Hydrogen sulfide (H$_2$S) production in the intestinal microbiota has many contributions to human health and disease. An important source of H$_2$S in the human gut is anaerobic respiration of sulfite released from the abundant dietary and host-derived organic sulfonate substrate in the gut, taurine (2-aminoethanesulfonate). However, the enzymes that allow intestinal bacteria to access sulfite from taurine have not yet been identified. Here we decipher the complete taurine desulfonation pathway in *Bilophila wadsworthia* 3.1.6 using differential proteomics, in vitro reconstruction with heterologously produced enzymes, and identification of critical intermediates. An initial deamination of taurine to sulfoacetaldehyde by a known taurine:pyruvate aminotransferase is followed, unexpectedly, by reduction of sulfoacetaldehyde to isethionate (2-hydroxyethanesulfonate) by an NADH-dependent reductase. Isethionate is then cleaved to sulfite and acetaldehyde by a previously uncharacterized glycyl radical enzyme (GRE), isethionate sulfite-lyase (IslA). The acetaldehyde produced is oxidized to acetyl-CoA by a dehydrogenase, and the sulfite is reduced to H$_2$S by dissimilatory sulfite reductase. This unique GRE is also found in *Desulfovibrio desulfuricans* DSM6422 and *Desulfovibrio alaskensis* G20, which use isethionate but not taurine; corresponding knockout mutants of *D. alaskensis* G20 did not grow with isethionate as the terminal electron acceptor. In conclusion, the novel radical-based C-S bond-cleavage reaction catalyzed by IslA diversifies the known repertoire of GRE superfamily enzymes and enables the energy metabolism of *B. wadsworthia*. This GRE is widely distributed in gut bacterial genomes and may represent a novel target for control of intestinal H$_2$S production.

*The metabolism of dietary and host-derived sulfur-containing compounds to hydrogen sulfide (H$_2$S) by members of the human gut microbiota has many prominent connections to host health and disease (1, 2). H$_2$S is a potent genotoxin and may contribute to the onset of colorectal cancer (3). This metabolite can also reduce disulfide bonds in the mucus layer of the gut epithelium, disrupting its barrier function and potentially playing a role in inflammatory bowel disease (IBD) (4). As H$_2$S can induce antioxidant resistance, production of this compound in the gut, taurine (2-aminoethanesulfonate), an abundant source of H$_2$S, has been associated with appendicitis and colorectal cancer (13). In mice, *B. wadsworthia* can cause systemic inflammation (14) and proliferates concomitantly with the onset of ulcerative colitis when taurine-conjugated bile acids are more abundant in the gastrointestinal tract (15).

Metabolism of taurine and isethionate by *B. wadsworthia* involves a desulfonation reaction (Fig. 1 A and B) to generate free sulfite, which is then reduced to H$_2$S via the action of dissimilatory sulfite reductase (Der; desulfovirdin) for energy conservation by anaerobic sulfite respiration (10, 16). However, the enzymes involved in this critical C-S bond-cleaving step have not yet been identified in *B. wadsworthia*. The known metabolic pathways for taurine and isethionate, deciphered almost exclusively in aerobic bacteria, are diverse but invariably involve sulfoacetaldehyde as the critical intermediate (17) (see also MetaCyc pathways taurine degradation I–IV). In these bacteria, sulfoacetaldehyde is desulfonated by the oxygen-insensitive, thiamine-diphosphate (TDP)-dependent sulfoacetaldehyde acetyltransferase (Xsc) (18, 19) to produce acetyl phosphate, which is used to generate ATP or acetyl-CoA.

