Keywords: Arabidopsis thaliana, bioengineering, ethylene, hormone receptor, phytohormone, plant hormone, signaling, signal transduction, constitutive triple response1 (CTR1), ethylene insensitive2 (EIN2)
Ethylene (IUPAC name ethene) is the simplest olefin gas and was the first gaseous molecule shown to function as a hormone (1). It is biosynthesized by plants and is well-known to affect various developmental processes such as seed germination, fruit ripening, senescence, and abscission as well as responses to various stresses such as flooding, high salt, and soil compaction (2,3). The ethylene signal transduction pathway has been extensively studied, in part because ethylene affects so many traits related to plant vigor and postharvest physiology and storage.

Once biosynthesized, ethylene diffuses throughout the plant and binds to ethylene receptors to stimulate ethylene responses. It can also diffuse to surrounding plants and is the basis of the saying *one bad apple spoils the bunch* where ethylene produced by an apple hastens the ripening of bananas. The ethylene signaling pathway was predominantly delineated with research on *Arabidopsis thaliana* and is comprised of a combination of components that is not found in other pathways. This review will mainly focus on this research using *Arabidopsis*. However, it is worthwhile pointing out that similar signaling pathways occur in diverse plants (4-11) so that information from *Arabidopsis* about ethylene signaling is usually applicable to other species.

Early molecular genetic studies uncovered several key components for ethylene signaling including a family of receptors, the CTR1 protein kinase, EIN2 which is a transmembrane protein of unknown biochemical activity, and transcription factors such as EIN3, EILs, and ERFs. This led to a linear, genetic model where in the absence of ethylene the receptors activate CTR1, which negatively regulates downstream signaling (Fig. 1). Ethylene functions as an inverse agonist by inhibiting...
the receptors leading to release of inhibition by CTR1 resulting in ethylene responses (12). This genetic model provided a general framework that has been refined with further research resulting in a more complete and detailed model for ethylene signaling including surprising cases of cross-talk from the receptors to other signaling pathways, details for how a signal perceived at the ER membrane affects transcription in the nucleus, and multiple roles for EIN2. Details from this research have led to various ways to control ethylene signaling. Most of these controls are geared towards inhibiting ethylene responses to prevent post-harvest spoilage. However, there is also a need for stimulating ethylene responses such as to cause premature germination of parasitic plants so that fields can be cleared of these problematic plants. These discoveries and applications will be summarized in this review.

**Ethylene signaling components and the canonical pathway**

The first step in ethylene perception is the binding of ethylene to receptors. Ethylene receptors have homology to bacterial two-component receptors that signal via autophosphorylation on a histidine residue followed by phosphotransfer to an aspartate residue in the receiver domain of a response regulator protein (13). Ethylene receptors, as well as other two-component-like receptors such as the phytochromes and cytokinin receptors, are believed to have been acquired by plants from the cyanobacterium that gave rise to chloroplasts (14-18). Data from a recent phylogenetic analysis suggests a common origin for the ethylene binding domain in cyanobacteria and plants (19). It is thus interesting to note that ethylene binding has been observed in diverse cyanobacteria and at least one cyanobacterium, *Synechocystis*, has a functional ethylene receptor that regulates cell surface properties to affect biofilm formation and phototaxis (20-22). Additionally, ethylene binding affinities to some of these cyanobacteria and the heterologously expressed *Synechocystis* ethylene receptor are similar to what has been observed in plants (23) showing a conservation of this domain between these organisms. However, the organism where ethylene receptors first arose remains unknown. The observation that genes encoding for proteins with putative ethylene binding domains are found in other phyla of bacteria (22) will make answering this question difficult.

By contrast, as will be discussed in more detail below, even though some of the plant ethylene receptor isoforms have retained histidine kinase activity, this activity is not crucial for ethylene perception. This is in contrast to the one cyanobacterial system so far characterized where phosphotransfer is central to the function of the receptor (22,24,25). Additionally, some plant ethylene receptor isoforms have serine/threonine kinase activity indicating that the outputs of these receptors in plants are now diverged from the ancestral proteins. Recent reviews present more information about ethylene receptors in non-plant species (26,27).

Plants contain multiple ethylene receptor isoforms. Early studies identified ethylene-binding sites in the ER membranes of plants (28,29) and subsequent research on specific receptor isoforms from various plants confirmed that ethylene receptors are localized to the ER (30-35). In *Arabidopsis*, five isoforms have been identified and are referred to as ethylene response1 (ETR1), ethylene response sensor1 (ERS1), ETR2, ERS2, and EIN4 (36-40). Mutations in any one of these receptors that prevent ethylene
binding leads to an ethylene-insensitive plant (12,20,36,37,41). There are also some mutations in these receptors that have no effect on ethylene binding, but prevent signaling through the receptor, which also leads to ethylene insensitivity (20).

