An iron corrosion-assisted $\text{H}_2$-supplying system: a culture method for methanogens and acetogens under low $\text{H}_2$ pressures

Souichiro Kato\textsuperscript{1,2,\*}, Motoko Takashino\textsuperscript{1}, Kensuke Igarashi\textsuperscript{1}, Hanako Mochimaru\textsuperscript{3}, Daisuke Mayumi\textsuperscript{3} & Hideyuki Tamaki\textsuperscript{4}

H$_2$ is an important fermentation intermediate in anaerobic environments. Although H$_2$ occurs at very low partial pressures in the environments, the culture and isolation of $\text{H}_2$-utilizing microorganisms is usually carried out under very high H$_2$ pressures, which might have hampered the discovery and understanding of microorganisms adapting to low H$_2$ environments. Here we constructed a culture system designated the “iron corrosion-assisted $\text{H}_2$-supplying (iCH) system” by connecting the gas phases of two vials (one for the iron corrosion reaction and the other for culturing microorganisms) to achieve cultures of microorganisms under low H$_2$ pressures. We conducted enrichment cultures for methanogens and acetogens using rice paddy field soil as the microbial source. In the enrichment culture of methanogens under canonical high H$_2$ pressures, only \textit{Methanobacterium} spp. were enriched. By contrast, \textit{Methanocella} spp. and \textit{Methanoculleus} spp., methanogens adapting to low H$_2$ pressures, were specifically enriched in the iCH cultures. We also observed selective enrichment of acetogen species by the iCH system (\textit{Acetobacterium} spp. and \textit{Sporomusa} spp.), whereas \textit{Clostridium} spp. predominated in the high H$_2$ cultures. These results demonstrate that the iCH system facilitates culture of anaerobic microorganisms under low H$_2$ pressures, which will enable the selective culture of microorganisms adapting to low H$_2$ environments.

Molecular hydrogen (H$_2$) is an important intermediary metabolite and an energy carrier in anaerobic environments\textsuperscript{4-6}. Because H$_2$ is rapidly turned over in natural anaerobic environments, it occurs at very low partial pressures of only a few to several tens of pascals (Pa)\textsuperscript{4}. In conventional studies, however, culture and isolation of H$_2$-utilizing microorganisms have commonly been performed under high H$_2$ partial pressures (100 kPa or more). Under such laboratory conditions, it is difficult to draw conclusions about the ecophysiology of H$_2$-utilizing microorganisms in their natural environment, nor can microorganisms that have adapted to conditions with low H$_2$ be isolated. In fact, the presence of uncultured H$_2$-utilizing methanogens and acetogens in anaerobic environments where H$_2$ concentrations are estimated to be quite low (i.e., environments with low available organic matter, including subsurface environments, peat soils, and deep-sea sediments) has been inferred by molecular environmental analyses such as metagenomics\textsuperscript{5-7}.

Because H$_2$ supplied at low partial pressure is rapidly consumed, sufficient microbial growth cannot be obtained in conventional batch culture systems. To date, several research groups have developed methods that can continuously supply H$_2$ at low partial pressure to elucidate ecophysiology of hydrogenotrophic methanogens in low H$_2$ environments. Morgan et al.\textsuperscript{8} reported a low-H$_2$ culture of a hydrogenotrophic methanogen by using a continuous culture system with a continuous influx of a mixed gas containing H$_2$. By using this system, the authors found that the expression of some metabolic enzymes in the methanogenic pathway is regulated by
H₂ concentration. Similar methods have frequently been utilized in subsequent studies on low H₂ responses of hydrogenotrophic methanogens⁹,¹⁰. Sakai et al.¹¹ developed the "coculture method", in which methanogens are cocultured with heterotrophic H₂-producing bacteria to achieve a continuous supply of H₂ at low concentration. The coculture method enabled selective enrichment of uncultured hydrogenotrophic methanogens that were expected to adapt to low H₂ pressures, which finally resulted in the isolation of phylogenetically novel methanogens such as *Methanocella* spp. and *Methanothermlinea* spp.¹²,¹³. The coculture method has also been employed to analyze physiological responses of methanogens to low H₂ pressures¹⁴,¹⁵. Although these methods yielded laboratory cultures under low H₂ pressures, several issues still need to be addressed. The continuous gas influx process cannot be carried out in parallel with a large number of cultures because it requires relatively complex systems, including large- or small-scale reactors and gas supply devices. Although the coculture method only requires simple systems, which makes it suitable for enrichment cultures, it cannot be directly utilized for isolation of H₂-utilizing microorganisms because it relies on coexistence with fermentative bacteria. Furthermore, it cannot be excluded that metabolites other than H₂ (e.g., organic acids such as acetate) affect the growth of H₂-utilizing microorganisms.