Significance

This paper describes a pathway for anaerobic bacterial metabolism of taurine (2-aminoethanesulfonate), an abundant substrate in the human intestinal microbiota, by the bacterial microbiota and opportunistic pathogen, *Bilophila wadsworthia*. This metabolism converts taurine to the toxic metabolite hydrogen sulfide (H$_2$S), an activity associated with inflammatory bowel disease and colorectal cancer. A critical enzyme in this pathway is isethionate sulfite-lyase, a member of the glycy1 radical enzyme family. This enzyme catalyzes a novel, radical-based C-S bond-cleavage reaction to convert isethionate (2-hydroxyethanesulfonate) to sulfite and acetaldehyde. This discovery improves our understanding of H$_2$S production in the human body and may also offer new approaches for controlling intestinal H$_2$S production and *B. wadsworthia* infections.

sulfite, which is then oxidized to sulfate by sulfite dehydrogenase in most aerobic bacteria (not depicted in Fig. 1B).

Notably, the sulfocatecholase-de-sulfonating Xsc enzyme is also used by strictly anaerobic *Desulfonispora thiosulfatigenes* GKNTAU, which ferments taurine to acetate, ammonium, and thiosulfate (19).

Although an analogous C-S bond-clearing reaction has been proposed to operate in the strictly anaerobic, taurine- and isethionate-respiring, sulfidogenic bacterium *B. wadsworthia*, no valid Xsc homologs can be detected in the genomes of these organisms (not depicted in B). Instead, the GRE IslA with its GRE-activase component (IslB) are found in both *B. wadsworthia* and the *Desulfovibrio* spp., and a novel NADH-coupled, isethionate-forming sulfocatecholase reductase (SarD) is found only in *B. wadsworthia*. The sulfite released by the GRE is reduced to sulfide by Dar and coupled to proton translocation for ATP synthesis (symbolized as [H]) when using electrons from oxidation of an alternative electron donor, such as lactate (gray box). AckA, acetate kinase; Pta, phosphotransacetylase. (C) The gene clusters identified in this study. In *B. wadsworthia*, two separate clusters encode for taurine transport and conversion to isethionate (ald, tpa, and sarD), and also for isethionate desulfonation and the conversion of acetate to isethionate by acetyl-CoA (adhE, islA, and islB). The *Desulfovibrio* strains harbor only one gene cluster for isethionate transport (dctP and fused dctMQ) and desulfonation (islA and islB), and acetyl-CoA dehydrogenases are encoded elsewhere in their genomes (not depicted in C). Single-gene knockouts in *D. alaskensis* G20 that result in an inability to use isethionate (but not free sulfite) are indicated by squared gene symbols.

(Fig. 1B), and sulfite, which is then oxidized to sulfate by sulfite dehydrogenase in most aerobic bacteria (not depicted in Fig. 1B).

Notably, the sulfocatecholase-de-sulfonating Xsc enzyme is also used by strictly anaerobic *Desulfonispora thiosulfatigenes* GKNTAU, which ferments taurine to acetate, ammonium, and thiosulfate (19).

Although an analogous C-S bond-clearing reaction has been proposed to operate in the strictly anaerobic, taurine- and isethionate-respiring, sulfidogenic bacterium *B. wadsworthia*, no valid Xsc homologs can be detected in the genomes of these organisms; that is, all homologs are annotated as catalytic, TDP-binding subunits of acetolactate synthase genes and are coencoded with their small-subunit genes (<33% amino acid sequence identity). Furthermore, no sulfocatecholase-de-sulfonating Xsc enzyme activity can be observed in cell-free extracts of taurine-grown cells (20).

In the present study, we first investigated taurine and isethionate catabolism in the Human Microbiome Project (HMP) reference strain *Bilophila wadsworthia* 3.1.6 (21), and then examined isethionate catabolism in *Desulfovibrio desulfuricans* DSM642 (16) and *Desulfovibrio alaskensis* G20 (22), once we realized that these two pathways involve the same type of oxygen-sensitive desulfonation reaction. *Desulfovibrio* spp. are sulfate-reducing bacteria also found in the human intestinal microbiota (11, 23) and these organisms are also of clinical importance, associated with abdominal infections and bacteremia (24).