The different receptor isoforms in plants have similar domain architecture (Fig. 2) with three transmembrane α-helices at the N-terminus, which comprises the ethylene binding domain, followed by a GAF (for cGMP-specific phosphodiesterases, adenylyl cyclases, and FhlA) and kinase domain. Three of the five receptors also contain a receiver domain that is similar to what is found in bacterial two-component receptors (42,43). The receptors fall into two subfamilies with ETR1 and ERS1 in subfamily 1 and the other three isoforms in subfamily 2 (20). The subfamily 2 receptors contain additional amino acids at the N-terminus that are unknown in function. The receptors can be further distinguished by their kinase activity. ETR1 has histidine kinase activity, whereas, ETR2, ERS2, and EIN4 have serine/threonine kinase activity and ERS1 has been documented to have both depending on assay conditions, although, it is believed to be a serine/threonine kinase in vivo (44,45).

The receptors form homodimers that are stabilized at their N-termini by two disulfide bonds (46-48). Nevertheless, these disulfide bonds are neither necessary for binding of ethylene to ETR1 (48), nor for a functional ETR1 receptor in planta (49). In ETR1 it is thought that dimerization between monomers also occurs between the dimerization and histidine phosphotransfer (DHp) domains of each kinase domain (43). It is unclear if dimerization between kinase domains of the other receptor isoforms occurs. It has also been suggested that heterodimers are possible (35,50). Evidence that these are receptors is that all of these proteins bind ethylene with high affinity (41,47,51,52) and specific mutations in any one of these proteins leads to ethylene-insensitivity (36,38-40,53). Similar proteins from tomato also bind ethylene with high affinity and when mutated lead to ethylene insensitivity (51,54-56).

Ethylene binds to the N-terminal, transmembrane portion of heterologously expressed receptors with \( K_d \) values reported in the nM range (21,41,52), which corresponds to ethylene binding affinities reported in plants (57-64). One difference between heterologously expressed receptors and those in planta is that ethylene dissociates from the former with a single, slow rate having a half-time of release of approximately 10-12h (41,51,52), whereas, there are two rate constants of release in planta (64,65). In planta, there is an initial, rapid release of ethylene in the first 30 minutes after ethylene removal, followed by slow release with similar kinetics to the heterologously expressed receptors. Since ethylene can enhance the proteolysis of ethylene receptors (31,66,67), this rapid release of ethylene from receptors in plants is likely due to proteolysis of the ethylene-bound receptors.

The cytosolic domains of ETR1 have been structurally characterized (42,43,68). This has led to a model of the ETR1 dimer where the DHp domain of the histidine kinase domain dimerizes with the DHp of the other monomer (Fig. 2). In this model, the catalytic domain associates with the DHp domain. The catalytic and receiver domains are modeled to extend outward from the DHp pair. The orientation of the receiver domain in relationship to the remainder of the protein is predicted to be different from prokaryotic histidine kinases suggesting that this domain may be diverged in function.
from prokaryotes (68). Additionally, structural studies show that the γ-loop of ETR1, which is part of the catalytic region of receiver domains, is in a different orientation from characterized prokaryote receiver domains (42,68). No structural information is published characterizing the ethylene-binding domain, but a computational model is available (69). This study coupled with prior research (20) suggests that ethylene binds in the middle of helices 1 and 2 and the signal is transduced via helix 3. The mechanistic details of this transduction through the receptor are unknown.

A key issue in ethylene signaling has been to determine how proteins bind ethylene with high affinity and mutational studies have identified amino acids in helices 1 and 2 that are important for ethylene binding (20,21,41). Based on olefin chemistry, several transition metals were initially suggested as cofactors for binding activity (70-73). It was later determined that ETR1 coordinates copper ions which act as the cofactor for ethylene binding (21). Cys65 in helix 2 is required for coordination of copper since the etr1-1 mutant receptor with a Cys65Tyr mutation is unable to bind copper or ethylene (21,36,37,41). Mutants such as this render the plant ethylene insensitive. Additionally, several studies have determined that the ER membrane-localized copper transporter, responsive to antagonist1 (RAN1), physically interacts with at least some of the receptors and is needed for delivery of copper and proper biogenesis of the ethylene receptors (74-78). Because copper co-purifies with the ETR1 dimer with a 1:1 stoichiometry, it was long thought that each receptor dimer contains one copper ion (21). Recent experimental evidence, however, indicates that there are two copper ions per receptor dimer that are modeled to be coordinated by amino acids in helices 1 and 2 of each monomer (69).

The biochemical output of the receptors has yet to be determined. The GAF, kinase, and receiver domains are the likely output domains, but the specifics of how ethylene signal is transduced are unknown. This is complicated by research showing that even though the receptors have overlapping roles for many traits, for specific traits or under specific conditions individual receptor isoforms have a role, whereas, others do not (52,79-87). In some cases, individual isoforms display opposite roles from other isoforms. For instance, ETR1 is necessary and sufficient for ethylene-stimulated nutational bending of hypocotyls in dark grown Arabidopsis seedlings, whereas, the other four receptor isoforms have a role, whereas, others do not (52,79-87). Ethylene receptors are homologous to bacterial two-component receptors. The simplest bacterial two-component system signals by histidine autophosphorylation followed by relay of the phosphoryl to a conserved aspartate on a receiver domain of a response regulator protein, although, more complex variations of this exist (13).
Despite the fact that ETR1 possesses histidine kinase activity that is modulated by ethylene (44,45,88), this activity is not required for responses to ethylene (89,90). Rather, it may subtly modulate receptor signaling to downstream components (81,89,91-93) including interactions with EIN2 (94). Similarly, receptor serine/threonine kinase activity does not appear to be required for ethylene responses, but may have a modulatory role in ethylene receptor signal transduction and responses (95).

