregnancy, breastfeeding, inadequate contraception
- compliance with medication and scheduled investigations

No side events were recorded in a Japanese trial of 2185 postmenopausal osteoporotic women receiving 45 mg menatetrenone for 3 years [10]. Vitamin K intake was not associated with stroke risk in a prospective cohort of 35 476 healthy subjects [11]. Another potential problem relates to the vitamin K-dependent carboxylation of osteocalcin, also termed Bone Gla protein [12]. Besides its known role in bone health, osteocalcin may affect glucose homeostasis. So far, no clinical data suggest a potential adverse effect of vitamin K intake or supplements on diabetes control [12], but strict vigilance remains warranted.

Vitamin K antagonists are frequently used in chronic haemodialysis patients, mainly for the prevention of stroke and systemic embolism in atrial fibrillation, a condition that is highly prevalent in this population [13]. - pregnancy, breastfeeding, inadequate contraception
- compliance with medication and scheduled investigations
Interventions and measurements

Patients in the first treatment arm are started on a vitamin K antagonist or continue their vitamin K antagonist, with dose adjustments to achieve an international normalized ratio (INR) of 2–3 on the basis of weekly INR measurements. Time within the therapeutic range is recorded. Patients in the second treatment arm receive a daily dose of 10 mg rivaroxaban. Patients in the third treatment arm receive a daily dose of 10 mg rivaroxaban and a thrice weekly dose of 2000 µg MK-7.

Clinical data, biochemical data, imaging and PWV data are collected at baseline, 6 months, 12 months and 18 months. Subjective tolerability is evaluated by questioning the patients about any adverse events or by spontaneous reporting of adverse events by the patients. Objective tolerability is evaluated by monitoring vital signs and routine clinical laboratory tests.

Analysis of dp-uc-MGP

Venous blood samples are taken at the start of dialysis at the dialyser inlet line. EDTA plasma is obtained by 15 min of centrifugation at Rotina 38R and stored at −80°C in 3 aliquots of 1 mL until dry ice shipment for analysis. Circulating dp-uc-MGP is quantified using a previously described dual antibody enzyme-linked immunosorbent assay [22].

Imaging

For calcification assessment, an unenhanced electrocardiographically gated computed tomography of the heart and thoracic aorta is performed at 120 kV on a Revolution (GE Healthcare), Aquilion One (Toshiba) or Somatom Definition Flash (Siemens) scanner. To limit artefacts owing to high heart rates (>70 bpm), beta-blockade (bisoprolol 2.5–5 mg) is administered orally 60 min before scanning when necessary. Calcium scores are calculated on 2.5 mm slices using Smartscore v.4.0 (GE Healthcare) by the Agatston method [23], by the volume method [24] and by the mass score. All foci within the arteries with attenuation >130 Hounsfield units (Hu) and a minimum area of 1 mm² are considered significant and will be counted into the total score. An Agatston score for each calcific lesion is calculated by multiplying the density factor (1 = 130–199 Hu, 2 = 200–299 Hu, 3 = 300–399 Hu and 4 = ≥400 Hu) by the area. A total Agatston score is obtained by adding up the scores of all individual lesions in all slice levels. The total volume score is obtained by adding the volumes of all >130 Hu lesions. The mass score calculates the mass (mg) of calcified plaque above the 130 Hu threshold. One experienced investigator reviews all scans for consistency of interpretation. For each subject, all imaging procedures are done on the same equipment using the same parameters at each session to permit valid image comparisons. Scans start in the upper thorax above the aortic arch, advancing caudally to the level of the diaphragm to include the coronary arteries, the aortic and mitral valve, and the ascending and descending thoracic aorta.

Pulse wave velocity

Haemodynamic measurements are performed in the supine position by trained research nurses during a haemodialysis session. PWV is obtained by sequential recording of electrocardiogram-gated carotid and femoral artery pressure waves using applation tonometry (SphygmoCor version 7, AtCor Medical, Sydney, Australia), as described previously [25]. The path length is calculated as 0.8 times the direct distance between the carotid and femoral recording site. PWV is calculated as the path length divided by transit time (m/s). A mean of three measurements is made. Based on a combination of practical and theoretical issues, PWV is measured during the first hour of the mid-week dialysis session [26].

Endpoints

Primary endpoints

(i) Progression of CAC (absolute and relative change versus baseline).
(ii) Progression of thoracic aortic calcification (absolute and relative change versus baseline).
(iii) Absolute and relative change in PWV.