Because taurine and isethionate catabolism are inducible in these bacteria, we adopted a differential-proteomics and reverse-genetics approach (25, 26) to identify the complete organosulfonate catabolic pathways.

**Results**

**Proteomic Experiments Reveal Putative Desulfonating Glycol Radical Enzymes in *Bilophila* and *Desulfovibrio* Strains.** We initially investigated the missing desulfonation step in taurine and isethionate catabolism using the HMP reference isolate *B. wadsworthia* 3.1.6 (21). Strain 3.1.6 was grown in media containing either taurine or isethionate as an electron acceptor. Proteomics experiments implicated two gene clusters in taurine catabolism (Fig. 2A), one of which was also linked to isethionate catabolism (Fig. 1C). These gene clusters are conserved in all sequenced *Bilophila* genomes. The first gene cluster encodes the known enzymes taurine:pyruvate aminotransferase (Tpa) and alanine dehydrogenase (Ald), as previously identified in a different *B. wadsworthia* isolate (27, 28). Tpa converts taurine to sulfocatecholase, and Ald regenerates the amino group acceptor for Tpa (Fig. 1B). Both proteins were detected with a high relative abundance (i.e., with a higher protein score and hit rank) in taurine-grown cells, but not in isethionate-grown cells (Fig. 2A).
Another protein encoded in this gene cluster, a predicted iron-dependent alcohol dehydrogenase (SarD in Fig. 1), was also detected in higher relative abundance specifically in taurine-grown cells but had not been previously characterized. Surprisingly, the second gene cluster encodes a glycolyl radical enzyme (GRE) and its cognate radical S-adenosylmethionine (SAM)-activating enzyme (Fig. 1C). These proteins were consistently detected at much higher relative abundance (and with the highest hit rank) in both taurine-grown and isethionate-grown cells (Fig. 2A). Another protein encoded directly upstream of the GRE was also detected in higher relative abundance in both taurine-grown and isethionate-grown cells (Fig. 2A), a predicted CoA-acylating aldehyde dehydrogenase (AdhE) (Fig. 1C).

The discovery of these gene clusters allowed us to formulate a biochemical hypothesis for taurine catabolism in *B. wadsworthia*. The initial deamination of taurine would generate sulfocetaldehyde (Fig. 1B). Rather than undergoing C-S bond cleavage by an Xsc-type enzyme, we hypothesized that sulfocetaldehyde instead could be reduced to isethionate by the coinduced alcohol dehydrogenase (sarD) encoded in the tpa-ald gene cluster. We then envisioned that the GRE from the second gene cluster might catalyze the conversion of isethionate to acetaldehyde and sulfate.

GREs are extremely oxygen-sensitive enzymes that use protein-centered radical intermediates in catalysis, with the key glycine-centered radical installed posttranslationally by a partner activating enzyme that is a member of the radical SAM enzyme family (SI Appendix, Fig. S1A). GREs catalyze challenging biochemical transformations that play important roles in primary metabolism under strictly anoxic conditions, including a range of C-C, C-O, and C-N bond-cleavage reactions (29). Although C-S bond cleavage had not been reported for any GRE, the amino acid sequence of the identified *Bilophila* GRE resembles the sequences of the C-O bond-cleaving GRE 1,2-propanediol dehydratase from *Roseburia inulinivorans* (32% identity), which converts 1,2-propanediol to water and propionaldehyde (propanal) (30), and the C-N bond-cleaving GRE choline trimethylamine-lyase (CutC) from *D. alaskensis* G20 (31% identity), which metabolizes choline to trimethylamine and acetaldehyde (31). This relationship suggests the potential for the *B. wadsworthia* GRE to function as a C-S bond-cleaving isethionate sulfite-lyase (IslA) of a desulfonation pathway for taurine (Fig. 1B).