Complexes of receptor dimers have been proposed to explain the large range of ethylene concentrations that plants respond to and to explain how one mutant receptor might affect other, non-mutant receptors (48,49,96-100). As an example, plants can respond to ethylene at levels down to 0.2 nL L⁻¹ (101), which is at least 300-fold below the Kᵰ of binding to the receptors (41). Receptor dimer clusters are proposed as a way for signal amplification to occur, much like how bacterial chemoreceptors function. In chemoreceptors, ligand binding to one receptor dimer can affect the signaling state of neighboring, unbound receptor dimers to increase signal output (102,103). Structural studies suggest that CTR1 or the receptor receiver domains or both, may be involved in the formation of ethylene receptor clusters (43,104). It remains to be determined if this is important in ethylene signaling.

The receptors also form higher order complexes with other proteins (48). Specific proteins have been identified as interacting partners with all or a subset of the ethylene receptors. This includes interactions with RAN1 which may be important for correct delivery of copper to the receptors (78). Other interacting partners are less characterized. Reversion to ethylene sensitivity1 (RTE1) interacts with ETR1 and tetratricopeptide repeat protein1 (TRP1) with ERS1 to modulate signaling (34,105-107). A homolog of TRP1 in tomato interacts with both SIETR1 and never ripe (NR or SIETR3)(108). As will be discussed more later, some of the receptors also interact with components of the cytokinin signaling pathway (105,106,109-111).

Two proteins, CTR1 and EIN2, are central components of ethylene signaling (112,113) that physically interact with the receptors (33,94,114-118) and each other (119). CTR1 is a serine/threonine protein kinase that functions as a negative regulator of ethylene signaling (113). EIN2 is required for ethylene signaling and is part of the NRAMP (for natural resistance associated microphage protein) family of metal transporters; it is comprised of a large, N-terminal portion containing multiple transmembrane domains in the ER membrane and a cytosolic C-terminal portion (112). In the case of ETR1, the kinase domain of the receptor is required for interactions with both CTR1 and EIN2, although, ETR1 histidine kinase activity is only important for modulating interactions with EIN2 (94,117,120). These physical interactions appear to be important since mutations in CTR1 that abolish receptor-CTR1 interactions result in a non-functional CTR1 (117,118) and blocking interactions between ETR1 and EIN2 results in ethylene insensitivity (121).

Current models predict that in the absence of ethylene the ethylene receptors keep CTR1 active (Fig. 3), CTR1 directly phosphorylates EIN2 (119) which may result in EIN2 ubiquitination via an Skp1 Cullen F-box (SCF) E3 ubiquitin ligase complex containing the EIN2-targeting protein1 (ETP1) and ETP2 F-box proteins and subsequent proteolysis by the 26S proteasome (122), as hypothesized in several
OsEIN2 abundance; similar genes have been tested. Ethylene enhances the interaction between ETR1 and both CTR1 and EIN2 (66,94,117). Thus, an alternative explanation for reduced EIN2 phosphorylation by CTR1 is that the binding of ethylene to the receptors results in conformational changes in the receptors that reduces the physical interaction between CTR1 and EIN2 leading to less EIN2 phosphorylation. It is thought that when EIN2 phosphorylation is reduced there is less EIN2 ubiquitination resulting in an increase in EIN2 levels and subsequent cleavage of EIN2 by an unknown protease to release the C-terminal portion of EIN2 (EIN2-C) from the membrane bound N-terminal (EIN2-N) portion (119,122,124,125).

The role of EIN2-N is unknown, but it has diverged from other NRAMP proteins since no metal transport activity has been detected in heterologously expressed EIN2 and it cannot rescue yeast deficient in metal uptake (107,112). However, there are hints that EIN2-N has a role in ethylene signaling. In rice, mao huzi3 (mhz3) mutants are ethylene insensitive and the MHZ3 protein physically interacts with OsEIN2-N and regulates OsEIN2 abundance; similar genes have been identified in Arabidopsis that affect ethylene signaling (131,132). These data indicate the need to further study EIN2-N to delineate the mechanism by which it affects ethylene signaling.

