A Massively Parallel Associative Memory Based on Sparse Neural Networks

Zhe Yao*, Vincent Gripon† and Michael G. Rabbat*

Abstract—Associative memories store content in such a way that the content can be later retrieved by presenting the memory with a small portion of the content, rather than presenting the memory with an address as in more traditional memories. Associative memories are used as building blocks for algorithms within database engines, anomaly detection systems, compression algorithms, and face recognition systems. A classical example of an associative memory is the Hopfield neural network. Recently, Gripon and Berrou have introduced an alternative construction of the Gripon-Berrou associative memory on a general purpose graphical processing unit (GPU). The work of Gripon and Berrou proposes two retrieval rules, SUM-OF-SUM and SUM-OF-MAX. The SUM-OF-SUM rule uses only matrix-vector multiplication and is easily implemented on the GPU. The SUM-OF-MAX rule is much less straightforward to implement because it involves non-linear operations. However, the SUM-OF-MAX rule gives significantly better retrieval error rates. We propose a hybrid rule tailored for implementation on a GPU which achieves a 880-fold speedup without sacrificing any accuracy.

I. INTRODUCTION

We are all familiar with conventional memory systems where the address space and the information content stored in the memory are kept separate. For instance, given a mailbox number, we can fetch the parcels inside, and in a modern computer, the CPU retrieves a stored integer from RAM by accessing a specified 32- or 64-bit hardware address.

An associative memory is a device or data structure that maps input patterns to output patterns. It differs from conventional memory systems in that no explicit addresses are constructed. Associative memories store paired patterns. Then, given an input pattern, the associative memory produces the paired output pattern. Since no explicit address is involved in its operation, the content of the input pattern itself associates directly with the paired output pattern, from which the name associative memory originates. Although associative memories could be implemented using conventional memory systems, neural networks have been used as associative memories which retrieve patterns without having to search through the stored pattern space. It is worth noting that hash tables, implemented using conventional memory systems, resemble associative memories since they map keys (inputs) to values (outputs), but still an explicit address needs to be generated first.

Associative memories can be categorized into two types [1]: hetero-associative (e.g., linear associator [2], [3], bidirectional associative memories [4] and Willshaw networks [5]) and auto-associative (e.g., Hopfield networks [6], [7]). Hetero-associative memories associate input with output patterns of possibly distinct nature and formats, whereas auto-associative memories are a special case where input and output patterns coincide. This paper focuses on auto-associative memories.

Associative memories have applications in a variety of domains. For instance, in communication networks [8], routers need to quickly determine which port an incoming frame should be forwarded to based on the destination IP address. In signal and image processing [9], one commonly needs to match noisy or corrupted data to a predefined template. Similar tasks appear in database engines [10], anomaly detection systems [11], data compression algorithms [12], face recognition systems [13] and many other machine learning frameworks.

A. Historical Background

Associative memories have a long history within the field of neural networks. Associative memories provide two operations: storing and retrieving. In the storing operation, pairs of patterns are fed into the memory and the internal connections between neurons are modified, forming an aggregated representation of the stored pairs. In the retrieving operation (also referred to as “decoding”), the associative memory is presented with a probe pattern, which may be a corrupted or modified version of the stored pattern, and the memory should retrieve the most relevant pattern that was previously stored in a quick and reliable manner.

The linear associator [2], [3] is one of the simplest and earliest associative memory models; see Fig. 1 for an illustration. A linear associator has an input layer and an output layer. Synapses only exist between these two layers, hence the network can be viewed as a bipartite graph. Connections in the network are directed from input to output neurons. The number of neurons in each layer can be different in general, so the linear associator can be used as both an auto-associative and a hetero-associative memory. While storing patterns, the linear associator modifies link weights according to Hebb’s rule [14]. While decoding a pattern, the network is presented with a given input pattern, and the paired output pattern is retrieved from the output layer immediately after one step of feed forward computation. Since the paired pattern depends on
a linear combination of the input pattern values, if all the input patterns are pairwise orthogonal, then the linear associator can reconstruct the paired patterns perfectly. However, in most cases the orthogonality does not hold, thus the network diversity (i.e., the number of patterns that the network can store) is extremely low.

The first formal analysis of associative memories by Willshaw [5], [15] dates back to early 1970’s. The structure of a Willshaw network is similar to a linear associator; it is a two-layer fully connected network, with the exception that the weights on the synapses are constrained to be 0 or 1. The plausibility of biological neural networks discourages a fully connected network. Therefore, Buckingham and Willshaw [16] study an incomplete connected network and propose several retrieval strategies to recall the patterns. Although simple, the Willshaw network is one of the most efficient model in terms of information stored per bit of memory (0.68 for hetero-associative and half of that for auto-associative [17], [18], compared to 0.14 for a Hopfield network [19]). For the history and interesting developments of the Willshaw network, see the recent survey [20] and the references therein.

Hopfield’s seminal work [6], [7] on associative memories brought these structures to the attention of the neural network community in the early 1980’s. Fig.2 shows an example of a Hopfield network, which is a bidirectional complete graph. Instead of having two layers, Hopfield networks comprise one layer of a bidirectional complete graph, acting as both input and output. Therefore, it can only be used as an auto-associative memory. Retrieval of a pattern from the network proceeds recurrently; i.e., when an impulse enters the network, the (output) values at iteration \( t \) serve as the input values at iteration \( t + 1 \), and the values iterate until the network reaches its stable configuration if it ever converges. Kosko [4] extends the Hopfield network into a two-layer bidirectional associative memory (BAM). BAMs are different from linear associators because the edges in a BAM are not directed, and the retrieval rule is different. In a BAM, values at the input and output iterate until an equilibrium is reached. Since a BAM incorporates distinct input and output layers, it can be used as both a hetero-associative and an auto-associative memory, filling the gap between the linear associator and Hopfield networks.