To obtain further evidence for this biochemical hypothesis and the role of the putative isethionate metabolizing GRE, we examined the genomes and proteomes of two additional bacteria that use isethionate (but not taurine) as a terminal electron acceptor and, like *B. wadsworthia*, do not encode an Xsc homolog: *Desulfovibrio desulfuricans* subspp. *Desulfuricans* DSM642 (16) and *D. alaskensis* G20 (22). Using an analogous differential-proteomics and reverse-genetics approach, we identified similar enzymatic machinery in these organisms that were specifically produced during growth with isethionate. A candidate GRE and GRE-activating enzyme were detected in high abundance in cells grown with isethionate but not in control cells (Fig. 2B). The sequences of these enzymes strongly resembled the corresponding GRE and activase from *B. wadsworthia* (pairwise identities of >73% and >52%, respectively). A protein encoded next to the putative isethionate-metabolizing GRE/activase was also detected in high abundance only in isethionate-grown cells (Fig. 2B). This predicted substrate-binding protein (DctP) of a tripartite ATP-independent periplasmic transporter (Fig. 1B) may be involved in isethionate transport (SI Appendix, Fig. S2). We found highly similar gene clusters in the genomes of a wide range of sulfidogenic *Desulfovibrio* spp., including *Desulfovibrio faerleri*, *Desulfovibrio piger*, *Desulfovibrio termitidis*, *Desulfovibrio vulgaris*, and *Desulfovibrio ruminis*, as well as in the genomes of many *Desulfitobacterium*, *Desulfomicrobiurn*, and *Desulfotomaculum* strains (see below). The presence of the putative C-S bond-cleaving GRE in these organisms strongly implicates this enzyme in isethionate metabolism.

**Activities of Cell-Free Extracts and Genetic Knockouts Confirm the Proposed Organosulfonate Catabolic Pathways.** We next sought to further verify these proposed taurine and isethionate catabolic pathways by examining cell-free extracts of *B. wadsworthia* and *Desulfovibrio* spp. for the newly postulated enzyme activities. First, high specific activity of an NADH-coupled sulfite reductase was detected in extracts of taurine-grown *B. wadsworthia* cells (mean ± SD, 1.2 ± 0.12 U/mg; n = 5), with much less activity observed in extracts of isethionate-grown cells (<0.5 U/mg). Second, formation of sulfite and acetaldehyde, the predicted products of the isethionate sulfite-lyase reaction, was detected in extracts of the two *Desulfovibrio* strains when grown with isethionate only in the presence of isethionate as substrate. This activity—6.6 and 3.8 μM U/mg for strains DSM642 and G20, respectively, calculated from the rate of sulfite formation and for representative reactions shown in SI Appendix, Fig. S3—was observed only when great care was taken to perform the cell harvest, cell extract preparation, and the enzyme assays under strictly anoxic conditions in presence of a strong reducing agent, titanium(III) nitritrotriacetate (SI Appendix, Materials and Methods).

![Fig. 2.](image-url) Proteomics experiments with cell-free extracts reveal a putative desulfonating GRE. (A and B) Proteins encoded by the taurine and isethionate utilization gene clusters, including the predicted isethionate GRE (IslA) and GRE-activase (IslB) components, are specifically and strongly expressed during growth with taurine (*B. wadsworthia*) and isethionate (*B. wadsworthia*, *Desulfovibrio* strains). Constitutively expressed proteins for, for example, sulfite reduction (Dsr) and metabolism of acetyl-CoA (Pta and AckA), are shown for comparison. IMG locus tag numbers are given; their prefixes are shown in Fig. 1C. Shown are results of representative total proteomic analyses replicated at least twice with extracts prepared from independent growth experiments.
and Methods). The air sensitivity of this activity is consistent with involvement of a GRE. Strictly anaerobic extracts of taurine-grown B. wadsworthia cells also exhibited sulfite formation when exposed to isethionate as substrate (5.3 ± 0.8 mM for a representative reaction shown in SI Appendix, Fig. S3), indicative of a desulfonation reaction, but we were not able to detect acetacetaldehyde formation in these extracts (see below). When isethionate was replaced with taurine as a potential substrate for the GRE, no sulfite formation was observed. We also observed no sulfite formation in reactions additionally containing the cosubstrates needed to generate isethionate from taurine (pyruvate and NADH) in B. wadsworthia (Fig. 1B). In summary, we confirmed an oxygen-sensitive IslA activity in extracts of the two isethionate-grown Desulfovibrio strains and in taurine-grown B. wadsworthia, but we were not able to demonstrate desulfonation of taurine by successfully coupling all three enzymes of B. wadsworthia (Tpa, sulfoacetaldehyde reductase, and putative GRE) in cell-free extract under the conditions tested.