By contrast, EIN2-C has two known roles. One is to bind the mRNAs that encode for EBF1 and EBF2, whereupon, this protein/RNA complex associates with processing bodies (133,134). This results in the degradation of these mRNAs by exoribonuclease4 (XRN4, also known as EIN5), which is a 5’ → 3’ exoribonuclease known to affect ethylene signaling (133-136). A consequence of the degradation of EBF1 and EBF2 mRNA is that degradation of EIN3 and EIL1 and probably EIL2 is reduced leading to more ethylene signaling (126,128,129). EIN2-C also contains a nuclear localization sequence (NLS). EIN2-C diffuses into the nucleus where it associates with EIN2 nuclear associated protein1 (ENAP1) which is required for the ability of EIN2-C to regulate EIN3-dependent transcription (137). Thus EIN2-C provides both transcriptional and translational control to regulate EIN3 and the related EIL1 transcription factor to cause most ethylene responses. This is supported by a recent study where ethylene-stimulated changes in the metabolome did not always correlate with changes in the transcriptome (138). The exception to this model is that short-term, transient responses occur independently of these transcription factors, yet require EIN2 (101). Thus, there are more functions for EIN2 that have yet to be discovered.

The increase in EIN3, EIL1, and EIL2 activity caused by EIN2-C leads to changes in the transcription of other ethylene response genes, including other transcription factors such as the ERFs (139-141). Recent studies have identified histone modifications...
as having a role in this transcriptional control. Mutational experiments revealed that several histone acetyl transferases and histone deacetylases affect ethylene signaling (142-144). Additionally, research has identified specific histone acetylation marks that are important in ethylene-regulated gene expression by EIN3 (145-147). Even though more details about transcriptional regulation are being discovered, it is also clear from a recent metabolome study that changes in metabolism occur in response to ethylene that are not predicted by changes in the transcriptome (138). This indicates that there is additional regulation for responses to this hormone.

In summary, the model for the canonical ethylene signaling pathway has developed from a simple genetic model to a more complex model with many more biochemical details. However, there are still gaps in our understanding of this signal transduction pathway.

**Non-canonical signaling**

The model discussed above is largely linear and it summarizes the main pathway by which ethylene affects plants. Nonetheless, it is clear from diverse studies that the ethylene signaling pathway involves feedforward and feedback regulation leading to sensitization and adaptation (101,148-160). Most of this research has identified adaptation mechanisms at the level of the receptors. For instance, the levels of the receptors themselves can regulate sensitivity where higher levels lead to less sensitivity and lower levels to more sensitivity (89,90,114,161-164). However, it is also now clear that other proteins affect sensitivity at the levels of the receptors. This includes negative regulation by RTE1 and the family of proteins called auxin-regulated gene involved in organ size (ARGOS) (149,154,165,166). An RTE1-like protein, green ripe (GR), has a similar role in tomato (166). The exact mechanisms for regulation by these proteins are under investigation. More information about this is contained in a recent review (167).

The existence of non-linear components to what has been considered the canonical pathway raises the possibility that other ethylene signaling pathways exist outside of or as branch points from this core pathway. This is an area of active research and in the cases discussed below, evidence is provided showing that signaling occurs, at least in part, via components not contained in the canonical pathway presented above. These alternative (non-canonical) pathways are not necessary for ethylene responses, but appear to have roles in modulating responses to ethylene or in altering responses to other hormones.

Results from several studies have led to the suggestion that the ethylene receptors signal independently of CTR1 or EIN2 (44,80,82-85,168-170). For instance, epistasis analysis has shown that the role of ETR1 and ETR2 in the control of seed germination by ABA is, at least in part, independent of CTR1 (84). It is possible that such alternative signaling occurs via CTR1 homologues, but so far no CTR1 homologue has been identified as being involved in this. Even though ETR1 histidine kinase activity is not required for ethylene signaling, this activity does modulate sensitivity to ethylene, growth recovery kinetics when ethylene is removed, growth of root apical meristem, seed germination under stress conditions or in response to ABA, and interactions with EIN2 (81,83,84,89-91,93,94,111). Likely targets for phosphorelay from ETR1 are components of the cytokinin signaling pathway (Fig. 1). The cytokinin receptors
are two-component receptors in plants that, unlike the ethylene receptors, use phosphorelay as the primary route for signaling (18,171). In this pathway, the phosphoryl is transferred from the cytokinin receptors to histidine-containing phosphotransfer proteins (AHP family in Arabidopsis) and finally to response regulator proteins (ARR family in Arabidopsis) that function as transcription factors. Various studies have demonstrated that ETR1 physically interacts with ARR and AHP proteins (109-111,172). This interaction involves the C-terminal portion of ETR1 (109,111). The affinity between ETR1 and AHP1 is altered by their phosphorylation state where it is highest if one protein is phosphorylated and the other is not (172).

