Abstract Nanostructured α-MnO₂ thin films with different morphologies are grown on the platinum substrates by a facile solution method without any assistance of template or surfactant. Microstructural characterization reveals that morphology evolution from dandelion-like spheres to nanofoles of the as-grown MnO₂ is controlled by synthesis temperature. The capacitive behavior of the MnO₂ thin films with different morphologies are studied by cyclic voltammetry. The α-MnO₂ thin films composed of dandelion-like spheres exhibit high specific capacitance, good rate capability, and excellent long-term cycling stability.

Keywords Supercapacitor · MnO₂ · Nanostructure · Thin film · Cyclic voltammetry

Introduction

In recent years, manganese oxides (MnO₂) have attracted considerable interests due to their distinctive physical and chemical properties and wide applications in catalysis, ion exchange, molecular adsorption, biosensor, and energy storage [1–5]. Specifically, manganese oxides have been extensively evaluated as electrode materials for supercapacitors due to their low cost and environmental benignity compared to noble metal oxides such as RuO₂ [6–8]. In the development of supercapacitors, nanostructured electrode materials have received great interests as they exhibit higher specific capacitance and rate capability compared to traditional bulk materials. Over the years, various nanostructured manganese oxides, including one-dimensional (1-D) (nanoropes, nanowires, nanobelts, nanoneedles, and nanotubes), two-dimensional (2-D) (nанosheets, nanoflakes), and three-dimensional (3-D) (nanospheres, nanoflowers, hollow urchins) nanostructures, have been synthesized [9–16]. 3-D hierarchical porous structures often produce more active sites and exhibit more favorable electrochemical properties than 2-D and 1-D structures. However, facile synthesis and mass production of complex 3-D nanostructures are still a challenge in the areas of materials science [17–20]. It has been reported that a core-shell structure with spherically aligned nanorods of α-MnO₂ can be prepared through a simple room temperature reaction between MnSO₄ and (NH₄)₂S₂O₈ with a catalyst of Ag⁺ in an acid solution [21]. A similar method used by Gong et al. is able to synthesize MnO₂ hollow urchins with a reactive template of carbon spheres [22]. Wang et al. also reported the synthesis of hierarchical α-MnO₂ spheres by the reaction between MnSO₄ and K₂S₂O₇ with the addition of CuSO₄ in an acidic solution [23]. However, the preparation of 3-D nanostructured MnO₂ in the thin film form has never been reported. Since the use of composite electrodes introduces additional undesirable interfaces in the electrode material with the risk of negating the benefits of electrochemistry using nanostructures, thin film electrodes enable us to investigate the electrochemical properties of the active material itself without the influence of binders and conductive additives as required for composite electrodes.

In this paper, we propose the stratagem to synthesize 3-D α-MnO₂ dandelion-like spheres and 2-D α-MnO₂ nanoflakes by a reaction between MnSO₄ and (NH₄)₂S₂O₈ in a Na₂SO₄ solution at low temperatures. With a platinum (Pt) substrate submerged into the reaction solution, the nanostructured MnO₂ can be directly deposited on the Pt
substrate in the thin film form. The effects of the synthesis temperature on the morphology of the films are investigated, and the capacitive behaviors of nanostructured MnO₂ thin films with different morphologies are studied and compared.

**Experimental**

**Synthesis of Nanostructured MnO₂**

Analytical grade MnSO₄, (NH₄)₂S₂O₈, and Na₂SO₄ from Sigma–Aldrich were used. A typical synthesis of nanostructured MnO₂ was performed by dissolving MnSO₄, (NH₄)₂S₂O₈, and Na₂SO₄ with a molar ratio of 1:1:1 in 30 mL deionized water at room temperature. The concentrations of Mn²⁺, S₂O₈²⁻, and SO₄²⁻ in the solution are the same as 0.1 mol L⁻¹. A Pt substrate was submerged into the solution, while the solution was magnetically stirred in a beaker at room temperature (RT) for 12 h or at 80°C for 2 h. One side of the Pt substrate was covered with Parafilm, so that MnO₂ can only be deposited on one side. After the reaction, the Pt substrate was washed using distilled water and then dried in the vacuum at 60°C overnight.