Secondary endpoints

(i) Progression of aortic valve calcification (absolute and relative change versus baseline).
(ii) Progression of mitral valve calcification (absolute and relative change versus baseline).
(iii) Mortality from any cause.
(iv) Myocardial infarction, acute coronary syndrome, symptom-driven revascularization, hospitalization for heart failure and death from cardiovascular cause.
(v) Stroke, defined as sudden onset of focal neurological deficit consistent with the territory of a major cerebral artery and categorized as ischaemic, haemorrhagic or unspecified. Haemorrhagic transformation of ischaemic stroke is not deemed to be haemorrhagic stroke. Systemic embolism, defined as an acute vascular occlusion of a limb or organ documented by imaging, surgery or autopsy.

(vi) Major bleeding, defined as a requirement for transfusion of two or more units of blood or a decrease in haemoglobin of 2 g/dL or more. Life-threatening bleeding, defined as fatal bleeding, symptomatic intracranial bleeding, a decrease in haemoglobin of 5 g/dL or more, or a requirement for transfusion of four or more units of blood, inotropic agents or surgery. All other bleedings are regarded as minor.

Table 1. Characteristics of ongoing trials evaluating the effect of Vitamin K supplements on vascular calcification

| ClinicalTrials.gov Identifier | Study design | Country | Population | Type of vitamin | Duration (months) | Primary endpoint |
|-----------------------------|-------------|---------|------------|-----------------|-------------------|------------------|
| NCT01742273a                | International, multicentre, prospective, controlled, open label, randomized, interventional clinical trial | Europe | 348 prevalent haemodialysis patients | Vitamin K1 (phylloquinone) 5 mg thrice weekly | 18 | Progression of thoracic aorta and coronary calcification |
| NCT01528800b                | Prospective, placebo controlled, double-blinded, randomized, interventional clinical trial | Canada | 80 incident haemodialysis patients | Vitamin K1 (phytonadione) 10 mg thrice weekly | 12 | Progression of CAC, cardiovascular events |
| NCT00785109c                | Prospective, placebo controlled, open label, randomized, interventional clinical trial | Germany | 200 patients >50 years with echocardiographically verified aortic valve calcification | Vitamin K1 2 mg daily | 18 | Progression of aortic valve calcification |
| NCT01002157d                | Prospective, placebo controlled, double-blinded, randomized, interventional clinical trial | Netherlands | 180 patients with established CAC | Vitamin K2 (MK-7) dose not mentioned | 24 | Progression of coronary calcification |
| NCT01922804e                | Prospective, placebo controlled, double-blinded, randomized, interventional clinical trial | Denmark | 150 postmenopausal women with osteopaenia | Vitamin K2 (MK-7) 375 µg daily | 36 | Change in bone mineral density, insulin sensitivity, arterial stiffness |
| NCT02404519f                | Prospective, placebo controlled, double-blinded, randomized, interventional clinical trial | Netherlands | 240 men and women between 40 and 70 years with functional Vitamin K deficiency | Vitamin K2 (MK-7) 180 µg daily | 12 | Change in arterial stiffness |
| Our studyg                  | Multicentre, prospective, controlled, open label, randomized, interventional clinical trial | Belgium | 117 prevalent haemodialysis patients with AF | Vitamin K2 (MK-7) 2000 µg thrice weekly | 18 | Progression of thoracic aorta and CAC, progression of arterial stiffness |

Subgroup analysis

Prevalent users of vitamin K antagonists versus patients with incidental indication for vitamin K antagonists.

Sample size calculation

Assuming an average CAC score of 800 at baseline and accounting for an anticipated annual CAC progression of 60% in the vitamin K antagonist arm, 30% in the rivaroxaban arm and 0% in the rivaroxaban + MK-7 arm [27-30], power calculations revealed that 27 patients in each arm are required to provide 80% statistical power at the α = 0.05 significance level. Based on an estimated drop-out rate of 30% during 18 months of follow-up, 39 patients per arm are included in the trial.

Randomization and blinding

Patients are assigned to groups through computer-generated randomization. The patients, site investigators, and members of the data analysis committee are aware of the treatment assignments. Due to the requirement for frequent INR measurements to adjust the dose of warfarin, an adequate complete blinding would be challenging. Therefore, the study is performed open-labelled. To exclude information bias, the primary endpoints are objectively measured by investigators blinded to the treatment allocation.

