Abstract

We show that the only Tolman models which permit a Vaidya limit are those having a dust distribution that is hollow — such as the self-similar case. Thus the naked shell-focussing singularities found in Tolman models that are dense through the origin have no Vaidya equivalent. This also casts light on the nature of the Vaidya metric. We point out a hidden assumption in Lemos’ demonstration that the Vaidya metric is a null limit of the Tolman metric, and in generalising his result, we find that a different transformation of coordinates is required.

PACS: 04.20.-q, 04.40.+c, 98.80.-k
Introduction

Recently Lemos [1992] showed that the Vaidya metric, describing radially directed incoherent radiation (spherically symmetric null dust), can be obtained from the Tolman metric, which represents a spherically symmetric distribution of pressureless matter (dust), by taking a null limit. This surprising and intriguing insight was inspired by the very strong similarities, quantitative as well as qualitative, between the naked shell-focussing singularities (discovered by Eardley and Smarr [1979]) that appear in the self-similar forms of these metrics at the moment the crunch singularity forms [see for example Christodoulou 1984, Newmann 1986, Ori and Piran 1987, Rajagopal and Lake 1987, Hellaby and Lake 1988, Waugh and Lake 1988, 1989, Grillo 1991, Lemos 1991, and extensive references in footnote 2 of Lake 1992]. We discuss the nature of an origin of spherical coordinates in Tolman models, and show that a Vaidya limit cannot be extended to such a point. We show that one of Lemos’ assumptions can be relaxed if a different coordinate transformation is used.

The incoming Vaidya metric [Vaidya 1951, 1953, see also Lindquist Schwarz and Misner 1965] is

\[ ds^2 = 2dvdR - \left(1 - \frac{2M}{R}\right)dv^2 + R^2d\Omega^2 \]  

where \(d\Omega^2 = d\theta^2 + \sin^2(\theta)d\phi^2\) is the metric on a 2-sphere, the areal radius is positive, \(R > 0\), and \(M = M(v) > 0\) is an arbitrary function of the null coordinate \(v\), representing the effective gravitational mass inside \(v\). The only non-zero Einstein tensor component and the Kretschmann scalar \(K = R^\alpha\beta\gamma\delta R_{\alpha\beta\gamma\delta}\) are

\[ G_{\nu\nu}^V = \frac{2}{R^2}M^* \]  
\[ K^V = \frac{48M^2}{r^6} \]

where \(* = \frac{\partial}{\partial v}\), and superscripts \(V\) and \(T\) are used where necessary to distinguish quantities in the Vaidya and Tolman models.

The Tolman metric [Lemaitre 1933, Tolman 1934] uses synchronous coordinates that are comoving with the dust particles,

\[ ds^2 = -dt^2 + \frac{R^2}{1 + f}dr^2 + R^2d\Omega^2 \]  

where \(t \equiv \frac{\partial}{\partial r}\), \(f = f(r)\) is an arbitrary function of coordinate radius that determines the local spatial geometry, as a function of \(r\) [see Hellaby and Lake 1985, Hellaby 1987]. The areal radius \(R = R(t, r)\) is a solution of

\[ \ddot{R} = 2\frac{M}{R} + f \]

where \(t \equiv \frac{\partial}{\partial t}\), and \(M = M(r) > 0\) is a second arbitrary function. Comparing this equation with its Newtonian analogue for the kinetic plus potential energy of a radially moving particle of mass \(m\) at a distance \(x\) from the centre of a spherically symmetric dust cloud with density distribution \(\rho_N(x)\)

\[ \frac{m}{2}\left(\dot{x}^2 - 2\frac{M_N(x)}{x}\right) = E \]

where

\[ M_N(x) = \int_0^x 4\pi x^2 \rho_N(x)dx \]
we obtain the interpretation that $M(r)$ is the gravitational mass within co-moving radius $r$, and $f(r)$ is twice the energy per unit mass of the particles at $r$. (The principal difference between these two equations is the replacement of the radial distance $x$ by the areal radius $R$.) For $f > 0$ (or rather $Rf/M > 0$) the evolution of the areal radius for a collapsing model is hyperbolic