B. Related Work

The recent work of Gripon and Berrou [21], [22] proposes a new family of sparse neural network architectures for associative memories. We refer to these as Gripon-Berrou neural networks (GBNNs). In short, GBNNs are a variant of the Willshaw networks with a \( C \)-partite structure for some \( C > 0 \). The GBNN combines the notion of recurrence from Hopfield networks with ideas from the field of error correcting codes, and achieves nearly optimal retrieval performance. A detailed description of the GBNN architecture and operation is given in Section II.

The GBNN is not the first attempt to link the associative memory with error correcting codes. For example, Berrou and Gripon [23] successfully introduce a set of Walsh-Hadamard codes in the framework of BAMs. The same authors also consider the use of sparse coding in a Hopfield network. They show that, given the same amount of storage, the GBNN outperforms conventional Hopfield networks in diversity, capacity (i.e., the maximum amount of stored information in bits), and efficiency (i.e., the ratio between capacity and the amount of information in bits consumed by the network when diversity reaches its maximum), while decreasing the retrieval error. In [24], GBNNs are interpreted using the formalism of error correcting codes, and a new retrieval rule is introduced to further decrease the error rate. Jiang et al. [25] modify the GBNN structure to learn long sequences by incorporating directed edges into the network. Aliabadi et al. [26] make the extension to learn sparse messages.

The literature mentioned in the paragraphs above focuses on studying theoretical properties of GBNNs. To be useful in many applications, it is also essential to develop fast and efficient implementations of GBNNs. Jarrollahi et al. [27] demonstrate a proof-of-concept implementation using the field programmable gate array (FPGA). Due to hardware limitations, their implementation is constrained to have at most 400 neurons. Larras et al. [28] implement an analog version of the same network which consumes 1165× less energy but is 2× more efficient both in the surface of the circuit and speed, compared with an equivalent digital circuit. However, the network size is further constrained to 208 neurons in total.
C. Contributions

The primary contribution of this paper is to demonstrate an implementation of GBNNs on a GPU using the *compute unified device architecture* (CUDA). Our massively parallel implementation supports a much larger number of neurons than existing ones, and is $880 \times$ faster than a CPU implementation using optimized C++ libraries for linear algebra operations, without any loss of retrieval accuracy. All the existing algorithms can hopefully benefit from the exciting result we present.

Towards developing an efficient parallel GBNN implementation, we study two retrieval rules: SUM-OF-SUM and SUM-OF-MAX, which have been previously proposed in [22] and [24]. SUM-OF-SUM is fast to implement in CUDA, because it requires only a matrix-vector multiplication, a highly optimized operation. SUM-OF-MAX is slower because it involves non-linear operations, but it gives superior retrieval performance (lower error rates). We illustrate that, although faster, SUM-OF-SUM can lead to problematic oscillations. We also prove that the SUM-OF-MAX rule is guaranteed to converge, and we derive properties of both rules.

The tremendous speedup mentioned above comes from two main sources. First, we exploit the highly parallel architecture of the GPU to carry out operations efficiently. Second, we develop a hybrid retrieval scheme using aspects of both SUM-OF-SUM and SUM-OF-MAX, which is tailored to parallel decoding architectures. Although we discuss a GPU implementation, we believe the ideas presented here can be used to accelerate associative memory implementations on other parallel architectures.

We emphasize that this work neither focuses on the GBNN model itself (see [21], [22]), nor carries out comparative studies with other associative memory implementations, e.g., [29]. Instead, we are interested in developing robust and fast procedures to recall stored information given incomplete probes. As a motivating example, consider recovering messages over an erasure channel, which is a common scenario, especially in the ubiquitous IP-based communications. The errors encountered by the IP packets can be mitigated by checksums and error correcting codes. However, missing packets have to be recovered to avoid time-consuming and unreliable retransmissions.

D. Paper Organization

The rest of this paper is structured as follows. Section II reviews the GBNN associative memory architecture. Section III reviews the SUM-OF-SUM and SUM-OF-MAX retrieval rules. Section IV presents the proposed acceleration techniques and discusses the customized CUDA kernel functions which implement these techniques. Section V provides theoretical analysis and discussion of some properties of the retrieval rules considered in this work. Section VI proposes the novel hybrid retrieval rule. Section VII presents experimental results demonstrating the significant performance improvements obtained using GPUs. The paper concludes in Section VIII.
We number the clusters from left to right and from top to bottom as Fig. 3. An example of a network with 4 clusters of 16 neurons each. We number the clusters from left to right and from top to bottom as 1⋯4. The same scheme applies for neurons 1⋯16 within each cluster.

be changed significantly and the decoding rules studied in this paper are no longer applicable.

B. Characteristics

In a classic Willshaw network model, a unique activation threshold needs to be chosen globally, e.g., either the number of active neurons in the input probe or the maximum number of signals accumulated in output neurons. This global threshold is no longer required in a GBNN, since each cluster can naturally decide for itself. The most closely related model in the literature is that of Shim et al. [30]. However, there are two main advantages of GBNNs, both of which are supported by simulations in Section VII.

1) GBNNs incorporate a self excitation term (see the reinforcement factor γ in Eq. (3) and Eq. (6)).

2) The retrieval rule used in [30] is essentially the same as the SUM-OF-SUM rule. Below we point out fundamental issues with SUM-OF-SUM and we also advocate using the alternative SUM-OF-MAX rule [24] for decoding, which significantly increases the retrieval rate.

Sparseness has been heavily exploited to perform machine learning tasks and statistical inferences. One of the most famous example is compressive sensing [31]. Neuroscientists are also aware of the sparseness principle [32], not only because of its practical applications but also the low firing rate of the neurons in biological networks [33]. The cluster structure of GBNN produces an extremely sparse binary code by definition (one active neuron per cluster), which makes the network biologically plausible, and also makes fast implementations possible. It is also mentioned in [34] that the performance of an associative memory is severely affected given correlated patterns. There, an intermediate “grandmother cell” layer is suggested to encode each pair of patterns using a neuron. However, for GBNN, this particular problem can be mitigated by padding messages with extra random symbols at the cost of additional materials. The cluster structure again makes the extension straightforward.