Support that interactions between ETR1 and the cytokinin pathway have functional consequences is that mutational analyses revealed that the ARRs are involved in ethylene responses such as sensitivity to ethylene, recovery kinetics after ethylene is removed, stomatal aperture control, and the regulation of root apical meristem (92,93,111,173). Null mutants of ARRI are less responsive to ethylene and this appears to depend upon ETR1 histidine kinase activity (93). Similarly, null mutants in several AHPs and ARRs prolong growth recovery when ethylene is removed similar to what is observed in plants deficient in ETR1 histidine kinase activity (81,92). Additionally, ETR1 histidine kinase activity is involved in both ethylene- and cytokinin-induced changes in root apical meristem (111). Together, these results are consistent with a model where ETR1 histidine kinase activity is directly involved in affecting components of the cytokinin pathway resulting in changes in transcription that modulate ethylene responses (Fig. 3). There is some overlap between transcriptional changes caused by ethylene and cytokinin (174), raising the possibility that there are both overlapping and non-overlapping targets of transcriptional control from this signaling pathway involving ETR1 histidine kinase and the well-known pathway involving EIN3 and EILs. It is interesting to note that in rice, a histidine kinase (MHZ1/OsHK1) that may have a role in cytokinin signaling functions downstream of the OsERS2 ethylene receptor and signals independently of OsEIN2 (175). Thus, our model for canonical ethylene signaling probably needs to be expanded to include secondary pathways such as phosphorelay from some of the ethylene receptors to the AHPs and ARRs.

It should be noted that biochemical experiments show ETR1 histidine autophosphorylation decreases upon binding of ethylene or ethylene receptor agonists (88,94), whereas, genetic experiments suggest ethylene leads to more phosphotransfer (81,89). Histidine kinases can carry out multiple enzymatic reactions including kinase, phosphatase, and phosphotransfer reactions and receiver domains can catalyze both phosphotransfer and autodephosphorylation reactions (13,176). Given this complexity, one possible resolution to this discrepancy between biochemical and genetic data is that histidine autophosphorylation occurs in the absence of ethylene, but phosphotransfer to the receiver domain does not occur until ethylene binds to the receptor to bring the DHp (site of histidine phosphorylation) and receiver domains into the correct orientation. Thus, ethylene may be increasing phosphotransfer through the pathway causing the steady-state level of ETR1 histidine phosphorylation to decrease. This will only be answered conclusively when we have structural data.
Non-canonical signaling is also likely to occur downstream of the receptors. For instance, PpCTR1 in *Physcomitrella patens* has a role in both ethylene and ABA signal transduction raising the possibility that CTR1 has more functions than simply phosphorylating EIN2 (177). Also, mutants of EIN2 have altered responses to various hormones (Reviewed by 178), but whether this reflects alternative signaling from EIN2 or is due to many pathways converging on EIN2 has yet to be completely explored.

The signaling pathway downstream of EIN2 is complex since it involves at least two levels of transcriptional regulation. Because of this, it is harder to distinguish “canonical” from “non-canonical” signaling. EIN3 is the transcription factor with the largest role in ethylene signaling (128,139) and it homodimerizes to interact with its target DNA (141). However, environmental factors such as dark versus light or the presence of other hormones can affect this so that depending on conditions, EIN3 interacts with other transcription factors leading to outputs not predicted by the common ethylene signaling models (179-181). As an example, ethylene is well known for inhibiting hypocotyl growth in dark-grown eudicot seedlings (36,182) and stimulating hypocotyl growth in the light (183-187). In the dark, EIN3 directly interacts with another transcription factor, phytochrome interacting factor3 (PIF3), forming an output module distinct from either transcription factor alone (181). A recent meta-analysis of transcriptomic datasets comparing ethylene responsive genes in the light versus the dark uncovered a set of genes that were similarly regulated in both conditions, but also many that were differentially regulated (188). It will be interesting to determine which of these differentially regulated transcripts are controlled by this EIN3/PIF3 module.

The above summarizes evidence that specific ethylene receptor isoforms signal to affect other hormone pathways such as cytokinin and ABA. The exact pathways for this have yet to be delineated, but it appears that at least some of these roles are independent of CTR1. This also raises the interesting possibility that the ethylene receptors are affecting other signaling pathways via yet to be discovered mechanisms. Additionally, environmental factors can affect the output of this pathway adding an additional layer of complexity to understanding all the nuances of how ethylene signaling occurs and how we can manipulate this signaling.

**Regulating Ethylene Signal Transduction for Agricultural and Horticultural Uses**

As can be seen from the information provided above, our understanding about the signaling pathways for the perception of ethylene has grown and become increasingly complicated. This increased complexity provides challenges in determining how to modulate responses to ethylene for commercial purposes. But, it also provides opportunities to perhaps modulate specific responses without off-target outcomes.

It is likely that comparable signaling pathways to those outlined above in *Arabidopsis* also occur in most land plant species since similar genes have been uncovered in diverse plants including rice, tomato, strawberry, the clubmoss *Selaginella moellendorffii*, and the moss *Physcomitrella patens* (4-11). However, it is important to keep in mind that there are also likely to be variations on this general signaling pathway that occur from species to species that need to be taken into account when trying to manipulate ethylene responses. Because ethylene affects many processes that are important in horticulture...
and agriculture, a great deal of research has used the information outlined above to develop ways to regulate ethylene signal transduction. Even though ethylene itself is used for some applications, such as to cause uniform fruit ripening, most applications involve minimizing ethylene signaling. These approaches have generally been either genetic or chemical in nature.