Table 2. Characteristics of ongoing trials evaluating the effect of Vitamin K antagonists (VKA) versus novel oral anticoagulants (NOAC) on vascular calcification

| ClinicalTrials.gov Identifier | Study design | Country | Population | NOAC (versus VKA) | Duration (months) | Primary endpoint |
|------------------------------|-------------|---------|------------|-------------------|------------------|-----------------|
| NCT02066662^a                 | Single centre, prospective, controlled, open label, randomized, interventional clinical trial | Germany | 253 patients with AF or PE and eGFR >15 mL/min/1.73 m² | Rivaroxaban 15/20 mg | 12 | Progression of coronary and aortic valve calcification (Agatston score) |
| NCT02161965^b                 | Prospective, controlled, open label, randomized, interventional clinical trial | France | 150 patients with AF, PE or venous thrombosis and eGFR > 30 mL/min/1.73 m² | Rivaroxaban 15/20 mg | 12 | Progression of coronary calcification and arterial stiffness |
| NCT02090075^c                 | Prospective, controlled, open label, randomized, interventional clinical trial | USA | 66 patients with AF and eGFR >50 mL/min/1.73 m² | Apixaban 5 mg | 12 | Progression of coronary calcification |

VC or cardiovascular endpoints in some [31–33] but not all [11, 34] studies. Dietary intake of phylloquinone (vitamin K1) was not associated with vascular health in any of the studies [11, 31, 32, 34, 35]. In a study of 387 haemodialysis patients, deficiency of the vitamin K2 species MK-4 and MK-7 correlated with the presence of VC [36]. A few interventional trials with vitamin K on intermediate cardiovascular endpoints have yielded inconsistent results. In 388 older men and women with normal renal function, 500 µg daily phylloquinone did not reduce CAC progression at the end of 3 years of follow-up [37]. However, in a subgroup analysis of participants who were ≥85% adherent to treatment, there was less CAC progression in the phylloquinone group than in the controls [37]. In healthy postmenopausal women, a daily supplement of 1000 µg phylloquinone and vitamin D preserved the elastic properties of the vessel wall, as compared with placebo or vitamin D alone [38]. On the other hand, CAC progression was not significantly affected by a 270-day course of 90 µg MK-7 in 42 patients with chronic kidney disease stage 3e76. Three years of supplementation with 180 µg daily MK-7 improved arterial stiffness in a trial of 244 healthy postmenopausal women [40]. In contrast, CAC progression was not significantly affected by a 270-day course of 90 µg MK-7 in 42 patients with chronic kidney disease stage 3–5 not on dialysis [41]. We searched for ongoing trials of the effect of vitamin K supplementation on the progression of VC entering ‘vitamin K’ and ‘vascular calcification’ as search terms in the ClinicalTrials.gov search engine. Seven studies were retrieved (Table 3), three of which are conducted in the haemodialysis population. All use pharmacological doses of either vitamin K1 (three studies) or vitamin K2 (four studies).

New oral anticoagulants (NOAC) compare favourably with vitamin K antagonists for the prevention of stroke and systemic embolism, with a beneficial effect on total mortality in a recent meta-analysis [42]. However, none of the individual trials was designed to specifically answer the question whether warfarin accelerates progression of VC. We searched for ongoing trials comparing NOACs with vitamin K antagonists in terms of their effects on vascular calcification. The following search terms were entered in random combinations in the ClinicalTrials.gov search engine: ‘rivaroxaban’, ‘apixaban’, ‘dabigatran’, ‘novel oral anticoagulant’, ‘vascular calcification’, ‘vitamin K antagonist’, ‘warfarin’. Five studies were retrieved, using rivaroxaban (four studies) or apixaban (one study) as the comparator for warfarin (Table 2). The present study is the first to test the hypothesis in haemodialysis patients, using information obtained in a recent pharmacokinetic study of rivaroxaban in this population [18].

Conclusion

Over the past decade, a large body of evidence has accumulated establishing that vitamin K is essential for vascular health. Vitamin K supplementation may be a simple means to prevent progression of VC in haemodialysis patients, a population characterized by severe functional vitamin K deficiency. Conversely, Vitamin K antagonists have garnered attention as they may potentially aggravate progression of VC in dialysis patients. The scientific community is now poised to conduct randomized controlled trials to supersede the evidence from basic science and observational studies and yield therapies that may improve the dire prognosis of dialysis patients.