In addition, we confirmed that the genes encoding the putative isethionate-metabolizing GRE, activase, and other proteins encoded in the gene cluster are required for isethionate utilization by examining single-deletion strains from a D. alaskensis G20 transposon library (22). While wild-type and mutant strains grew equally well in media containing sulfite as the sole electron acceptor, knockout of any of the genes in the putative isethionate utilization gene cluster (activase and transporter genes) or of a predicted regulator gene (isiR) (Fig. 1C) abolished growth with isethionate (SI Appendix, Fig. S4), confirming that these genes are essential for the use of isethionate-derived sulfite, but not free sulfite, as an electron acceptor.

**In Vitro Reconstruction of Taurine Catabolism.** Having identified the complete pathways for taurine and isethionate metabolism in these strictly anaerobic bacteria, we sought to characterize the key enzymes from these processes in vitro. We first cloned and heterologously expressed the genes from the two B. wadsworthia gene clusters in Escherichia coli and purified the enzymes (SI Appendix, Fig. S5). We verified that aminotransferase Tpa catalyzes the deamination of taurine with pyruvate to generate sulfoacetaldehyde and alanine (28). We then confirmed that the putative sulfoacetaldehyde reductase SarD reduces sulfoacetaldehyde to isethionate in an NADH-dependent manner (SI Appendix, Figs. S6 and S7). SarD did not accept acetacetaldehyde as a substrate. Combining Tpa and SarD resulted in the conversion of taurine to isethionate via sulfoacetaldehyde as confirmed by LC-MS (SI Appendix, Fig. S8). Taken together, these results confirm that the SarD enzyme provides the link between taurine and isethionate catabolism in B. wadsworthia.

We then investigated the proposed C-S-cleaving GRE that generates sulfite, isethionate sulfite-lyase (IslA). The B. wadsworthia GRE-activating enzyme (IslB) was expressed, purified, and characterized under anaerobic conditions, whereas the B. wadsworthia IslA was expressed and isolated under oxic conditions and then rendered anaerobic (SI Appendix, Material and Methods). The purified activase IslB was reconstituted by reduction with dithionite (SI Appendix, Fig. S9) and then incubated with the purified GRE IslA in the presence of SAM and acriflavine as a photosensitizer. This installed the glyyd radical on 13 ± 0.1% (mean ± SD of three replicates) of all GRE polypeptides as determined by electron paramagnetic resonance spectroscopy (Fig. 3B). Incubation of the activated IslA with isethionate resulted in substrate consumption (SI Appendix, Fig. S10) and formation of sulfite (Fig. 3C) and acetacetaldehyde (Fig. 3D). No reaction was observed when oxygen was present or when the activase, GRE, or the substrate was omitted (Fig. 3 C and D). The steady-state kinetic parameters of the isethionate cleavage were determined spectrophotometrically using a coupled enzyme assay with yeast alcohol dehydrogenase (Fig. 3E). The apparent $k_{cat}/K_m$ was $1.8 \times 10^{3}$ M$^{-1}$ s$^{-1}$ under these conditions was lower than the catalytic efficiencies reported for other GRES (31, 32), but we did not detect turnover with any alternate organosulfonate (SI Appendix, Fig. S11) or with (S)-1,2-propanediol or choline as a substrate (SI Appendix, Fig. S12), strongly suggesting that isethionate is the native substrate. Characterization of the recombinant and reconstituted activase IslB and the GRE IslA of D. desulfuricans DSM642 yielded similar results, including selectivity for the cleavage of isethionate to sulfite and acetacetaldehyde, but a modest apparent $k_{cat}/K_m$ (1.2 x 10$^{-5}$ M$^{-1}$ s$^{-1}$) (SI Appendix, Fig. S13).