Early attempts to bioengineer plants that do not respond to ethylene involved the heterologous expression of the Arabidopsis etr1-1 gene, which as mentioned above contains a mutation that leads to ethylene insensitivity in Arabidopsis. Heterologous etr1-1 expression leads to ethylene insensitivity and reduced flower senescence and longer vase life in several plant species, delayed fruit ripening in tomato and melon, and altered regeneration in lettuce leaf explants (189-197). It is likely that any ethylene-insensitive receptor transgene will have similar outcomes since Nemesia strumosa flower life was extended when heterologously expressing a cucumber etr1-1 homolog (198). A drawback of constitutive expression of ethylene receptor mutants that cause ethylene insensitivity is unintended effects which can have adverse agricultural and horticultural outcomes. These adverse outcomes include increased stress in tomato plants, increased pathogen susceptibility in tobacco, reduction in seed germination, pollen viability, number of adventitious roots and root performance in petunias, and reduced femaleness in melon flowers (194,195,199-203). These unwanted effects reduce the efficacy of this approach for commercial use.

One potential way around this is to target etr1-1 or other similar receptor mutant that causes ethylene insensitivity to tissues of interest. For instance, flower-specific expression of etr1-1 reduced flower senescence and increased flower life of two plant species (189,190,204). A potential problem with this approach is that ethylene insensitivity can lead to increased biosynthesis of ethylene (36), which in turn could affect tissues not expressing the mutant receptor (194). Another way to address these issues is to use an inducible promoter for heterologous expression of the mutant receptor. Relevant to this is the observation that some ethylene receptors are ethylene-inducible including ETR2 from Arabidopsis and NR from tomato (51,54). Both etr2-1 and nr mutants contain point mutations that result in ethylene insensitive plants with long-term ethylene treatments (40,54). However, both show a transient response to ethylene and only become insensitive to ethylene when levels of the mutant receptor increase due to increased ethylene levels (205). Thus, controlling mutant receptor expression with inducible heterologous gene expression could provide control over both the timing and amount of expression. This has been used in tomato to delay ripening (206), but it remains to be determined whether or not this reduces the severity of unwanted effects from the transgene.

Another alternative is to find mutants in other genes that affect ethylene signaling. For instance, down-regulation of SIEIN2 in tomato results in inhibition of ripening (207,208). One ethylene signaling mutant that alters ripening is in the GR gene in tomato which has homology to RTE1 in Arabidopsis (165,166). A drawback is that it requires overexpression of GR to inhibit ripening in tomato (209) leading to similar issues outlined above for heterologous expression of genes. Fruit ripening, as with other developmental processes, is complex and is regulated by a network of transcription factors (210). Thus, to avoid unwanted effects of mutations, it may be
necessary to target specific transcription factors for mutagenesis to regulate specific traits affected by ethylene, without altering other responses to this hormone. For instance, virus-induced gene silencing of SlEIN3 leads to delayed tomato fruit ripening, but no other traits were analyzed to determine if there were detrimental outcomes (211). This will require more research to link specific transcription factors with specific ethylene-related traits.

Research has also focused on developing chemicals that can regulate ethylene signal transduction. Silver has long been known to block ethylene responses in plants (73). Silver ions are larger than copper ions (212-214), yet support ethylene binding to heterologously expressed ETR1 (21,215). This led to an early hypothesis that silver ions replace the copper in the ethylene binding site of the receptors allowing for ethylene binding, but preventing stimulus-response coupling through the receptors because of steric effects (21,99,215,216). This model may be incorrect since silver largely functions via the subfamily I receptors, in particular ETR1 (49,52,114). Also, silver functions as a non-competitive inhibitor suggesting that it binds to a site other than the ethylene binding site to inhibit the receptor (52,73). Although, it is possible that silver has the characteristics of a non-competitive inhibitor yet acts at the ethylene binding site (217). Even though silver ions are effective at blocking ethylene responses in plants, the adverse human health and environmental effects of silver limits its use. Additionally, silver has off-target effects such as altering auxin transport (218).

Because of this, other compounds have been developed. Strained alkenes such as cyclic olefins can inhibit ethylene binding and action (219) and they have been studied for commercial use (examples in Fig. 4). They have also been used to characterize the ethylene-binding site of the receptors. For instance, even though ethylene is a symmetric molecule, the use of different enantiomers of trans-cyclooctene, a competitive antagonist of ethylene receptors, showed that the ethylene binding site is asymmetric (220). Of these cyclic olefins, 1-methylocyclopropene (1-MCP) has a high binding affinity to the ethylene receptors and has been patented (221-223). Even though it is gaseous, it has become commercially successful because a solid formulation was developed where 1-MCP is released when the formulation is dissolved in water. This effectively blocks ethylene responses and is currently used to prolong the storage life of a variety of produce (224). Because the active component is a gas, its use is generally limited to enclosed spaces, such as for post-harvest storage.