**Characterization**

Structure and crystallinity of thin films were characterized using a Shimadzu XRD-6000 X-ray diffractometer with Cu Kα radiation at a scanning rate of 1°min⁻¹. Surface morphology of the as-deposited thin films was characterized using a Hitachi S-4100 field emission scanning electron microscope (FESEM). Weights of the MnO₂ thin films were measured using a microbalance with an accuracy of 0.01 mg.

All electrochemical measurements were conducted using a Solartron 1287 electrochemical interface combined with a Solartron 1260 frequency response analyzer. For the electrochemical measurements, a three-electrode cell system composed of a MnO₂ thin film electrode as the working electrode, a high surface carbon rod as the counter electrode, and an Ag/AgCl reference electrode was employed. The capacitive behaviors of the as-deposited MnO₂ thin films were characterized by cyclic voltammetry (CV) in 1 M Na₂SO₄ electrolyte at room temperature. CV measurements were performed on the three-electrode cells in the voltage window between 0 and 0.9 V at different scan rates from 20 to 200 mV s⁻¹. Electrochemical impedance spectra (EIS) of different thin film electrodes were measured at the open-circuit potential in the frequency range from 100 kHz to 10 mHz.

**Results and Discussion**

Figure 1a, b shows the XRD patterns of the MnO₂ thin films synthesized at different temperatures. Notably, major diffraction peaks in Fig. 1a, b can be indexed as a tetragonal symmetry of α-MnO₂ with a space group of I4/m (JCPDS Card, No. 44-0141). Comparing Fig. 1a with Fig. 1b, it can be seen that the diffraction peaks in Fig. 1a are sharper and stronger, indicating that the degree of crystallinity of the products is enhanced as the synthesis temperature increases. However, some small impurity peaks observed from both Fig. 1a, b can be indexed as Mn₃O₄, which is probably due to the incomplete oxidation reaction between Mn²⁺ and S₂O₈²⁻. The complete formation of MnO₂ from the solution can be expressed as the following reaction:

\[
\text{MnSO}_4 + (\text{NH}_4)_2\text{S}_2\text{O}_8 + 2\text{H}_2\text{O} \rightarrow \text{MnO}_2 + (\text{NH}_4)_2\text{SO}_4 + 2\text{H}_2\text{SO}_4
\]

α-MnO₂ has usually been found to be the product of the oxidation of Mn²⁺ by S₂O₈²⁻ either through a hydrothermal reaction [24] or through a mild solution reaction [21–23]. It has been observed in this study that the formation of nanostructured MnO₂ is preferred to deposit on the Pt substrate rather than in the solution. Therefore, the preparation of MnO₂ thin films (as shown in Fig. 1c) in this study is quite simple and convenient compared with electrochemical deposition, which is usually employed to prepare MnO₂ thin films.

The morphologies of the MnO₂ thin films synthesized at different temperatures are shown in Fig. 2. It can be seen from Fig. 2a that the film synthesized at RT is composed of uniform microscopic spheres with diameters ranging from 0.5 to 1 µm. The magnified FESEM image (Fig. 2b) shows that these microscopic spheres are composed of