$$ R = \frac{M}{f}(\cosh \eta - 1) \hspace{1cm} (8) $$
$$ (\sinh \eta - \eta) = \frac{f^{3/2}(a - t)}{M} \hspace{1cm} (9) $$

where the third arbitrary function $a = a(r)$ gives the time at which $R = 0$ — the big crunch. (Parabolic and elliptic solutions exist for $f = 0$ and $f < 0$.) Since the pressure is zero, the dust particles (which stay at constant $r, \theta, \phi$) follow geodesics of the spacetime. It can be shown in general [Hellaby and Lake 1984, 1985] that for the collapsing models

$$ R' = \left( \frac{M'}{M} - \frac{f'}{f} \right) R + \left[ a' - \left( \frac{M'}{M} - \frac{3f'}{2f} \right)(a - t) \right] \dot{R} \hspace{1cm} (10) $$

The density and the Kretschmann scalar are given by

$$ 8\pi \rho_T = G^T_{tt} = \frac{2M'}{R^2 R'} \hspace{1cm} (11) $$
$$ K^T = \frac{48M^2}{R^6} - \frac{32MM'}{R^5 R'} + \frac{12M'^2}{R^4 R'^2} \hspace{1cm} (12) $$

**Lemos’ Method**

We here outline the approach used by Lemos, although we find it convenient to delay taking the null limit until a slightly later stage in the working. He initially makes the assumption of self-similarity in both metrics, for simplicity, and later drops it. That assumption is not made here. The Tolman line element (4) may be transformed from coordinates $(t, r)$ to $(t, R)$ by means of

$$ dR = \dot{R}dt + R'dr \hspace{1cm} \rightarrow \hspace{1cm} R'dr = dR - \dot{R}dt \hspace{1cm} (13) $$

which leads to

$$ ds^2 = -\left( 1 - \frac{2M}{R} \right) \frac{dt^2}{(1 + f)} - \frac{2\dot{R}}{(1 + f)} dtdR + \frac{dR^2}{(1 + f)} + R^2 d\Omega^2 \hspace{1cm} (14) $$

where the new $g_{tt}$ has been simplified using (3).

Now the limit of interest is that in which $f$ is allowed to diverge, while $M$ and $R$ are both required to remain finite

$$ f \to +\infty \hspace{1cm} , \hspace{1cm} 0 \leq R, M < \infty \hspace{1cm} (15) $$

Eq (8) shows that in this limit $\cosh \eta$ must also diverge, so that $\cosh \eta \to \sinh \eta \to e^\eta/2$ and (8) plus (3) simplify to

$$ R \to \sqrt{f}(a - t) \hspace{1cm} (16) $$

and, for finite $R$, $(a - t)$ must be vanishingly small. Similarly (5) for collapsing models becomes

$$ \dot{R} \to -\sqrt{f} \hspace{1cm} (17) $$
and the derivative of (16) (or alternatively substituting for \((a-t)\) and \(\dot{R}\) from (13) and (17) in (10)) gives

\[
R' \rightarrow \frac{Rf'}{2f} + a'\sqrt{f}
\]  (18)

Lemos then states that the transformation

\[
v = \frac{t}{\sqrt{f}} + \frac{R}{f}
\]  (19)

converts (14) into the Vaidya metric (1), in the limit \(f \rightarrow \infty\). Since (19) and (16) imply that

\[
v \rightarrow \frac{a}{\sqrt{f}}
\]  (20)

the new coordinate becomes a function of \(r\) only, in the limit, so we can now write \(M \rightarrow M(v)\).