III. Retrieval Rules

In this section, we review two existing retrieval rules for GBNN, i.e., SUM-OF-SUM and SUM-OF-MAX.

A. The SUM-OF-SUM Rule

The simplest rule [22] is to add all the signals a neuron receives in the current iteration. When presented with an incomplete message, we initialize the network by deactivating (i.e., setting to 0) all the neurons within the clusters associated with erased symbols. We then repeat the following iterations. First, each neuron compute the sum of all connected neurons which are presently active. Then the neurons within each cluster with the most active connected neurons remain activated at the beginning of the next iteration.

Formally, let \( \text{neuron}(c, l) \) denote the \( l \)th neuron in the \( c \)th cluster, and let \( w_{(cl)}(c', l') \) denote an indicator variable for whether or not a connection is present between \( \text{neuron}(c, l) \) and \( \text{neuron}(c', l') \); i.e.,

\[
w_{(cl)}(c', l') = \begin{cases} 1 & \text{neuron}(c, l) \text{ connected to } \text{neuron}(c', l') \\ 0 & \text{otherwise} \end{cases} \tag{1}
\]

We also denote by \( s^t_{cl} \) and \( v^t_{cl} \) respectively the score function for the number of signals \( \text{neuron}(c, l) \) receives and the indicator function for whether or not \( \text{neuron}(c, l) \) is activated at iteration \( t \), with \( v^0_{cl} \) being the corresponding value for \( \text{neuron}(c, l) \) in the probe; i.e.,

\[
v^t_{cl} = \begin{cases} 1 & \text{neuron}(c, l) \text{ activated in iteration } t \\ 0 & \text{otherwise} \end{cases} \tag{2}
\]

As a consequence, the retrieval procedure can be formalized as

\[
s^t_{cl} = \gamma v^t_{cl} + \sum_{c'=1}^{C} \sum_{l'=1}^{L} (v^t_{c'l'} w_{(cl)(c'l')} \gamma) \tag{3}
\]

\[
s^t_{c,\text{max}} = \max_{1 \leq l \leq L} s^t_{cl} \tag{4}
\]

\[
v^{t+1}_{cl} = \begin{cases} 1 & \text{if } s^t_{cl} = s^t_{c,\text{max}} \\ 0 & \text{otherwise} \end{cases} \tag{5}
\]

where \( \gamma \geq 0 \) is a reinforcement factor. Essentially, Eq. (3) counts the score for each neuron. It involves summing over all clusters and all neurons within each cluster, hence the name SUM-OF-SUM. Eq. (4) finds the value of the neurons with the strongest signal in each cluster, and Eq. (5) keeps them activated.

At the retrieval stage, the variables \( w_{(cl)}(c', l') \) are fixed. These binary-valued variables are only changed when storing new messages. The only parameter to be tuned for retrieval using SUM-OF-SUM is \( \gamma \), which influences the extent to which a neuron’s own value influences its signal at the current iteration.
B. Problems with the SUM-OF-SUM Rule

The SUM-OF-SUM rule, although straightforward and natural, might lead to unnecessary errors. This is due to the fact that during iterations, after evaluating Eq. (5), there might be multiple neurons in one cluster achieving the maximum value $s_{c,\text{max}}^t$ simultaneously. In this case, all these neurons will stay activated and contribute to the signal strengths in the next iteration.

Consider the scenario shown in Fig. 4, where two neurons $l_1$ and $l_2$ both receive the same number of signals. Neuron $l_1$ receives two signals from cluster 1, while $l_2$ receives one signal from each cluster. In this case, $l_2$ should be favored, because we know that for any individual pattern that has been stored, only one neuron in each cluster should be activated. A possible but worse situation arises when $l_1$ receives more signals than $l_2$, since then $l_1$ will be the only activated neuron in this cluster at the beginning of the next iteration, even if $l_2$ was actually the correct neuron in cluster 3. An increasing number of clusters will complicate the problem even further. This can also cause SUM-OF-SUM to diverge see Section V.

C. The SUM-OF-MAX Rule

To avoid the problem mentioned in the previous subsection, the SUM-OF-MAX rule is proposed in [24]. The rule is formally described as follows:

$$s_{c,\text{max}}^t = \gamma v_{c,\text{max}}^t + \sum_{c' = 1}^C \max_{1 \leq c' \leq L} (v_{c',t}^t w^{c'c}(c)(c'))$$

$$v_{c,\text{max}}^{t+1} = \begin{cases} 1 & \text{if } s_{c,\text{max}}^t = \gamma + C - 1 \\ 0 & \text{otherwise} \end{cases}$$

Eq. (6) involves a summation over max operation, hence the name SUM-OF-MAX. The basic idea is that, to retrieve the correct message, the score of a neuron should not be larger if it receives multiple signals from the same cluster, and the maximum taken in Eq. (5) ensures each neuron receives at most one signal from each cluster. Since each stored message corresponds to a clique of $C$ neurons, one in each cluster, a neuron should be activated if it receives exactly $C-1$ signals from the other clusters plus some value $\gamma$ from the self loop.

For SUM-OF-MAX to work properly, the network must be initialized appropriately when a probe is presented. Instead of initializing all neurons associated with erased symbols to be 0 as in SUM-OF-SUM, we initialize them to be 1. In that case, other neurons will definitely receive signals from these missing clusters, $L$ signals per missing cluster, but they will be regulated by Eq. (7).

IV. ACCELERATING RETRIEVAL

In this section, we will first briefly introduce the CUDA architecture. We discuss different approaches to speeding up the GBNN retrieval procedure in general, and then we focus on specific techniques for SUM-OF-SUM and SUM-OF-MAX separately. We also illustrate graphically the dedicated CUDA kernel functions for both rules. Note that, although we implement GBNN using CUDA, the accelerating techniques do not depend on any CUDA specific attribute, thus can be easily extended to other architectures.

A. CUDA

The Compute Unified Device Architecture (CUDA), introduced in 2007, is NVIDIA’s computing platform solution to general purpose computing on graphics processing units (GPGPU), which enables dramatic increases in computing performance by harnessing the massively parallel resources of GPUs. See [34] by Kirk and Hwu for more information.