In this study, we aimed to develop a simple method capable of selective culture of microorganisms under low H₂ pressures. The reaction on which we focused was the corrosion of metallic iron in anoxic solution: Fe⁰ + 2H⁺ ↔ Fe²⁺ + H₂. The concept of culturing microorganisms using H₂ derived from iron corrosion has already been reported¹⁶,¹⁷. The authors demonstrated that hydrogenotrophic methanogens can be cultured using H₂ derived from metallic iron as sole energy source. However, this method has not been applied to culture microorganisms adapted to low H₂ environments. Considering that iron corrosion proceeds very slowly in anoxic and circumneutral solution because of the small difference in the standard redox potentials of Fe⁰ oxidation (E₀ʹ ≈ −0.47 V) and the reduction of protons to generate H₂ (E₀ʹ ≈ −0.41 V), we can expect that H₂ supply via iron corrosion is suitable to culture hydrogenotrophic microorganisms under low H₂ pressures. Here we report that a culture system based on iron corrosion reactions has been successfully used for the selective enrichment of hydrogenotrophic methanogens and acetogens, which have the potential to adapt to environments with very low H₂ content.

**Results and discussion**

**Validation of continuous H₂ supply by iron corrosion.** Because the growth of microorganisms is considered to be very slow under low H₂ pressures, the culture system requires a continuous supply of H₂ over a long period of time. Hence, we first determined whether H₂ can be continuously supplied for a long time by the iron corrosion reaction. Furthermore, to develop a culture system capable of regulating the H₂ supply rate, we added various amounts of Fe⁰ with different particle sizes (Fe⁰ granules with a diameter of 1–2 mm or Fe⁰ powder with a diameter < 45 µm) to the anoxic buffer solution and determined the H₂ production rates (Fig. 1).

We observed continuous H₂ production for more than 6 months in the vials supplemented with Fe⁰ granules (Fig. 1A). The H₂ production rates were almost proportional to the amount of Fe⁰ granules added (0.03 to 3 g vial⁻¹) and were in the range of 0.12 to 4.4 µmol vial⁻¹ day⁻¹ (Fig. 1C). With Fe⁰ powder, H₂ production ceased after approximately 2 weeks, 1 month, and 3 months in the vials supplemented with Fe⁰ at 3, 1, and 0.3 g vial⁻¹, respectively (Fig. 1B). The highest H₂ accumulation was approximately 1000 µmol vial⁻¹, corresponding to approximately 50 kPa. We assume that H₂ production ceased for thermodynamic reasons (increase in H₂ partial pressure and decrease in proton concentration). The H₂ production rates were also proportional to the amount of Fe⁰ powder added, with a range of 2.0 to 93 µmol vial⁻¹ day⁻¹ (Fig. 1C). Since the specific surface area of the spherical material is inversely proportional to the diameter, the Fe⁰ powder (< 45 µm) has a surface 20 times larger than the Fe⁰ granule (1–2 mm), if used particles are assumed to be spherical. The H₂ production from Fe⁰ powder was 16–22 times greater than from Fe⁰ granule (Fig. 1C), suggesting that surface area is the major determinant of H₂ production rate. These results demonstrate that it is possible to supply H₂ over a long period of time by utilizing the iron corrosion reaction, and also that it is possible to regulate the rate of H₂ supply by altering the size and amount (i.e., total surface area) of Fe⁰ particles.
Development of a culture system with low H₂ pressures. It has been reported that H₂-utilizing anaerobic microorganisms grow on H₂ derived from iron corrosion. If microorganisms are cultured in the coexistence with Fe₀, however, some undesirable phenomena can occur. For example, the iron corrosion reaction produces a high concentration of ferrous iron and induces an increase in pH due to the consumption of protons. Furthermore, it can promote growth of anaerobic microorganisms that use Fe₀ itself as the energy source. These phenomena likely hamper the culture of target microorganisms. We therefore constructed a culture system in which the gas phases in two vials (one for the culture of microorganisms and the other for the iron corrosion reaction) are connected by a stainless-steel tube (Fig. 2), in reference to the system developed by Daniels et al. This system, hereafter referred to as the “iron corrosion-assisted H₂-supplying (iCH) system,” was expected to allow the culture of microorganisms under low H₂ pressures while avoiding the unfavorable effects of the iron corrosion reaction.