We note however that a constant \(f\), inherited from the self-similar case, must still be assumed in order to get this result. If we don’t make this assumption, then (19) leads to

\[
dv = \frac{dt}{\sqrt{f}} + \frac{dR}{f} - \left(\frac{t}{2f^{3/2}} + \frac{R}{f^2}\right)\frac{f'}{f}dr
\]  (21)

and, after substituting for \(t\), \(\dot{R}\), and \(R'\) from (10)-(18), to

\[
dv \rightarrow \left(\frac{dt}{\sqrt{f}} + \frac{dR}{f}\right)(1 - X)
\]  (23)

where

\[
X = \frac{R + a\sqrt{f}}{R + 2f^{3/2}(a'/f')}
\]  (24)

so that (14) in the limit becomes

\[
ds^2 \rightarrow -\left(\frac{f}{1+f}\right)\left[2 + \frac{1}{f}\left(1 - \frac{2M}{R}\right)\right]dR^2 + \left(\frac{f}{1+f}\right)\left(\frac{2}{1-X}\right)\left[1 + \frac{1}{f}\left(1 - \frac{2M}{R}\right)\right]dvdR
\]

\[-\left(\frac{f}{1+f}\right)\left(\frac{1}{1-X}\right)\left(1 - \frac{2M}{R}\right)dv^2 + R^2d\Omega^2
\]  (25)

The limiting behaviour of \(X\) is not at all clear, as the relationship between \(a(r)\) and \(f(r)\) is arbitrary in general, and the limiting behaviour of \(a\) is not specified.

**The Problem of the Origin and the Form of \(f(r)\)**

In all Tolman models describing a collapsing dust cloud which exhibit a naked singularity, this singularity occurs at the moment of collapse \(t = a\), at the origin (\(r = 0\) being the natural choice). The origin of spherical coordinates is specified by \(R(t, r = 0) = 0, \forall t\) and we also have \(\dot{R}(t, r = 0) = 0, \forall t\), which, by eq (3), requires \(M(0) = 0\) as well as \(f(0) = 0\) at the origin, for example the homogeneous case (dust FLRW). Can we extend Lemos’ result for the null limit
to cases where \( f \) does not diverge at the origin? Clearly the functional form of \( f(r) \) must allow \( f(0) = 0 \) — for example \( f = pr^2, \, p \to \infty \).

Consider cases with \( f \) finite at \( r = 0 \), such as the non-parabolic self-similar models. Assuming \( R, M \geq 0 \), eq (5) shows that \( \dot{R}(t,r=0) \geq f \neq 0 \). If \( r = 0 \) is approached along a constant \( t \) surface, with \( a(r) \) finite near \( r = 0 \), (8) and (9) show that either (a) \( M \to 0 \) so that \( \eta \to \infty \) and \( R \to \sqrt{f}t \), or (b) \( M \) remains finite so that \( \eta \) and \( R \) also remain finite. Case (a) represents a hollow dust cloud — it can be matched at \( r = 0 \) onto a vacuum Tolman (Minkowski) spacetime with \( M(r) = 0 \) and a true origin at some negative \( r \) value where \( f = 0 \). Case (b) either (i) contains more dust inside \( r = 0 \), with the true origin again at \( f = 0 \) — i.e. \( r = 0 \) is not the centre of the cloud, or (ii) it contains the Schwarzschild vacuum inside \( r = 0 \), with no origin, or (iii) it contains a dust filled version of the Schwarzschild-Kruskal-Szekeres topology [Hellaby 1987]. In (ii) and (iii), \( f \) must pass through zero and reach \(-1\) in order to form the throat, rising to \( f \geq 0 \) in the second sheet, and \( M, R < \infty \) everywhere that \( f < 0 \). Clearly particle worldlines having \( f(0) > 0 \) are not at the origin, but they do collapse to zero and begin the formation of the singularity.

Furthermore, since shell-focussing singularities do form in Tolman models with normal origins, can the detailed similarity between the naked singularities of the two metrics be extended to such cases, or is constant \( f \) required?