The basic programming pattern in CUDA is as shown in Fig. 5, where CPUs play the role of managers, invoking on the GPUs some computational intensive functions called kernel functions. After the kernel function is executed on the GPU, the CPU collects the results back to the host and then may invoke more kernel functions if necessary. Although a GPU can spawn many threads working simultaneously, each thread must run the same sequence of instructions. Kernel functions, and hence GPU computing in general, fit the category of “single instruction multiple data” (SIMD) parallel computing platforms. The data are transferred back and forth between the CPU and GPU over the (slow) PCI or PCIe bus, one of the performance bottlenecks. Unfortunately, since the code control flow is on the CPU side, the time-costly transfers between the host and the video card are inevitable. Therefore, keeping the transfer of data to a minimum is one of the crucial concerns.

B. General Tricks

1) Vectorization: Although GBNN is a recurrent model, conceptually we can treat it as a layered network nevertheless. We repeat each iteration $t$ as one layer, so that the number of layers can grow as large as the network needs to converge. Let $T$ denote the the total number of iterations to be run. The only two constraints to be satisfied are

$$w_{ij}^1 = w_{ij}^2 = \cdots = w_{ij}^T \text{ and } w_{ij}^t = w_{ij}^t, t = 1, 2, \cdots, T.$$  

The benefit is to borrow the matrix notation from layered networks which is more efficient in the parallel implementation. We map the original clustered structure into a flat space, where neuron $(c, l)$ becomes neuron $(i)$, with $i = (c-1)L + l$,.
Batch retrieval arises naturally in applications where simultaneous retrievals are preferred. For instance, in face recognition, an associative memory can be used to recognize face features even when areas are obstructed by sun glasses or a scarf. If we treat each image as a single message, the hardware requirement is simply prohibitive. A 256-level gray image of the size $512 \times 512$ requires an adjacency matrix $W$ of $(2^8 \times 2^8)^2 = 2^{252}$ elements. Alternatively, we can divide the image into smaller patches, treat each patch as a different message, and process them in parallel. For another example, consider a network anomaly detection algorithm where we are given a batch of IP addresses, and we would like to check whether each belongs to a predefined blacklist. In Section VII below, we will refer to Eq. (11) as parallel decoding and Eq. (10) as serial decoding.

3) Reduction: Reduction refers to an operation that aggregates a vector of elements into a scalar (e.g., sum, max and min). In SUM-OF-SUM, the max operation is needed when evaluating Eq. (4) to determine which neurons remain active in the next iteration. In both rules, when deciding whether or not the retrieval procedure has converged, we need to compare two long vectors $v^t$ and $v^{t+1}$ of length $n$, and test if all of the neuron values stay unchanged. This reduction operation can be done in an efficient manner as illustrated in Fig. 6, where we invoke $n$ threads in the first step, afterwards halving the number of threads in every successive operation. The time complexity thus decreases from $O(n)$ to $O(\log_2 n)$.

4) Sparsification: Memory access is an expensive operation on the video card, where both reading from and writing to memory cells are much slower than on the host CPU. In order to combat this inefficiency, we can reduce the number of memory accesses by accounting for the fact that GBNN is actually a sparse network; i.e., for a given message, ideally only one neuron should be activated for each cluster. Typically, the network structure should also be sparse, so we could implement both $W$ and $V^t$ as sparse matrices using compressed format, where we only record the nonzero elements and their coordinates. Then evaluating Eq. (3) and Eq. (6) requires many fewer terms. However, the compressed format does not lead to a significant performance gain for both rules — SUM-OF-MAX benefits from the sparsification, while SUM-OF-SUM does not. The reason is that the dense matrix product in Eq. (11) for SUM-OF-SUM is an optimized operation on the GPU, whereas
the compressed format deviates from the optimized pattern. Moreover, since $V^t$ changes from one iteration to the next, it is not economical to implement $V^t$ using compressed format either. On the contrary, $W$ is fixed at the retrieval stage. We use a sparse matrix representation $W$ only for SUM-OF-MAX. Detailed numerical results are presented in Section VII.

C. Accelerating the SUM-OF-SUM Rule

The pseudocode for the SUM-OF-SUM procedure is given in Algorithm 7. It requires as inputs the maximum number of iterations permitted $t_{max}$, the weight matrix $W$ with all of the clique structures preserved during the storing stage, and the message matrix $V^0$, with the $k^{th}$ column being the value vector for test message $k$ and the erased clusters deactivated. On Line 4, $S^t$ is the score matrix for iteration $t$, where the $k^{th}$ column is the score vector of length $n$ for test message $k$. On Line 5, the kernel function takes $S^t$ as input and essentially produces $V^{t+1}$ by evaluating Eq. (4).

Algorithm 1 The SUM-OF-SUM retrieval procedure.

Input: the maximum number of iterations permitted $t_{max}$
the weight matrix $W$, the message matrix $V^0$ with each column as a partially erased message for recovery

Output: the recovered matrix $V^t$

1: $t = -1$
2: repeat
3: $t = t+1$
4: $S^t = WV^t$
5: $V^{t+1} =$ the kernel function as in Fig. 7
6: until $V^{t+1} == V^t$ or $t == t_{max}$

The first two columns of $S^t$ are drawn in Fig. 7. In this particular example, each message can be divided into $C = 3$ clusters. In our implementation, a dedicated thread processes one cluster, finding the maximum value in that cluster, and then keeping the neurons that reach the maximum value activated. Assuming that there are $K$ messages to be recovered, a total of $CK$ threads are used. The retrieval procedure terminates when either the network converges or it reaches the maximum number of iterations permitted.

D. Accelerating the SUM-OF-MAX Rule

The pseudocode for SUM-OF-MAX is almost the same with Algorithm 1 except that Lines 4 and 5 are replaced by another kernel function illustrated in Fig. 8. In order to better explain the concept, the serial decoding of a single message $v^t$ is presented here, where the same number of threads are needed as the number of neurons $n$ in the network. The extension to the parallel decoding scheme of $K$ bundled messages is straightforward, where $nK$ threads are needed.