Pure culture of a hydrogenotrophic methanogen in the iCH system. We evaluated the capability of the iCH system to culture microorganisms under low H₂ pressures using a hydrogenotrophic methanogen Methanobacterium formicicum, which is known to be able to grow under both high and low H₂ partial pressures, as a model strain. We inoculated the iCH system with M. formicicum using Fe₀ powder at 1 g vial⁻¹ as the H₂ source, and monitored the amounts of CH₄ and H₂ in the gas phase (Fig. 3). We observed continuous CH₄ production by M. formicicum in the iCH system for almost 1 month. Although there was accumulation of H₂ at the beginning of the culture (around 190 Pa at day 3, corresponding to 7.4 µmol vial⁻¹), the partial pressure of H₂ subsequently decreased and remained extremely low (30 to 50 Pa after day 14). The observed H₂ partial pressures are comparable to those observed in natural anaerobic environments and laboratory cocultures of methanogens with fermentative bacteria. These results demonstrated that the iCH system is capable of long-term culture of H₂-utilizing microorganisms under low H₂ pressures.

Enrichment cultures of hydrogenotrophic methanogens using the iCH system. We performed enrichment cultures of methanogens to demonstrate the capability of the iCH system to selectively culture
Microorganisms adapted to low H₂ pressures. We used rice paddy field soil as the microbial source, because it is known as a low H₂ environment and was the isolation source of Methanocella spp. that is known to adapt to low H₂ environments. In addition to the iCH system (with Fe₀ powder at 1 g vial⁻¹ as the H₂ source), we set up conventional cultures under high H₂ pressures (160 kPa of H₂ in the gas phase, hereafter referred to as “high H₂ enrichments”) and cultures under iron corrosion conditions (microorganisms cultured in the same vial with 1 g vial⁻¹ of Fe₀ powder, hereafter referred to as “Fe₀ enrichments”) as control experiments.

Hydrogenotrophic methanogens were enriched in inorganic medium supplemented with rifampicin to suppress growth of bacteria. After three successive subcultures, the metabolic products (CH₄ and H₂) were analyzed during incubation (Fig. 4A–C). In the high H₂ enrichments, we observed CH₄ production almost equal to the theoretical value calculated from the consumption of H₂ (Fig. 4A). In the Fe₀ enrichments, we observed CH₄ production comparable to the theoretical value (broken line in Fig. 4B) calculated from the H₂ production via iron corrosion in the early phase of the incubation (day 0–14). However, CH₄ production levelled off in the later phase (after day 14). The pH of the culture solution increased from 7.0 to around 8.1 during the incubation, whereas the pH of the culture solution remained around 7.0 in the other enrichments. The increase in pH, and possibly the increase in concentration of ferrous iron, might have inhibited the growth of methanogens in the Fe₀ enrichments. In the iCH enrichments, CH₄ was produced almost proportional to the theoretical value (broken line in Fig. 4C) without levelling off. We observed accumulation of H₂ at the beginning of culture (around day 10), which then decreased below the detection limit (< 10 Pa). These results indicate that enrichment cultures of methanogens under low H₂ pressures were achieved in the iCH system.

Microbial community analysis of the methanogenic enrichment cultures. To confirm the capability of the iCH system to specifically enrich microorganisms adapting to low H₂ pressures, we assessed the microbial community structures of the enrichment cultures and the inoculum soil by high throughput sequencing analysis of 16S rRNA gene amplicons. A total of 56,388 16S rRNA gene reads (3744–5531 reads per sample) were retrieved and classified into 2949 operational taxonomic units (OTUs) using a 97% sequence identity cut-off.