---

Fig. 1 a XRD pattern of the MnO₂ thin film synthesized at RT, b XRD pattern of the MnO₂ thin film synthesized at 80°C (The dotted lines in red color represent the diffraction peaks from Mn₃O₄), and c photos of the Pt substrate before and after the deposition.
nanowhiskers, resulting in a dandelion-like morphology. Li et al. [22] reported that a core-shell structure microspheres (2–3 μm) of α-MnO₂ can be obtained by the reaction between MnSO₄ and (NH₄)₂S₂O₈ with the addition of AgNO₃ catalyst at RT for 1–2 days. The thin shell of this structure is composed of nanorods, and this morphology can only be obtained with the existence of Ag⁺. Wang et al. [23] reported that sea urchin-shaped microspheres (~1 μm) of α-MnO₂ can be obtained by the reaction between MnSO₄ and K₂S₂O₈ with the addition of CuSO₄ at 70 °C for 3 days. In the present work, the 3-D hierarchical structure of α-MnO₂ can be obtained at RT in a relatively short synthesis time (12 h) without using any AgNO₃ or CuSO₄ since the addition of catalyst of AgNO₃ or CuSO₄ may induce Ag⁺ or Cu²⁺ impurities in the final MnO₂ products [23]. It is assumed that reaction between Mn²⁺ and S₂O₈²⁻ in the Na₂SO₄ solution with a Pt substrate is relatively faster compared to the previous studies [22, 23]. It is interesting to observe a morphology evolution of the film, as the synthesis temperature increases. As shown in Fig. 2d, the film synthesized at 80 °C exhibits another type of porous structure with nanoflakes almost vertically aligned on the Pt substrate. The magnified FESEM image (Fig. 2e) shows that the average size of the nanoflakes is about 500 nm, and the thickness of the nanoflakes is less than 50 nm.

The possible formation mechanism for the hierarchical MnO₂ spheres is schematically illustrated in Fig. 2c. Generally speaking, the crystal growth process always includes two steps: the initial nucleation stage and following crystal growth stage [25, 26]. Initially, MnO₂ colloids are slowly formed and attached to the Pt substrate. After which, the absorbed MnO₂ colloids on the Pt substrate tend to aggregate loosely to form spherical appearance due to their high surface energies. Because the reaction temperature is at RT, Gibbs energy for nucleation of new MnO₂ sites is low. As a consequence, MnO₂ colloids tend to attach on the habit planes of existing MnO₂ sites, leading to the formation of 1-D nanowhiskers. However, on the contrary to Wang’s finding [23], the increase in reaction temperature in this study is unable to improve the formation of 3-D hierarchical microspheres of MnO₂ but leads to the formation of 2-D nanoflakes. This phenomenon can be explained by the change in growth mechanisms as shown in Fig. 2f. When the reaction temperature is

![Fig. 2 FESEM images for RT synthesized MnO₂: a low magnification and b high magnification, c schematic illustration for the possible formation mechanism of dandelion-like MnO₂ microspheres, FESEM images for 80 °C synthesized MnO₂: d low magnification and e high magnification, and f schematic illustration for the possible formation mechanism of MnO₂ nanoflakes.](image-url)
increased to 80 °C, the reaction rate is greatly enhanced along with the high rate of adsorption of MnO₂ colloids to the Pt substrate. Under such circumstances, in addition to the one-dimentional growth of the nuclei along the low energy direction [27], the growth of the nuclei along other directions can also happen due to the fast nucleation and adsorption rates of MnO₂ at an elevated temperature. Therefore, nanoflakes instead of nanowhiskers form resulting in the morphology evolution.

The 3-D and 2-D nanostructured MnO₂ are promising as electrode materials for supercapacitors due to their porous structure, large surface area, and short diffusion length for protons or alkali cations. In order to evaluate the electrochemical properties of the as-deposited thin films, the thin film samples with different nanostructures were characterized in aqueous 0.1 M Na₂SO₄ electrolyte with CV measurements. The CV curves at various scan rates from 20 to 200 mV s⁻¹ for the sample A and B are shown in Fig. 3a, b (sample A represents MnO₂ with dandelion-like sphere morphology, and sample B represents MnO₂ nanoflakes). It can be seen that the curves at the low scan rate of 20 mV s⁻¹ for both samples exhibit ideal symmetrical rectangle-like shape indicating ideal capacitive behavior. As the scan rate increases, slight distortion from the ideal symmetrical rectangle shape can be observed from the CV curves for both samples. However, it is clear to see that the distortion from the rectangularity of the CV curves for the sample A is much less than that for the sample B, indicating much better rate performance of the sample A due to its finer nano-architecture. The specific capacitance of the nanostructured MnO₂ film can be obtained by the following equation:

\[
C(F/g) = \frac{Q}{\Delta E \cdot m}
\]