We do not follow strictly Eq. (6) and Eq. (7) to evaluate a max function. Instead, we apply an alternative procedure. Essentially, we check if a neuron receives signals from every cluster; hence, for neuron(i), the $i^{th}$ row of $W$ and $v^t$ require examination. Since $W$ is symmetric and the memory storage on the GPU is column major, we check the $i^{th}$ column of $W$ instead to make the computation more pleasant. To update a neuron value $v_{i}^{t+1}$, a dedicated thread $i$ is required, scanning through both $v^t$ and the $i^{th}$ column of $W$.

Thread $i$ loops through cluster $c$, from 1 to $C$.
- For any positive $\gamma$, if neuron(i) belongs to cluster $c = \lfloor \frac{i-1}{L} \rfloor + 1$, we directly set $s_i^{t} = s_i^{t} + 1$. ($\lfloor \cdot \rfloor$ is the standard floor operator.)
- Otherwise, we check within the same cluster, i.e., $w_{ji}$ and $v_j^t$, where $j$ goes from $(c-1)L + 1$ to cL. The first time we encounter $w_{ji} > 0$ and $v_j^t > 0$, we set $s_i^{t} = s_i^{t} + 1$, and proceed to the next cluster $c+1$ without further investigation.
- If cluster $c$ does not contribute any signal to neuron(i), i.e., $s_i^{t}$ does not change, we stop right away without checking following clusters.

We call this procedure BAIL-OUT-EARLY and favor it over Eq. (6) and Eq. (7) for two reasons:
1) It explicitly clarifies the requirement that every cluster should contribute one and only one signal.
2) It proceeds to subsequent clusters or stops processing as quickly as possible so that further expensive memory accesses are avoided.

Theorem 1. The BAIL-OUT-EARLY approach is equivalent to SUM-OF-MAX, i.e., for any positive $\gamma$, given $W$ and $v^t$, BAIL-OUT-EARLY produces the same $v^{t+1}$ as SUM-OF-MAX.

Proof: For cluster $c = \lfloor \frac{i-1}{L} \rfloor + 1$, there is only one
nonnegative $w_{ii} = \gamma > 0$, since by design, within the same cluster, a neuron can only receive contributions from itself. BAIL-OUT-EARLY directly sets $s^1_t = s^1_t + 1$, which effectively makes any positive $\gamma$ equivalent to $\gamma = 1$.

For other clusters, $w_{ij}$ is either 0 or 1, depending on whether or not a connection exists between neuron $j$ and neuron $i$. Notice in either case, $v^i_t$ is always a binary vector.

Consider $\{a_j = v^j_i w_{ji}\}$, for $j = 1, 2, \cdots, L$. The BAIL-OUT-EARLY approach treats Eq. (6) recursively by implementing the following equation,

$$\max(a_1, a_2, \cdots, a_L) = \begin{cases} a_1 & \text{if } a_1 > 0 \\ \max(a_2, \cdots, a_L) & \text{otherwise} \end{cases}$$

and treats Eq. (7) by setting $\gamma = 1$.

For a neuron to be activated, it needs to receive $C - 1$ signals from the other clusters, plus some self contribution $\gamma$ from itself. Since any $\gamma > 0$ does not affect the dynamic due to Eq. (6) and Eq. (7), we deliberately set $\gamma = 1$. The weight matrix $W$ thus becomes binary valued, which can be more efficiently implemented.

V. Properties

In this section, we discuss properties of GBNNs and the two retrieval rules introduced in previous sections. We illustrate these properties via examples and theoretical claims.

A. The SUM-OF-SUM Rule May Oscillate

We first give an example which illustrates that SUM-OF-SUM may oscillate. Consider a small network with $C = 3$ clusters, each cluster has $L = 3$ neurons, i.e., 9 neurons in total. We set $\gamma = 1$. There are 4 messages to store: $(1, 1, 1), (2, 2, 1), (3, 2, 1)$ and $(1, 3, 1)$. The test message is $(?, ?, 1)$. Clearly all of the stored messages match the non-erased part of the test message. In such a scenario, we expect that the retrieval rule either returns an arbitrary stored message which matches the input, or returns all of the stored messages matching the input. Unfortunately, SUM-OF-SUM does not converge to any output. After constructing the network and initializing the neurons to be deactivated for the 1st and 2nd clusters of the test message, we have

$$W = \begin{pmatrix} 1 & 0 & 0 & 1 & 0 & 1 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}$$

and $v^0 = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 1 \\ 0 \\ 0 \end{pmatrix}$

It is easy to verify that

$$s^0 = (1, 1, 1, 1, 1, 1, 1, 0, 0)^T, \quad v^1 = (1, 1, 1, 1, 1, 1, 1, 0, 0)^T$$

$$s^1 = (4, 3, 3, 3, 3, 7, 0, 0, 0)^T, \quad v^2 = (1, 0, 0, 0, 1, 0, 1, 0, 0)^T$$

$$s^2 = (2, 2, 2, 2, 2, 2, 0, 0, 0)^T, \quad v^3 = (1, 1, 1, 1, 1, 1, 1, 0, 0)^T$$

The underlined values indicate the maximum value within the same cluster. Note that every cluster activates its own neurons with the most signals respectively. Therefore, three neurons are activated in $v^2$. In this case, $v^3 = v^1$, so that the network does not converge, oscillating between $v^2$ and $v^3$ forever.

There is another level of complication: the reinforcement factor $\gamma$ plays a delicate role in the retrieval procedure. If we increase $\gamma = 2$, then the network converges. However, we will see in Section VII below that enlarging $\gamma$ leads to a worse retrieval rate in general.

B. The SUM-OF-MAX Rule Converges

We now show that SUM-OF-MAX (BAIL-OUT-EARLY) always converges when all the neurons in erased clusters are initialized to be activated.

**Lemma 1.** For SUM-OF-MAX, once deactivated, a neuron stays deactivated forever, i.e., if $v^i_t = 0$ then $v^i_{t+1} = 0$.