Figure 4. Production and consumption of H₂, CH₄ and acetate in enrichment cultures. (A–C) Enrichment cultures for methanogens (supplemented with rifampicin). (D–F) Enrichment cultures for acetogens (supplemented with 2-bromoethanesulphonate [BES]). (A, D) “High H₂ enrichments” supplemented with 160 kPa of H₂ in the gas phase. (B, E) “Fe₀ enrichments” in which microorganisms were cultured in the same vial with 1 g vial⁻¹ of Fe₀ powder. (C, F) Enrichment cultures with the iron corrosion-assisted H₂-supplying (iCH) system, in which H₂ was continuously supplied by the iron corrosion reaction. For ease of comparison, the amounts of all metabolites are represented as electron equivalents in units of mmol e⁻ per culture vial, using the respective half reaction formulas; 2H⁺ + 2e⁻ ↔ H₂, HCO₃⁻ + 9H⁺ + 8e⁻ ↔ CH₄ + 3H₂O, and 2HCO₃⁻ + 9H⁺ + 8e⁻ ↔ CH₃COO⁻ + 4H₂O. The volumes of the liquid and gaseous headspace were 20 and 48 ml, respectively. The broken lines represent the rate of H₂ production via the iron corrosion reaction calculated from the data shown in Fig. 1C (35 µmol vial⁻¹ day⁻¹).
The microbial composition is displayed in Fig. S1A. All OTUs dominant in the enrichment cultures (relative abundance > 3% in at least one enrichment) had low abundance in the inoculum soil (~1.2%), suggesting that H2-utilizing microorganisms were sufficiently enriched. Principal component analysis was performed to quantitatively evaluate the similarity of microbial community structures of each sample (Fig. S1B). The results showed that the microbial community patterns of the duplicate enrichment cultures were very similar, and that the microbial community composition differs between the different experimental setups. Therefore, for further analysis we used the average values of community analysis data of the duplicate cultures.

We plotted the relative abundances of the dominant archaea (> 3% under at least one set of culture conditions) in the methanogenic enrichments (Fig. 5A). Different types of methanogens were enriched depending on the culture conditions. In the high H2 enrichments, two OTUs closely related to Methanobacterium spp. (OTU183, with 99% identity to Methanobacterium oryzae and OTU192, with 100% identity to Methanobacterium lacus) predominated. By contrast, OTU173 and OTU1307 (100% identity to Methanocella arvoryzae and Methanoculleus chikugoensis, respectively) were specifically enriched in the iCH cultures. The genera Methanocella and Methanoculleus have been frequently detected as dominant hydrogenotrophic methanogens in various anaerobic environments with low H2 concentrations, including rice paddy fields, peat bogs, marine and freshwater sediments, and subsurface environments28–33. Furthermore, methanogens closely related to these genera have been selectively enriched from rice paddy field soils and marine/freshwater sediments under the low H2 pressures achieved by the coculture method11. These findings suggest that the iCH system can selectively culture hydrogenotrophic methanogens adapting to low H2 pressures. By contrast, a different type of methanogen (OTU153, with 100% identity to Methanobacterium flexile) was enriched in the Fe0 enrichment cultures. This suggests that factors other than H2 concentration (e.g., increase in pH and/or high concentration of ferrous iron) were the main selective pressures in the Fe0 enrichments.

Acetogen enrichment culture and its microbial community analysis. In addition to methanogenic archaea, acetogenic bacteria are also one of the important H2-utilizing microorganisms in anaerobic environments34,35. Hence, we set up enrichment cultures of H2-utilizing acetogens with inorganic medium supplemented with 2-bromoethanesulphonate (BES) to inhibit methanogens. We followed the transitions of
metabolites during the incubations of enrichment cultures of acetogens in the high H₂, Fe⁰, and iCH cultures (Fig. 4D–F). As described below, the trends were similar to those observed with the enrichment of methanogens. In the high H₂ enrichments, we observed acetate production with concomitant consumption of H₂, and the H₂ consumption rate was much higher than in enrichment cultures of methanogens (Fig. 4D). In the Fe⁰ enrichments, we observed acetate production comparable to the theoretical value from day 0 to day 14, after which acetate production ceased (Fig. 4E), suggesting that the Fe⁰ cultures have inhibitory effects on acetogens as observed in the methanogenic enrichments. In the iCH enrichments, acetate was produced at a rate comparable with theoretical values (Fig. 4F). Although H₂ initially accumulated in the iCH enrichments, it was below the detection limit (< 10 Pa) after day 14. These results indicate that acetogens adapting to low H₂ pressures could be enriched in the iCH system.