Note also that the coordinate \( r \) is eliminated by the first transformation (13) and then effectively re-introduced, in the limit \( v = a(r)/\sqrt{f(r)} \), via the second one (19). Since the Tolman coordinate \( r \) is co-moving with the dust particles, and the Vaidya coordinate \( v \) is co-moving with the shells of radiation, one might expect \( v \) to be the direct limit of \( r \). This is consistent with the interpretation of \( f \) as an energy parameter which goes to infinity, meaning that the Tolman particle geodesics are asymptotically null. Since a particle staying at the origin of spherical symmetry cannot be moving at light speed, this suggests that a Vaidya limit is not achievable here.

The Null Limit for General \( f \) and \( a \)

Consider approaching the origin on a constant \( \eta \) surface. Equation (8) shows that \( Rf/M \) remains constant, whereas (3) shows that both \( M/R \) and \( f \) go to zero there. Thus the Vaidya limit could be described by

\[
\frac{Rf}{M} \to \infty , \quad 0 \leq R, M < \infty
\]

which doesn’t necessarily require \( f \to \infty \) at \( r = 0 \). The limiting forms (16)-(18) of \( R, \dot{R}, \) and \( R' \) are unchanged by this adjustment.

Starting again from (3), we transform from \((t, r)\) to \((R, r)\) as our coordinates, thus substituting for \( t \) rather than \( r \),

\[
dR = \dot{R}dt + R'dr \quad \to \quad dt = (dR - R'dr)/\dot{R}
\]

and apply (3) to simplify the resulting \( g_{rr} \)

\[
ds^2 = -\frac{1}{R^2}dR^2 + 2\frac{R'R}{R^2}dRdr - \left(1 - \frac{2M}{R}\right)\frac{R'^2}{(1 + f)R^2}dr^2 + R^2d\Omega^2
\]

From (17) and (18), we have the following limiting forms of the extra factors that don’t appear
\[
\frac{1}{R^2} \rightarrow \frac{1}{f}, \quad \frac{R'}{R} \rightarrow \left\{ \frac{a'}{\sqrt{f}} + \frac{Rf'}{2f^2} \right\}, \quad \frac{R'^2}{(1 + f)R^2} \rightarrow \left( \frac{f}{1 + f} \right) \left\{ \frac{a'}{\sqrt{f}} + \frac{Rf'}{2f^2} \right\}^2
\]

(29)

The limiting transformation (29) takes care of the first term in the curly brackets \((a'/\sqrt{f})\), but not the second \((Rf'/2f^2)\), and without knowing both \(a(r)\) and \(f(r)\) — i.e. \(f(a)\) — it can’t be discounted. The second term is dominant if

\[
\frac{Rf'}{2f^2} \bigg/ \left( \frac{a'}{\sqrt{f}} \right) = \frac{R}{2f^{3/2}} \frac{df}{da} \rightarrow \infty
\]

(30)

An example of an \(f(a)\) that makes the second term dominant almost everywhere is

\[
f = a \ln(p) + \sin(p^n a), \quad n \text{ const.}, \quad p \rightarrow \infty
\]

(31)

\[
df/da \rightarrow \frac{2 + \cos(f/2)}{2a\sqrt{f}}
\]

(32)

but this wildly oscillating form is very unrealistic. The conditions for no shell crossings [Hellaby and Lake 1985] for collapsing hyperbolic Tolman models require \(f' > 0\) and \(a' > 0\) wherever \(M' > 0\), i.e. \(df/da > 0\), so adding a linear term to remove negative gradients gives a vanishing second term

\[
f = 2p^n a + \sin(p^n a), \quad n \text{ const.}, \quad p \rightarrow \infty
\]

(33)

\[
df/da \rightarrow \frac{2 + \cos(f/2)}{2a\sqrt{f}}
\]

(34)

The most rapid uniform divergence of \(df/da\) relative to \(f\) we have been able to find for \(df/da > 0\) still leaves \((df/da)/f^{3/2}\) vanishing. It is expressed in terms of computer notation \(^\wedge\) for raising to the power,

\[
f = ap^\wedge(p^\wedge(p^\wedge(p^\wedge a))), \quad p \rightarrow \infty
\]