**Proof:** Recall, from Eq. (7), that $v^i_{t+1} = 1$ if and only if $s^i_t = \gamma + C - 1$. Assume in iteration $t$ that neuron $i$ is deactivated, i.e., $v^i_t = 0$. Then $v^i_j w_{ij} = 0$. Since the only possible contribution a neuron might obtain from its own cluster is the self loop, $s^i_t = \sum_{c=1}^{C} \max_j (v^i_j w_{ji}) < \gamma + C - 1$, thus $v^i_{t+1} = 0$.

**Lemma 2.** A clique is stable, i.e., once all neurons of a clique are activated, they stay activated forever.

**Proof:** By definition of a complete sub-graph, all neurons in an activated clique (see Fig. 3) will receive exactly $C - 1$ signals from other clusters and some positive feedback $\gamma$. Therefore by Eq. (7), all neurons in the clique stay activated in the next iteration.

**Lemma 3.** Given a partially erased message, SUM-OF-MAX always converges to a state which contains an ensemble of cliques.

**Proof:** As each previously stored message corresponds to a clique, a partially erased message corresponds to parts of the clique, with the neurons in the non-erased clusters activated. SUM-OF-MAX initializes all the neurons in the missing clusters to be activated. Therefore, the already activated neurons in non-erased clusters will receive contributions from the missing clusters, staying activated in the next iteration. The neurons in the missing clusters which, together with the already activated neurons in non-erased clusters, form a clique will also receive exactly $\gamma + C - 1$ signals and will stay activated in the next iteration. Hence by Lemma 2 the ensemble of these cliques will be present in the converged state.

**Theorem 2.** Given a partially erased message, if a neuron is the only one activated in its cluster, it remains activated, i.e., for a given cluster $c$, if there exists an $i \in \{(c-1)L + 1, \cdots, cL\}$ such that $v^i_t = 1$ and $v^j_t = 0$ for all $j \in \{(c-1)L + 1, \cdots, cL\}$, $j \neq i$, then $v^i_{t+1} = 1$.

**Proof:** Suppose, to arrive at a contradiction, that at some point, cluster $c$ has no neuron activated, i.e., $\forall i = (c-1)L + 1, \cdots, cL, v^i_t = 0$, the other clusters will not receive any
signal from cluster \( c \). By Eq. (7), every neuron throughout the network will be deactivated in the next iteration. By Lemma 1, the network converges to this all-deactivated state forever, which violates Lemma 3. Therefore, if a neuron is the only one activated in its cluster, it remains activated.

**Theorem 3.** For any given probe pattern, \( \text{SUM-OF-MAX} \) always converges.

**Proof:** For a partially erased message, this theorem has already been proved by Lemma 5.

We consider an input probe such that some parts of a previously stored message are modified (corrupted). If the probe can still be explained by a clique in the network, the memory converges to this clique by Lemma 2. If the probe cannot be explained by any clique in the network, the activated neurons in the unchanged clusters cannot receive signals from the corrupted clusters. Hence by Eq. (7), the memory converges to the all-deactivated state.

Since \( \text{BAIL-OUT-EARLY} \) is equivalent to \( \text{SUM-OF-MAX} \) (see Theorem 1), we also have the following.

**Corollary 1.** For any given probe pattern, \( \text{BAIL-OUT-EARLY} \) always converges.

It is worth emphasizing that \( \text{SUM-OF-MAX} \) converges to a state which contains an ensemble of cliques by Lemma 3. We can randomly choose one of them as the reconstructed message.

### VI. Joint Retrieval Rule

#### A. Proposal

We have just seen that \( \text{SUM-OF-SUM} \) is not guaranteed to converge, whereas \( \text{SUM-OF-MAX} \) is. In Section VII below we will see that \( \text{SUM-OF-SUM} \) is generally much faster than \( \text{SUM-OF-MAX} \), but the accuracy of \( \text{SUM-OF-MAX} \) is much better when either the number of stored messages or the number of erased symbols increases. It is natural to ask whether we can merge the two rules to obtain a fast and accurate reconstruction scheme.

In this section we propose such a hybrid retrieval scheme which combines the best aspects from both procedures. The pseudocode for the joint decoding scheme is given in Algorithm 2. Essentially this decoding algorithm performs one refined iteration of \( \text{SUM-OF-SUM} \) followed by subsequent, optimized iterations of \( \text{BAIL-OUT-EARLY} \) until a convergence criterion is satisfied.

#### B. Justification and Convergence

As mentioned in Section V memory access is extremely expensive on GPUs in comparison to on the host CPU. Therefore, it is of vital importance that we eliminate any unnecessary memory operations. We notice that Lemma 1 and Theorem 2 have crucial implications in designing our new scheme. The former suggests that if \( v^t_i = 0 \) then there is no need to loop through two long vectors of length \( n \), i.e., \( v^t \) and the \( i \)th column of \( W \), since we will have \( v^{t+1}_i = 0 \). Thus, we only need to focus on updating those neuron(i) for which \( v^t_i = 1 \). In this sense, the currently active neurons can be considered as a candidate pool that needs to be investigated further in the next iteration. The latter suggests that clusters with only one active neuron (including those which are not erased in the test message) will not change during decoding. Hence, we only update neurons in erased clusters that have not yet reached convergence. In general, this notion of “freezing good clusters” can also be justified as preventing good neurons from being altered undesirably by any retrieval procedure.

One final but important consideration is the all-activated initialization scheme. Although it is crucial for the correctness of the \( \text{SUM-OF-MAX} \) rule, it also introduces too many candidates from the beginning. We will show a motivating example later in Section VII-E. Fortunately, \( \text{SUM-OF-SUM} \) can help us bypass this particular problem.

**Theorem 4.** The first iteration of \( \text{SUM-OF-SUM} \) affects neither the correctness of \( \text{SUM-OF-MAX} \) nor its convergence.