We plotted the relative abundances of the dominant bacteria (> 3% under at least one set of conditions) in the enrichments for acetogens (Fig. 5B). As with the methanogen enrichments, the acetogen community structures were completely different for each culture condition. Only one phylotype (OTU898) closely related to Clostridium magnum, which is well known as an acetogen⁵⁶, was enriched in the high H₂ enrichments. In contrast, two phylotypes closely related to other acetogen species (OTU2305 and OTU2514, with 100% identities to Acetobacterium carbinolicum and Sporomusa sphaeroides, respectively) were selectively enriched in the iCH cultures. The phylotypes closely related to Clostridium glycolicum and Romboutsia lituseburensis (OTU316 and OTU1895, respectively) predominated in the Fe⁰ enrichments, in addition to OTU898 (C. magnum) and OTU2514 (S. sphaeroides), which were also detected in other enrichments. Clostridium glycolicum is a well-known acetogen species⁵⁵, Romboutsia spp. have often been detected in enrichment cultures of H₂-utilizing acetogens⁵⁶, although there is no report of their acetogenic metabolism.

It has been reported that affinities for H₂ and kinetics of H₂ consumption differ depending on the species of acetogens, mainly due to the differences in their energy-acquisition efficiencies⁵⁷. In contrast to methanogens, however, there are only few studies of the response of acetogens to low H₂ pressures. Generally, acetogens have lower affinity for H₂ than methanogens for thermodynamic reasons⁵⁸, which may be one of the reasons that the ecophysiology of acetogens under low H₂ pressures has not attracted much attention. Our result shows that different types of acetogens can be selectively enriched under conditions with different H₂ availability. This suggests that environmental H₂ concentration provides an ecological niche not only for methanogens but also for acetogens.

**Conclusion**

We constructed a simple system for culturing anaerobic microorganisms under low H₂ pressures by using the iron corrosion reaction as the source of H₂. The system, which we call the iCH system, can continuously supply H₂ for several months, and it is possible to control the H₂ supply rate by changing the amount and size of Fe⁰ particles. We demonstrated that the iCH system can selectively enrich anaerobic microorganisms adapting to low H₂ pressures. Although this study focused only on methanogens and acetogens, the iCH system is applicable to cultures of other H₂-utilizing microorganisms such as nitrate, iron, and sulfate reducers. The iCH system is also applicable to colony isolation using agar-solidified media (e.g., a roll-tube method), which is an on-going study in our research group. This culture method should enable selective enrichment and isolation of unidentified microorganisms adapting to or even specialized for low H₂ pressures from anaerobic environments with low H₂ availability, such as subsurface environments, peat soils, and deep-sea sediments, which would shed light on the novel ecophysiology of hydrogenotrophic microorganisms in anaerobic environments.

**Materials and methods**

**Bacterial strains and culture conditions.** To culture microorganisms we used a freshwater basal medium containing (per liter) 0.3 g KH₂PO₄, 1 g NH₄Cl, 0.1 g MgCl₂·6H₂O, 0.08 g CaCl₂·2H₂O, 0.6 g NaCl, 2 g KHCO₃, 0.02 g MgSO₄·7H₂O, 9.52 g 4-(2-hydroxyethyl)-1-piperazineethanesulfonate (HEPES), 0.1 g yeast extract, and 10 ml each of trace metal and vitamin solutions⁵⁹. The pH of the medium was adjusted to 7.0 by adding 6 N KOH solution. Methanobacterium formicicum (DSM1535) was cultured in the freshwater basal medium supplemented with 0.1 g L⁻¹ of sodium acetate and reducing agents (0.3 g L⁻¹ each of cysteine-HCl·H₂O and Na₂S·9H₂O) at 37 °C without shaking under an atmosphere of 200 kPa of H₂:CO₂ (80:20). CH₄ and H₂ in the gas phases were measured using a gas chromatograph (GC-2014; Shimadzu, Kyoto, Japan) equipped with a thermal conductivity detector (for quantification of H₂) and a flame ionization detector (for quantification of CH₄) as described previously⁶⁰. The concentration of acetate was determined using high-performance liquid chromatography (D-2000 LaChrom Elite HPLC system; Hitachi, Tokyo, Japan) equipped with an ion exclusion column (Aminex HPX-87H; Bio-Rad Laboratories, Hercules, CA, USA) and UV detector (L2400; Hitachi). The culture experiments were conducted in triplicate.