Since gaseous compounds cannot easily be used in open space applications such as open fields, research has focused on finding liquid agonists and antagonists of ethylene receptors that can be used in open locations. Using a chemical genetics approach, several such compounds have been identified (225-227). One of these compounds, triplin (Fig. 4), mimics the effects of ethylene and was used to help identify the protein antioxidant protein1 (ATX1) as a key transporter of copper to RAN1 (227).

Investigations using details about ethylene signaling, such as receptor-protein interactions and copper as a cofactor for ethylene binding, have also resulted in interesting compounds. One such compound is NOP-1, a synthetic octapeptide that was developed based on details about ETR1-EIN2 interactions (121). This peptide corresponds to the NLS in EIN2-C and disrupts the interaction between EIN2 and ETR1 in Arabidopsis as well as interactions...
between SlETR1 and SlEIN2 in tomato (121,228). NOP-1 binds to various ethylene receptors including ETR1 from *Arabidopsis*, NR and SlETR4 from tomato, and DcETR1 from carnation (229-231). Importantly, NOP-1 leads to reduced ethylene sensitivity in various plants and has been shown to delay tomato fruit ripening and carnation flower senescence (121,230). Also important is that it can achieve these effects by surface application to the plants. Since the NLS sequence in EIN2s is conserved across many flowering ornamental species (229), it is very likely that NOP-1 and derivatives will be effective at blocking ethylene responses in most, if not all, plants used in agriculture and horticulture.

There is also interest in applying ethylene or ethylene response agonists to open fields. Even though this may seem counter-intuitive because of the adverse agricultural effects this could have (such as increased senescence and abscission), there is strong interest in such compounds as a way to control parasitic weeds such as species of *Striga*. *Striga* is an obligate parasitic plant that is estimated to cause billions of dollars of crop damage annually and can result in 100% crop loss in may parts of sub-Saharan Africa (232,233). *Striga* germinates when other plants germinate nearby and one of the major cues for this is ethylene produced by the host plant, although, it is unclear if this is true for all parasitic weeds (234-240). A strategy being explored to control this weed is to stimulate seed germination in the absence of a host needed for survival (235). This has also been shown to work to varying degrees in Africa (245,246). Unfortunately, fumigating with ethylene is not a good solution in sub-Saharan Africa where this weed is a severe problem, because the farmers cannot afford the expensive equipment needed for fumigating soil. Therefore, alternative, less expense, and more easily deployed approaches need to be developed. One approach that was developed is the use of ethylene-producing bacteria to stimulate germination of *Striga* (247). Alternatively, application of ethylene-releasing agents or compounds that stimulate ethylene biosynthesis by *Striga* seeds have been shown to increase *Striga* seed germination (239,248,249). However, these approaches are either cost-prohibitive or less effective, so low-cost and effective measures still need to be developed to control parasitic weeds.

**Concluding remarks**

The details about ethylene signal transduction provided in this review illustrate that we now know many important aspects about how plants perceive ethylene. This includes a new appreciation that the ethylene receptors signal via alternative pathways, in addition to the canonical pathway that was originally delineated in genetic screens. Nonetheless, there are clearly gaps in our understanding of this pathway with unanswered questions.

Despite decades of research on the ethylene receptors, it is still not known what conformational changes occur when the receptors bind ethylene and what enzymatic activity or receptor-protein interaction is modulated by this binding event. Determining the output of the receptors is complicated by the fact that the receptor isoforms have both overlapping and non-
overlapping roles indicating that output from the receptors is not entirely redundant. We also do not know if we have uncovered all instances of cross-talk from the receptors to other pathways and we still lack fundamental details about the cross-talk that has been discovered. These details may prove crucial to develop better targeted control of ethylene responses. Despite recent advances in understanding EIN2, there are still open questions about this protein such as: What is the role of the N-terminal, transmembrane portion of EIN2? What additional roles does EIN2-C have? Given that EIN2 is a central regulator for ethylene signal transduction, such details are also important as we develop new methods of controlling ethylene responses. It is clear that transcriptional regulation by application of ethylene is influenced by environmental conditions. Thus, there is still a great deal we need to examine regarding transcriptional networks that are influenced by ethylene and the factors that affect these networks. Without this information, targeting specific transcription factors may have un-intended outcomes depending on environmental conditions.

No doubt, as we obtain answers to these and other questions, we will develop new methods to control responses to ethylene for agricultural and horticultural uses that will have fewer unwanted, off-target effects that decrease plant vigor and post-harvest storage. Such an improvement in methods will require more specific targeting (with either chemicals or genetic modification) that will only come with further research on this pathway.

CONFLICT OF INTEREST

The author declares that they have no conflicts of interest with the contents of this article.

ACKNOWLEDGEMENTS

I thank Caren Chang, Dan Roberts, Anna Stepanova, and Gyeongmee Yoon for helpful conversations and insights.