**Proof:** For correctness, let us revisit \( \text{SUM-OF-SUM} \). The only problem making \( \text{SUM-OF-SUM} \) inferior to \( \text{SUM-OF-MAX} \) is that during the retrieval procedure, as in Eq. 8 it is possible for multiple neurons to be activated simultaneously in one cluster without regulation, which in turn propagates the error or even causes oscillation. However, during the initialization phase, if we deactivate all the neurons in erased clusters, preserving good clusters only, by definition there will be at most one activated neuron per cluster. The aforementioned flaw does not exist anymore.

For convergence, recall a clique structure in Fig. 3. For a given message with \( e \) clusters erased, there are \( C - e \) good
neurons transmitting signals. Therefore, the desired neuron in the erased clusters should receive \( C - e \) signals exactly. After one iteration of SUM-OF-SUM, we only keep these neurons with \( C - e \) signals in the candidate pool. The sole effect of the first iteration SUM-OF-SUM is to shrink the pool size, with the convergence untouched.

Ideally, there should be only one such neuron per erased cluster in the candidate pool, rather than \( L \) candidates for SUM-OF-MAX, with two exceptional cases.

- There are two memorized messages \( m_1 \) and \( m_2 \) which only differ in erased clusters, e.g., we have \( m_1 = (1, 3, 1) \) and \( m_2 = (1, 3, 2) \), and the test message is \( m = (1, 3, ?) \). In this case, both neuron 1 and 2 in the erased cluster will be present in the pool.
- Spurious cliques. While storing messages, distinct cliques may overlap and produce a spurious clique that does not correspond to a stored message, where different edges in this clique were added for different stored messages. In other words, a stored message corresponds to a clique, but not vice versa.

We argue that for a relatively large network and a reasonable number of messages to memorize, the candidate pool size is sufficiently small.

**Corollary 2.** The new joint retrieval scheme always converges.

*Proof:* The joint scheme invokes one iteration of SUM-OF-SUM followed by iterations of BAIL-OUT-EARLY. According to Theorem 4, SUM-OF-SUM effectively reduces the size of the candidate pool, with the network’s convergence property untouched. The joint scheme thus always converges by Theorem 3.

Combining all these factors, we propose the joint scheme as in Algorithm 2.

### VII. Experiments

In this section, we compare SUM-OF-SUM and SUM-OF-MAX using the different acceleration approaches discussed previously in Section V and Section VI. We show that a significant performance gain is achieved in terms of running time after parallelizing the retrieval procedure and applying our new joint retrieval scheme.

All the CPU experiments are executed on a 2.6GHz AMD Phenom (tm) 9950 Quad-Core Processor with 16GB of RAM, and all the GPU experiments are executed on an NVIDIA C1060 card, which runs at a frequency of 1.3GHz with 4GB memory and has 30 stream multiprocessors. In order to make as fair a comparison as possible, our CPU code makes use of the Armadillo library [37], linked to BLAS and LAPACK, for optimized linear algebra operations.

#### A. SUM-OF-SUM versus SUM-OF-MAX

First, we compare SUM-OF-SUM and SUM-OF-MAX. In this experiment, we have \( C = 8 \) clusters with \( L = 128 \) neurons each, and the reinforcement factor \( \gamma = 2 \). We randomly generate and store 5000 messages, each of which consists of 8 symbols uniformly sampled from the integers 1 to 128. After the storing stage, we randomly select 3000 out of the 5000 stored messages, erase some parts of them and try to retrieve the erased messages from the GBNN associative memory. We refer to this experiment setting as Scenario 1. Since SUM-OF-SUM does not necessarily converge, we set the maximum number of iterations to 20. We vary the number of erased clusters, and plot the retrieval rate, i.e., the fraction of successfully retrieved messages, in Fig. 9.

Observe that when the number of erased clusters is relatively small (3 erased clusters), both rules perform equally well above 97%. As the number of erased clusters increases, although both rules make more errors, the performance of SUM-OF-SUM degrades more drastically than that of SUM-OF-MAX. When 5 out of 8 clusters are erased, SUM-OF-SUM can only recover slightly above 50% of the messages, while SUM-OF-MAX still recovers over 90%. If 6 clusters are erased, SUM-OF-MAX is still able to retrieve over 20%, which is significantly higher than SUM-OF-SUM.

#### B. Influence of \( \gamma \)

Second, we explore the subtle dependence of the retrieval rate on the value of the reinforcement factor \( \gamma \) used in SUM-OF-SUM. We plot the trend for different \( \gamma \) in Fig. 10 using the same experiment Scenario 1 as above. In general, increasing \( \gamma \) hurts the retrieval rate with the only exception of \( \gamma = 0 \), which suggests that \( \gamma = 1 \) can be used as a default value.

#### C. CPU versus GPU

Next, we consider the improvements in runtime achieved by running both rules on a GPU versus on a CPU. A larger network is simulated in this case. We have \( C = 16 \) clusters with \( L = 512 \) neurons each, out of which 7 clusters are erased. We generate and store 50000 random messages, and we use a random subset of 30000 of these to test. We refer to this experiment setting as Scenario 2. The runtime, in seconds, of both parallel decoding (i.e., decoding a batch of messages...
Fig. 10. Subtle dependence between the retrieval rate and the reinforcement factor $\gamma$. We have $C = 8$, $L = 128$, 5000 stored messages and 3000 test messages. We vary the number of erased clusters, and plot the retrieval rate.

Fig. 11. Running time in seconds of both rules running on CPU and GPU respectively. We have $C = 16$, $L = 512$, 50000 stored messages and 30000 test messages.

concurrently) and serial decoding (i.e., decoding message one after another) on both GPU and CPU are shown in Fig. 11.

We make three observations: First, for each CPU versus GPU and parallel versus serial decoding configuration, SUM-OF-MAX is always significantly slower than SUM-OF-SUM. For now, let us keep in mind that the fastest retrieval configuration of this entire experiment is roughly 40 seconds for SUM-OF-SUM parallel decoding on a GPU. We have previously seen that SUM-OF-MAX leads to a much better retrieval accuracy, and so below we focus on achieving the accuracy of the SUM-OF-MAX method while improving its runtime.