Finally, we examined the last putative enzyme from the B. wadsworthia taurine utilization pathway, AdhE. We found that the recombinant enzyme converted acetacetaldehyde to acetyl-CoA only in the presence of CoASH and NAD$^+$ (SI Appendix, Fig. S14); it preferred NAD$^+$ over NADPH. When we combined isethionate as substrate with activated GRE, NAD$^+$, CoASH, and AdhE, we observed formation of acetyl-CoA, as confirmed by LC-MS (SI Appendix, Fig. S14C). Hence, the work with recombinant enzymes confirmed all four reactions of the taurine pathway of B. wadsworthia 3.1.6 (Fig. 1B).

**Discussion.** Our efforts to decipher the molecular basis for the conversion of taurine to sulfite in strictly anaerobic gut bacteria has uncovered a previously uncharacterized GRE, isethionate sulfite-lyase (IslA) and its cognate activating enzyme (IslB). This enzyme catalyzes a radical-based desulfonation, generating acetacetaldehyde, \textbf{Fig. 3.} The B. wadsworthia GRE is a C-S bond-cleaving IslA. (A) The GRE-activating radical SAM enzyme IslB installs a protein-centered, stable glyyd radical within the GRE IslA. Activated IslA then catalyzes a C-S bond cleavage reaction with isethionate as the substrate. The mechanistic hypothesis is illustrated in SI Appendix, Fig. S1B. (B) Electron paramagnetic resonance spectroscopy demonstrating glyyd radical formation on recombinant produced and purified IslA after its activation by recombinant purified and reconstituted GRE-activase IslB. (C) Conversion of isethionate to sulfite by IslA was observed only in the absence of molecular oxygen and in the presence of all reaction components, as was acetacetaldehyde formation (D). The data in C are shown as the mean ± SD of three technical replicates, and data in D are shown as representative HPLC chromatograms of a minimum of two technical replicates. (E) The Michaelis-Menten kinetics of isethionate cleavage were determined by using a coupled spectrophotometric assay with yeast alcohol dehydrogenase and NADH. The $k_{cat}$ was 14 ± 0.4 s$^{-1}$, and the $K_m$ was 8.1 ± 0.8 mM. Data are shown as the mean ± SD of four technical replicates.
which can be further metabolized to acetyl-CoA, and sulfite, which can serve as a terminal electron acceptor. The reaction mechanism for isethionate desulfonation by the GRE IslA (Fig. 3A) may proceed in analogy to the mechanisms proposed for 1,2-propanediol dehydratase (PD) and CutC, which have been supported experimentally (33, 34). This proposed mechanism would involve an initial hydrogen atom abstraction to form an α-hydroxyalkyl radical at C₁ of isethionate, followed by a spin-center shift to eliminate the C₁ sulfonate group (SI Appendix, Fig. S1B). As this type of C-S bond-elevage reaction was not previously known to be catalyzed by GREs, the discovery of IslA further diversifies the known repertoire of radical reactions catalyzed by this superfamily (29) and adds to the limited number of characterized microbial desulfonative enzymes (17, 35), including Xsc (EC 2.3.3.15) (Fig. 1A), cysteate (3-sulfoalanine) sulfite-lyase (CuyA) (EC 4.4.1.25), 3-sulfolactate sulfite-lyase (SuyAB) (EC 4.4.1.24), and the range of mono-oxygenases and dioxygenases (EC 1.14.-) desulfonating aromatic and aliphatic sulfonates in aerobic bacteria (36).