where \(Q\) is the voltammetric charge, \(\Delta E\) is the voltage window (0.9 V), and \(m\) is the mass of the active material of the electrode. The specific capacitances at different scan rates for both samples are shown in Fig. 3c. At the scan rate 20 mV s⁻¹, the sample A exhibits a much higher specific capacitance of about 230 F/g than 180 F/g of the sample B. As the scan rate increases, the specific capacitance for both samples decreases, which is typical for electrochemically active MnO₂ materials. At the highest scan rate of 200 mV s⁻¹, the sample A can maintain 66% of its full capacitance (we set the specific capacitance at 20 mV s⁻¹ as the full capacitance) while the sample B can only maintain 55% of its full capacitance, indicating that the sample A has much better rate capability than that of the sample B. Figure 3d compares the Nyquist plots for the MnO₂ thin films with different nanostructures. A depressed semicircle in the high-frequency range corresponding to the charge-transfer resistance, and a straight sloping line in the low-frequency range corresponding to the diffusive resistance can be observed for both samples. As shown in Fig. 3d, it is clear that the sample A has lower charge-
transfer resistance and diffusive resistance compared with those of the sample B, confirming the superior capacitive behavior of the sample A. Based on the previous paper by Chou et al. [28], surface area of thin film can be derived from the double layer capacitance by fitting EIS using equivalent circuit. The calculated surface areas of the sample A and the sample B are about 414 and 125 m² g⁻¹ respectively. Pseudocapacitance of MnO₂ mainly originates from the adsorption of cations in the electrolyte (M⁺ = Li⁺, Na⁺, and K⁺) on the surface of MnO₂ and also possible intercalation/deintercalation of H⁺ and alkaline metal cations in the bulk of MnO₂ [29]. Since the 3-D dandelion-like microspheres of the sample A are composed of much finer nanowhiskers with very small size, they provide a much larger surface area per gram and shorter diffusion length for cations, comparing to the relatively large 2-D nanoflakes of the sample B. Therefore, the morphology advantage of sample A explains why it can exhibit a higher specific capacitance and better rate capability than those of the sample B.

The sample A, showing better capacitive behavior in rate capability test, was further investigated for long-term cycling stability. The CV curves at different cycling stages and variation of specific capacitance over 2,000 cycles are shown in Fig. 4a, b. As shown in Fig. 4a, the CV curves for the 1st, 500th, 1000th, and 2000th cycles almost overlapped with each other, indicating excellent cycling stability. After 2,000 cycles, there is no degradation of the capacitive behavior, indicating no significant structural or microstructural changes in the MnO₂ thin film electrodes. The CV curve after 2,000 cycles is noted to become more symmetrical with the rectangular shape compared with the first cycle, indicating improved capacitive behavior after long time cycling. The specific capacitance of the sample A (as shown in Fig. 4b) slightly decreases for the first 30–40 cycles then starts to increase very slowly with the cycling. As shown in the XRD results, there is a small amount of Mn₃O₄ exist in the film. Mn with a lower oxidation state in the Mn₃O₄ is probably oxidized to Mn⁴⁺ during the long time CV cycling, resulting in improved capacitive behavior and an small increase of specific capacitance.

Conclusions

MnO₂ thin films with nanostructures have been prepared on Pt substrates by a facile and mild solution method. The MnO₂ film prepared at RT with a long reaction time is composed of dandelion-like microspheres, which consists of nanowhiskers with very small size. The reaction temperature plays an important role in controlling the surface morphology of the film. As the reaction temperature was increased to 80 °C, a film composed of nanoflakes can be prepared in a very short time. The CV measurements indicate that MnO₂ thin films prepared by this method are promising as electrodes for supercapacitors. The film composed of dandelion-like microspheres exhibited a higher specific capacitance and better rate capability than the film composed of nanoflakes, which is probably due to the high surface area and smaller feature of the microspheres. The excellent cycling stability and good rate capability of the film composed of dandelion-like microspheres coupled with the simple and low cost synthesis method make this material attractive for large applications.