Second, in each group, the bars at the 1st and 3rd locations are results for the CPU implementation, and the 2nd and 4th bars show results for the GPU implementation. Comparing each adjacent pair, we see that the GPU versions consistently run much faster than CPU, as expected. The GPU accelerations without any further optimization are respectively (from left-to-right) 29×, 3×, 240× and 28× faster.

Finally, parallel decoding is faster than serial decoding on GPU, while the situation reverses on CPU. This is reasonable, since parallel decoding can take full advantage of the GPU’s computing power. However, in the CPU case, if we consider a bundle of $K$ messages, even if only one message does not converge, all $K$ messages will be updated. On the other hand, with serial decoding, the retrieval rule will stop as soon as each individual message converges.

D. Further Accelerating the SUM-OF-MAX Rule

In Fig. 12 we show the effect of applying the different techniques discussed in Sections V and V to accelerate the SUM-OF-MAX rule on a GPU. Although all of the techniques combined reduce the runtime eightfold, from roughly 4000 seconds to 500 seconds, the SUM-OF-MAX rule still cannot compete with SUM-OF-SUM’s 40-second spec, which is highlighted in yellow and bold font in the figure. However, the proposed joint scheme cuts the record by another two thirds, achieving the fastest runtime of only 14.86 seconds for Scenario 2.

In Fig. 11 the faster configuration for SUM-OF-MAX on CPU is the serial decoding scheme, to which we compare, our joint scheme achieves a 880× speedup while retaining the decoding accuracy.

E. Motivation for Combining Rules

Here we provide an example to better illustrate why the joint scheme achieves a significant speedup. We again use Scenario 2 and apply all of the acceleration techniques discussed in Section V. We initialize the matrix $V^0$ according to the vanilla SUM-OF-MAX, so that all neurons in clusters corresponding to erased symbols are activated, and only one neuron within each cluster corresponding to a non-erased symbol is active. Fig. 13 depicts a typical run of the experiment.
Fig. [13a] shows the total runtime spent in each iteration of the SUM-OF-MAX decoding. One observation is that every subsequent iteration requires less time than its previous one due to the application of Lemma 1 and Theorem 2, otherwise, the runtime of each iteration should be roughly the same. Another observation is that the majority of the total runtime is spent in the 1st iteration; this occurs because initially there are too many unnecessary active neurons in erased clusters, and SUM-OF-MAX demands time to process each one of them. Fig. [13b] shows the number of test messages (out of 30000) which have converged after each iteration.

**F. New Joint Scheme**

Finally, we demonstrate the behavior of the joint decoding scheme across a range of experimental settings. Fig. [14] shows the runtime (in seconds) and retrieval rate compared with SUM-OF-SUM and SUM-OF-MAX for both of Scenarios 1 and 2, while varying the number of erased symbols. The spikes in runtime for SUM-OF-MAX and for the joint scheme in Fig. [14a] are due to the fact that decoding becomes more difficult as the number of erased clusters increases, consequently more iterations are required in these cases. In these settings (6 out of 8 clusters erased for Scenario 1, and 14 out of 16 clusters erased for Scenario 2), although the SUM-OF-SUM rule is only a bit faster than SUM-OF-MAX and the joint scheme, the retrieval rate is significantly lower. Another reason that SUM-OF-SUM runs faster here is due to the limit on the number of iterations which we impose in our experiments. Note that increasing this limit does not improve the retrieval rate, but it can make the runtime arbitrarily worse because SUM-OF-SUM oscillates. Also observe that in both Fig. [14b] and Fig. [14c] the retrieval rates of SUM-OF-MAX and the joint scheme are identical. In Fig. [14d], all three approaches achieve effectively a 100% retrieval rate for up to 13 erased clusters. This is because the number of messages stored (50000) is relatively small for this network. If this number increases, the deviation in retrieval rate between the joint scheme (as well as SUM-OF-MAX) and SUM-OF-SUM will be more pronounced. We conclude from Fig. [14] that the joint retrieval scheme combines the benefits of both existing rules, achieving fast decoding while also maintaining a high retrieval rate.

**G. Correlated vs. Uncorrelated Messages**

The experiments above involve storing and retrieving random messages which are generated uniformly and independently. If messages are correlated and the GBNN architecture is unchanged, we expect the performance to degrade in comparison to the results reported above. Modifying GBNNs to accommodate correlated messages is an area of ongoing investigation. As mentioned in Section II, one approach is to use a “grandmother layer”, similar to [34]. Another approach is to append each message with i.i.d. uniform random bits. This requires additional neurons, but reduces the correlation.

**VIII. SUMMARY**

In this work, we present optimized implementations of the Gripon-Berrou neural network associative memory on a GPU. We analyze two existing retrieval rules, namely SUM-OF-SUM and SUM-OF-MAX. We show that SUM-OF-MAX lead to network oscillation. However, we manage to prove the convergence of SUM-OF-MAX. In order to achieve the full speedup, we combine the two rules and propose a hybrid scheme, minimizing the unnecessary computation burdens. The experimental results show an exciting acceleration against a CPU implementation using an optimized linear algebra library.

GBNNs embrace a LDPC-like sparse encoding setup, which makes the network extremely resilient to noises and errors. As associative memories serve as building blocks for many machine learning algorithms, we hope the parallel scheme proposed here can be helpful in paving the path to more widespread adoptions of large scale associative memory applications.

An obvious future work is to extend GBNNs to deal with correlated messages, which will severely impair the retrieval performance. However, the nice structure of GBNNs seems promising in this direction. In the future, we will try to develop other retrieval schemes, e.g., to handle corrupted patterns as well as incomplete probes. Since SUM-OF-SUM runs orders of magnitude faster, another sensible topic is to emulate SUM-OF-MAX using SUM-OF-SUM so that both performance and speed can be retained simultaneously. We may also seek the way to generalize GBNN and extend the sparse neural network’s use in tasks other than associative memory, e.g., classification and regression.