Remarkably, the logic of the two catabolic pathways that ultimately cleave taurine to acetyl-CoA and sulfite (Fig. 1B), either in the absence of molecular oxygen in strictly anaerobic bacteria by the highly oxygen-sensitive GRE IslA or in aerobic bacteria via the oxygen-insensitive TDP-dependent Xsc, parallels the catabolism of pyruvate to acetyl-CoA in E. coli. During anaerobic fermentation, E. coli can use the GRE pyruvate formate-lyase (37), while during aerobic respiration, this enzyme is replaced by a TDP-dependent, oxygen-insensitive pyruvate dehydrogenase. Furthermore, the observation that anaerobic D. thiosulfatigenes GKTNAU, which is highly specialized for taurine fermentation (19), uses an Xsc enzyme (18), while B. wadsworthia uses IslA for the respiration of the sulfite from taurine with external electrons such as from lactate or H₂ (38), may point to an interesting adaptation for maintaining redox balance under these different anaerobic growth conditions.

Searches for additional putative IslA enzymes in sequenced microbial genomes revealed more than 250 sequences in the National Center for Biotechnology Information’s nonredundant protein database (>35% amino acid identity to the B. wadsworthia sequence). A total of 115 of these sequences clustered together with the B. wadsworthia and the Desulfovibrio IslA sequences in a shared similarity network at a threshold of 62% (SI Appendix, Fig. S1A) (32) and thus are likely to process isethionate or similar organosulfonate substrates. Bioinformatic analyses revealed distinct distinctions between these sequences and GREs of known activity. For example, comparison of the sequences of characterized and putative IslAs with the sequences of other characterized GREs revealed a unique conserved glutamine residue (Q193) positioned to interact with the sulfite-leaving group in a homology model (29) (SI Appendix, Figs. S15 B and C). Furthermore, phylogenetic analysis (Fig. 4A) reveals IslA to be part of a deeply branching group of sequences previously designated as “GREs of unknown function” that typically are not colocalized with genes encoding bacterial microcompartment structural proteins (39). We note that while IslA homologs are found predominantly in Deltaproteobacteria, these enzymes are also encoded in the genomes of many Firmicutes (Clostridia, Negativicutes), as well as in several Gammaproteobacteria and Bacteroidetes (Fig. 4B and SI Appendix, Table S1). This observation suggests that anaerobic organosulfonate catabolism may be more widely distributed across microbial diversity than previously appreciated, and evaluating these organisms’ ability to metabolize isethionate, taurine, or other organosulfonates are important topics for future research.

Finally, the discovery of this gut microbial metabolic process reshapes our view of organosulfonate utilization in the human gut microbiota and unlocks new opportunities for investigating its contribution to human disease. Microbes derive several benefits from resiping organosulfonates, including the ability to occupy distinct metabolic niches. Compared with sulfate reduction, ATP expenditure is not required for generating sulfite as an electron acceptor (Fig. 1B). Notably, the two Desulfovibrio strains down-regulate APS reductase during isethionate utilization (Fig. 2B), while B. wadsworthia is unable (or has lost the ability) to use sulfite (10). Furthermore, many sulfite-respiring bacteria exhibit a hydrogenotrophic lifestyle in the human gut (11, 23, 38), and in this respect, the taurine/isethionate pathway can serve both dissimilatory and assimilatory functions when the acetyl-CoA produced from isethionate is funneled directly into gluconeogenesis (Fig. 1B).