The abbreviations used are: ABA, abscisic acid; AHP, Arabidopsis histidine-containing phosphotransfer protein; ARGOS, auxin-regulated gene involved in organ size; ARR, Arabidopsis response regulator; ATX1, antioxidant protein1; CTR, constitutive triple response; DHp, dimerization and histidine phosphotransfer; EBF, EIN3 binding F-box; EIL, EIN3-like; EIN, ethylene insensitive; ENAP1, EIN2 nuclear associated protein1; ERF, ethylene response factor; ERS, ethylene response sensor; ETP, EIN2-targeting protein; ETR, ethylene response; GAF, cGMP-specific phosphodiesterases, adenyl cyclases, and FhlA; GR, green ripe; 1-MCP, 1-methylcyclopropene; NLS, nuclear localization sequence; NR, never ripe; NRAMP, natural resistance-associated macrophage proteins; P-bodies, processing bodies; PIF3, phytochrome interacting factor 3; RAN1 responsive to antagonist1; RTE1, reversion to ethylene sensitivity1; SCF, Skp1 cullen F-box; TRP1, tetratricopeptide repeat protein1; XRN4, exoribonuclease4
**Figure 1: Simple genetic model of ethylene signaling.** In black is shown a model for ethylene signaling based on molecular genetic experiments in *Arabidopsis*. These experiments showed that ethylene signaling involves ethylene receptors (ETR1, ERS1, ETR2, EIN4, ERS2), the protein kinase CTR1, and EIN2 that signals to the transcription factors EIN3, EIL1, and EIL2. These, in turn, signal to other transcription factors such as the ERFs leading to ethylene responses. This has long been considered the canonical signaling pathway. In this model, CTR1 is a negative regulator of signaling. Ethylene functions as an inverse agonist where it inhibits the receptors which leads to lower activity of CTR1 releasing downstream components from inhibition by CTR1. More recent evidence has shown the existence of an alternative, “non-canonical” pathway (in gray) where ETR1 signals to histidine-containing phosphotransfer proteins (AHP) and then to response regulator proteins (ARR) to modulate responses to ethylene.
Figure 2. Diagram of domains of receptor isoforms. The receptors are dimers located in the ER membrane. Each dimer is stabilized by two disulfide bonds near the N-terminus. All of the receptors contain transmembrane helices that comprise the ethylene binding domain followed by a GAF and kinase domain. ETR1 is a histidine kinase and the other four isoforms are serine/threonine kinases. Three of the five contain a receiver domain at the C-terminus of the protein. The models for the receptors are based on published structural and computational studies on ETR1 (43,69) where each monomer coordinates a copper ion required for ethylene binding. In ETR1, the DHp domain of the kinase dimerizes and a flexible region allows each kinase catalytic domain to associate with the DHp domain. It is unknown if the kinase domains of the other isoforms also dimerize. The receiver domains are predicted to be orientated away from the central axis of the receptor dimer.
Ethylene signaling

Figure 3: Model for ethylene signaling. RAN1 is a copper transporter that delivers copper to the lumen of the ER where it is required for the biogenesis of the receptors and is used as a cofactor by the receptors to bind ethylene. **TOP:** In the absence of ethylene, the receptors signal to CTR1 which phosphorylates EIN2. This results in the ubiquitination of EIN2 by an SCF E3 containing the ETP1/2 F-box proteins leading to EIN2 degradation by the proteasome. Because EIN2 levels are low, an SCF-E3 containing the EBF1/2 F-box proteins ubiquitinates EIN3 and EIL1 leading to their degradation by the proteasome and preventing them from affecting transcription in the nucleus. **BOTTOM:** In the presence ethylene, the receptors bind ethylene via a copper cofactor. The binding of ethylene is modeled to cause a conformational change that
either reduces CTR1 kinase activity or as shown results in CTR1 being sequestered by the receptors so that CTR1 can no longer phosphorylate EIN2. The reduction in EIN2 phosphorylation results in less EIN2 ubiquitination and an increase in EIN2 levels. An unknown protease cleaves EIN2 releasing the C-terminal end (EIN2-C) from the N-terminal end (EIN2-N). One fate of EIN2-C is to bind the RNAs for *EBF1* and *EBF2* and become sequestered in processing bodies (P-bodies). The reduction of *EBF1/2* results in less ubiquitination of EIN3 and EIL1 causing higher EIN3/EIL1 levels. The other fate of EIN2-C is to translocate to the nucleus where it increases the transcriptional activity of EIN3/EIL1 via ENAP1. This leads to numerous transcriptional changes. In parallel with this pathway, phosphoryl transfer from a conserved histidine in the ETR1 DHp domain to an aspartate in the receiver domain occurs. This is followed by phosphoryl transfer from this residue to AHPs and finally ARRs resulting in transcriptional changes.
Figure 4. Chemicals that affect ethylene responses in plants. Many strained alkenes, such as 2,5-norbornadiene, trans-cyclooctene, and 1-methylcyclopropene, have been demonstrated to be effective antagonists of ethylene responses that function on the ethylene receptors. Other compounds, such as triplin, are agonists of ethylene responses. Triplin is believed to function by altering the delivery of copper ions to the receptors.
Ethylene signalling in plants