(35)

\[
df/da \rightarrow \frac{\ln(f) \ln(\ln(f)) \ln(\ln(\ln(f))\ldots)}{a\sqrt{f}}
\]

(36)

However, at a single point (or a finite number of discrete points) the divergence behaviour can always be made arbitrarily rapid, e.g.

\[
f = pa + a^p, \quad n \text{ const.}, \quad p \rightarrow \infty
\]

(37)

\[
df/da \rightarrow \frac{1}{a\sqrt{f}}, \quad 0 < a < 1
\]

(38)

\[
\rightarrow f^{n-3/2}, \quad a = 1
\]

(39)

\[
\rightarrow \frac{\ln(f)}{\ln(a)\sqrt{f}}, \quad a > 1
\]

(40)

Consequently, we now introduce the following transformation,

\[
v = \int_0^r \frac{a'}{\sqrt{f}} dr - \frac{R}{2f}
\]

(41)

\[
dv = \left( \frac{a'}{\sqrt{f}} + \frac{Rf'}{2f^2} \right) dr - \frac{dR}{2f}
\]

(42)
which incorporates both terms in the brackets of (29), and which converts (28) to

\[ ds^2 \to -\frac{1}{4f(1+f)} \left( 1 - \frac{2M}{R} \right) dR^2 + \left[ 2 - \frac{1}{(1+f)} \left( 1 - \frac{2M}{R} \right) \right] dv dR - \left( \frac{f}{1+f} \right) \left( 1 - \frac{2M}{R} \right) d\Omega^2 \]

(43)

It is already clear from (29) as well as this equation that \( f \to \infty \) is indeed required everywhere to obtain the Vaidya metric as the limit.

\[ ds^2 \to 2dv dR - \left( 1 - \frac{2M}{R} \right) dv^2 + R^2 d\Omega^2 \]

(44)

(The alternative transformation

\[ v = \int_0^r \frac{d'(r)}{\sqrt{f(r)}} dr - \sqrt{\frac{1+f}{f}} R, \quad dv = \sqrt{\frac{f}{1+f}} \left( \frac{d' + Rf'}{2f^2} \right) dr - \sqrt{\frac{1+f}{f}} dR \]

(45)

does not succeed in removing the factor of \( f/(1+f) \), and also leads to the wrong limit.) In the limit (13) then, it is evident from (41) that \( v \) becomes a function of \( r \) only, so that \( M \to M(v) \) holds once again. No assumptions about the functional form of \( f \) or the limiting behaviour of \( a \) were made to obtain the Vaidya metric as the null limit, and we find that the second term of (41) becomes negligible, even if the second term in the brackets of (42) doesn’t. The new transformation (41) can also be re-written in the limit as

\[ dv \to \frac{dt}{\sqrt{f}} + \frac{dR}{2f} \]

(46)

in order to recover (14) from (14). Equations (46) and (41) are the revised versions of (23) and (20).

The overall transformation from Tolman to asymptotically Vaidya coordinates then is

\[ v = \int_0^r \frac{d'(r)}{\sqrt{f(r)}} dr - \frac{R(t,r)}{2f(r)} \]

(47)

\[ R = R(t,r) \]

(48)

where \( R(t,r) \) is given by (8)-(9). Using the following limiting values of two of the partial derivatives of the inverse transformation

\[ \frac{\partial r}{\partial v}\bigg|_R = \frac{f}{R'}, \quad \frac{\partial t}{\partial v}\bigg|_R = \sqrt{f} \]

(49)

the Kretschmann scalar and the density may be converted to their Vaidya forms. Thus

\[ M^* = \frac{\partial M}{\partial v}\bigg|_R = \frac{\partial M}{\partial r}\bigg|_t \frac{\partial r}{\partial v}\bigg|_R = M' f \]