The widespread distribution of these anaerobic taurine and isethionate pathways in microbiota-relevant sulfidogenic bacteria indicates an important role for organosulfonate respiration in this microbial habitat, potentially in the context of competition with sulfate-reducing bacteria and methanogenic archaea for the H₂ produced by gut bacterial fermentation (23), or in the context of high availability of these organosulfonate substrates during consumption of high-fat (high taurocholate) (15) and/or high-meat (high taurine) diets (40). Furthermore, given that taurine is present in high concentrations in mammalian tissues (2–20 mM) (41), this pathway also may be important for B. wadsworthia pathogenesis.

Fig. 4. Anaerobic organosulfonate metabolism has an unexpectedly broad distribution in sequenced bacteria. (A) A maximum likelihood phylogenetic tree illustrating that the IslAs are phylogenetically distinct from previously characterized GREs. The listed sequence identifiers are GenBank accession codes. (B) Illustration of the distribution of 115 putative IslAs, as retrieved from the National Center for Biotechnology Information database at a threshold of 62% identity across sequenced bacterial genomes (SI Appendix, Table S1). The pie chart showing their relative taxonomic distribution on the phylum level (outer ring) demonstrates that the majority are found in genomes of Proteobacteria and Firmicutes, and at the class level (inner circle), that they are distributed predominantly across Deltaproteobacteria, Clostridia, and Negativicutes. The percentages shown in brackets indicate (at the class level) the number of genomes with putative IslAs relative to all known genome sequences for this class, confirming the enrichment of IslAs in the Deltaproteobacteria (encoded in 25% of all known genomes).
The discovery of the molecular basis for taurine metabolism in this organism and other gut microbes will not only enable future efforts to understand the biological roles of this metabolic activity in the human body, but also may inform new approaches to controlling intestinal H2S production and B. wadsworthia infections.

Materials and Methods

The materials and methods used in this work are described in detail in SI Appendix, Materials and Methods. The Bilophila and Desulfovibrio strains were grown in carbonate-buffered mineral salts medium reduced with Ti (III)-nitrilotriacetate. Cell-free extracts were prepared by French press disruption followed by centrifugation to remove unbroken cells; these extracts were used for proteomics analysis and measurement of Tpa, SarD, and iSLAB activity. Sulfite was detected by a colorimetric (fuchsin) assay as well as by HPLC after derivatization, and acetaldehyde was detected by HPLC after derivatization. A hydrophilic interaction liquid chromatography column and HPLC-MS system was used to detect taurine, alanine, sulfoacetaldehyde, and isethionate. His-tagged Tpa and SarD were produced using E. coli Rosetta 2 DE3 and the His-tagged GREs, AdhE, and DctP using E. coli BL21. The His-tagged GRE activating enzymes were overexpressed in E. coli BL21(DE3) J53R::kan. Before induction, these cultures were rendered anoxic by sparging argon.

ACKNOWLEDGMENTS. We thank Emma Allen-Vercoe for kindly providing B. wadsworthia 3.1.5, Adam Deutschbauer and Jennifer Kuehl for kindly providing the D. alaskensis G20 mutant strains, Patric Cao for help with characterizing the Bilophila pathway, Benjamin Levin for construction of the jscR expression strain and synthesis of (S)-1,2-propanediol, Andreas Marquardt for proteomic analyses, Dieter Spiteller for LC-MS support, and Thomas Hucker for chemical synthesis. We acknowledge helpful discussions with Paul Boudreau, Alasdair Cook, Stefan Kretz, and Bernhard Schink, and the helpful input offered by the anonymous reviewers of this manuscript. The work of A.B. and D.S. was funded by the German Research Foundation (DFG Grants SCHL1936-3/4), the University of Konstanz (Young Science, SACH), and Konstanz Research School Chemical Biology (KoRS-CB). The work of S.C.P. and E.P.B. was funded by the Bill & Melinda Gates Foundation (Howard Hughes Medical Institute-Gates Faculty Scholar Award), and the work of S.M.I. was funded by the NSERC Postgraduate Scholarship Doctoral Program.