**The iron corrosion-assisted H₂-supplying (iCH) system.** The iCH system consists of two vials (68 ml in capacity). One vial ("corrosion vial" in Fig. 2) was filled with 20 ml of the freshwater basal medium and supplemented with Fe⁰ granules (1–2 mm, 99.98% purity; Alfa Aesar, Ward Hill, MA, USA) or Fe⁰ powder (< 45 μm, 99.9% purity; Wako Pure Chemical, Osaka, Japan). The second vial ("culture vial" in Fig. 2) was also filled with 20 ml of the freshwater basal medium. After removing the air from the medium by bubbling with N₂:CO₂ (80:20) gas for 5 min, the vials were sealed with butyl rubber stoppers and aluminum seals, and sterilized by autoclaving. After the cultivation vials were supplemented with reducing agents, inhibitor chemicals, and/or microorganisms, the gas phases of the two vials were connected by sterile, stainless-steel tube with an inner diameter of 1.8 mm (Swagelok, Solon, OH, USA), which was separately sterilized by autoclaving, through a guiding hole made by a gauge 18 syringe needle. Before incubation, the vials were again purged with N₂:CO₂ (80:20) gas for...
5 min to remove trace oxygen. To confirm that the gases were uniformly diffused, CH₄ and H₂ in the gas phases of the two vials were measured during incubation by gas chromatography as described above.

**Enrichment cultures from rice paddy field soil.** High-H₂ and Fe⁰ enrichment cultures were performed in vials (not connected to the corrosion vial) filled with 20 ml of the freshwater basal medium supplemented with 200 kPa of H₂:CO₂ (80:20) gas and 1 g of Fe⁰ powder as the sole energy source, respectively. Rifampicin (final concentration, 10 µg l⁻¹) and BES (final concentration, 10 mM) were supplemented to the enrichment cultures for methanogens and acetogens, respectively, from filter-sterilized stock solutions. Approximately 50 mg (wet weight) of rice paddy field soil was suspended in 200 µl of the freshwater basal medium, inoculated into the culture vial using a syringe and incubated at 30 °C without shaking. After sufficient microbial growth, 0.4 ml of culture solution was transferred to fresh media in a culture vial connected to a fresh corrosion vial. After three transfers, the enrichment cultures were subjected to chemical and phylogenetic analyses. The enrichment culture experiments were conducted in duplicate.

**Microbial community analysis.** Microbial DNA was extracted with the FAST DNA Spin Kit for Soil (MP Biomedicals, Santa Ana, CA, USA) according to the manufacturer's instructions. Partial 16S rRNA gene fragments were amplified by PCR using Phusion Hot Start II High-Fidelity DNA Polymerase (Thermo Fisher Scientific, Waltham, MA, USA) with the primer pair 515F/805R²¹ prolonged by adaptor and index sequence tags⁴². PCR products were purified using a QIAquick PCR Purification Kit (Qiagen, Hilden, Germany), and were qualified and quantified using a spectrophotometer (DS-11; Denovix, Wilmington, DE, USA) and Qubit dsDNA HS Assay Kit (Thermo Fisher Scientific, respectively). The 16S rRNA gene amplicon libraries were adaptor trimmed at the 3′ end to remove adaptor sequences (cutadapt 1.1)⁴³, quality trimmed (Trimmomatic v. 0.32; TRAILING:20 MIN- LENGTH:50), and the individual read pairs were overlapped to form single synthetic reads (fastq-join v.1.1.2–537; python, 2.7.11). Representative sequences of each OTU were aligned using PyNAST⁴⁶ and chimeric sequences were removed using ChimeraSlayer⁴⁷. Taxonomic assignment of each OTU was carried out with a dataset obtained from the EMBL/GenBank under the accession numbers DRA007911 and DRA007912.

Acknowledgements

This research was supported by the Japan Society for the Promotion of Science KAKENHI Grant Numbers 15H01071, 16KK0154, 16K14895, 17H03800, and 19K22296.

Author contributions

S.K. designed the experiments, analyzed the data, and wrote the paper. M.T. and K.I. carried out the culture experiments and microbial community analysis, and analyzed the data. H.M., D.M. and H.T. were involved in the design of the experiments and helped the data interpretation. All authors reviewed the paper.

Competing interests

The authors declare no competing interests.