(50)

i.e. \( \frac{M'}{R'} = \frac{1}{f} M^* \)

ensures that the last two terms on the right of (12) vanish, giving (3) in the limit. For the ‘density’, (2) is obtained from (11) in the limit by writing

\[ G^V_{\nu\nu} = \left( \frac{\partial t}{\partial v}\bigg|_R \right)^2 \]

\[ G^T_{tt} = f \frac{2M'}{R^2 R'} = \frac{2}{R^2} M^* \]

(51)
The strengths of singularities are variously defined by [e.g. Tipler Clarke and Ellis 1980, Clarke and Królak 1986]

\[
\Psi_G = \lim_{\lambda \to 0} \lambda^2 G_{\alpha\beta} k^\alpha k^\beta \quad \text{or} \quad \Psi_R = \lim_{\lambda \to 0} \lambda^2 R_{\alpha\beta} k^\alpha k^\beta
\]

where \(k^\alpha\) is the tangent vector to a null geodesic with parameter \(\lambda\) that hits the singularity at \(\lambda = 0\). From the above, and since \(\Psi\) is a scalar, it is clear that the strengths of the Vaidya singularity, as measured along radial geodesics are given by the limits of the corresponding Tolman expressions.

Conclusions

Lemos originally demonstrated that the Vaidya model is a null limit of the Tolman model, by taking the limit \(f \to \infty\) and assuming \(f = \text{constant}\) in this limit. His transformation was completely valid for models with constant \(f\). However Tolman shell-focussing singularities also occur in models with matter at the origin. The existence of a normal origin of spherical coordinates at \(r = 0, (a - t) > 0\) in the Tolman model requires \(f(r = 0) = 0\), and we have found this cannot be made consistent with a null limit. The Vaidya limit does indeed require \(f \to \infty\), so it cannot be extended to a spherical origin, where \(f(0) = 0\), or a Schwarzschild-Kruskal-Szekeres type topology, which requires \(f = -1\) in the throat.

Thus we conclude that every Vaidya model is the limit of a hollow Tolman model, acquiring its arbitrary \(M(v)\) from a combination of \(M(r)\) and \(a(r)\), and must itself be hollow. If \(M(r = 0) = 0, M(v = 0) = 0\), then \(r = 0, v = 0\) is a collapsing shell of finite size surrounding Minkowski vacuum, and the limiting Vaidya model can form a shell-focussing. If \(M(r = 0) > 0, M(v = 0) > 0\) then it surrounds Schwarzschild vacuum, and no shell-focussing forms. In this latter case, the shells of incoming radiation (having \(f\) divergent) cannot pass through the throat (where \(f = -1\)) and must hit the future singularity first. A dust filled interior is not possible in the limit, since a coordinate line cannot be co-moving with both a dust particle and a light ray, but it may be possible to have an intervening vacuum region. Since \(t = a\) on the singularity, and \(R\) is only finite on a collapsing shell of radiation where \((a - t)\) is infinitesimal, the radiation is all at infinite \(R\) for any finite value of \((a - t)\).

If we assume that \(M^*\) is finite, then it is apparent from (41) that a finite change in \(M\) and \(v\) requires an infinite change in \(a\). It is interesting to note that a collapsing, unbound (i.e. hyperbolic) dust cloud of finite total mass may also have \(f, a \to \infty\) and \(M\) finite in the asymptotic regions. At finite \((a - t)\), \(R\) is infinite, from (8)-(9), but as these particles collapse towards the crunch, \(R\) becomes finite when \((a - t)\) is infinitesimal, and the Vaidya limit is achieved. In terms of Tolman time, this is infinitely long after the initial formation of the singularity, but only a finite retarded time in Vaidya coordinates.

The new coordinate transformation (17)-(18) — or (27) and (12) — makes no assumptions about the 3 arbitrary Tolman functions \(f, M, a\), and in particular the relationship between \(f\) and \(a\), beyond those normally made for a general Tolman model, and the limit \(f \to \infty\). Several important physical quantities — the Einstein tensor, the Kretschmann scalar, the null geodesics, and the strenghts of the singularities — all have the correct limit. This generalises Lemos’ unification of the two metrics and their shell-focussing singularities.
