Chapter 6

The diet of Nile perch, *Lates niloticus* (L.) after resurgence of haplochromine cichlids in the Mwanza Gulf of Lake Victoria

Mary A. Kishe-Machumu, Frans Witte, Jan H. Wanink, Egid F.B. Katunzi

Original version published in *Hydrobiologia* 682: 111-119 (2012)
ABSTRACT
Haplochromine cichlids used to be the main prey of the introduced Nile perch, *Lates niloticus*, in Lake Victoria. After depletion of the haplochromine stocks at the end of the 1980s, Nile perch shifted to the shrimp *Caridina nilotica* and to a lesser degree to its own young and the cyprinid *Rastrineobola argentea*. In the present study we investigated the Nile perch diet in the northern Mwanza Gulf after resurgence of some of the haplochromine species and compare it with data collected in the same area in 1988/89. It became clear that haplochromines are again the major prey of Nile perch. The dietary shift from invertebrate feeding (shrimps) to feeding on fish (haplochromine cichlids) occurs at a smaller size than it did when Nile perch were taking primarily dagaa and juvenile Nile perch as their fish prey. The apparent preference for haplochromines as prey has reduced the degree of cannibalism considerably, which may have a positive impact on Nile perch recruitment.
INTRODUCTION

Nile perch, *Lates niloticus* (Linnaeus), was introduced into Lake Victoria in the 1950s and early 1960s from lakes Turkana (Kenya) and Albert (Uganda) where it is native (Pringle 2005). A dramatic increase of the Nile perch in the 1980s (Ogutu-Ohwayo 1990a; Goudswaard et al. 2008) coincided with the disappearance of about 40% of the 500+ endemic haplochromine cichlid species (Witte et al. 1992b). Concomitant with the disappearance of haplochromine species, increases of the cyprinid *Rastrineobola argentea* (Pellegrin), locally called dagaa, and of the shrimp *Caridina nilotica* (Roux) were noted (Wanink 1999; Goudswaard et al. 2006). About a decade later, Nile perch yields declined due to intense fishing and resurgence of some haplochromine species was observed in the lake (Seehausen et al. 1997b; Balirwa et al. 2003; Getabu et al. 2003; Witte et al. 2007a).

During the period of the 1970s, when haplochromine cichlids were the dominant fish in the lake (Kudhongania & Cordone 1974), they were the major prey of the Nile perch (Hamblyn 1966; Gee 1969). In the course of the 1980s, when the density of haplochromines in the sub-littoral and off-shore waters declined to almost zero (Ogutu-Ohwayo 1990a; Witte et al. 1992b), Nile perch switched to shrimps, dagaa and to its own young (Ogari & Dadzie 1988; Ogutu-Ohwayo 1990b; Mkumbo & Ligtvoet 1992; Katunzi et al. 2006). A similar shift in diet was noted in Lake Kyoga, where Nile perch had been introduced as well (Ogutu-Ohwayo 1990b). In the Mwanza Gulf (Fig. 1.2 [Chapter 1]) the switch from haplochromines to shrimps, juvenile Nile perch and dagaa, was rather abrupt, and occurred between September 1986 and June 1987 (Mkumbo & Ligtvoet 1992). In absence of haplochromine cichlids, shrimps seemed to be the preferred prey of Nile perch up to 30 cm TL in the sub-littoral areas of the Mwanza Gulf in 1988/89. Even when juvenile Nile perch and dagaa were abundant, shrimps were eaten almost exclusively by this size class (Katunzi et al. 2006). However, it has been suggested that, with their recovery, haplochromines would take over the role as key prey again (Katunzi et al. 2006).

During the past 15 years, the abundance of some haplochromine species in the sub-littoral waters of the Mwanza Gulf has increased again and currently the total number of individuals of haplochromines is about the same as in the 1970s (Witte et al. 2007a; Chapter 2). Studies by Budeba & Cowx (2007) and by Ngupula & Mlaponi (2010) showed that after their resurgence in the Tanzanian waters of the
lake, haplochromines became important prey of Nile perch again. However, these studies were mainly aimed at the role of the shrimp *C. nilotica* in the Nile perch diet and did not make comparisons with Nile perch diets in the past from the same areas of the lake. To examine explicitly whether Nile perch from sub-littoral waters in the Mwanza Gulf switch back to haplochromines as their major food source after the resurgence of some of some species, we first quantified the diet of Nile perch on a research transect in the Mwanza Gulf between Butimba Bay and Kissenda Bay (Fig. 1.2 [Chapter 1]). We then compared these data to a subset of data that were collected in 1988-1998 by Katunzi et al. (2006) from an area that partially overlapped with the transect. To enable comparisons with earlier studies, we used both the frequency of occurrence method and the volumetric percentage method to characterize the Nile perch diet.

**MATERIALS AND METHODS**

**Study area**

The Nile perch samples were collected in the sub-littoral (6-20 m) waters on a research transect across the Mwanza Gulf, between Butimba Bay and Kissenda Bay (Fig. 1.2 [Chapter 1]). The research transect is approximately 5 km long and six sampling stations (E, F, G, H, I & J) with depths ranging from 5.5 to 13 m were sampled.

**Sampling techniques**

A small trawler, used for sampling haplochromine cichlids, was powered by a 25 hp outboard engine and towed a bottom trawl net with a 4.6 m head-rope and a 5 mm cod-end mesh. It only caught small-sized Nile perch (up to ca 30 cm TL). Therefore, large trawlers (165-215 hp) using nets with a head rope of 22-27 m and a wider stretched cod-end mesh (50-100 mm) were used to catch large-sized Nile perch. Trawl shots lasted for 10 minutes and 30 minutes with the small and large trawlers respectively. Sampling in 2006 and 2008 was mostly conducted in the morning hours between 08.00 and 12.00. The only exception was 7 March 2008, when 25 Nile perch with food in their stomachs were collected with a large trawler between 14.50 and 18.00 hours.

With the small trawler, a trawl-shot was made at each station once per month in 2006 and once per two months in 2008. The large trawlers were used in January,
March, May and December 2006 and in March, August, October and December 2008. In each month three to four hauls were made on one day, and each trawl shot covered 2-3 stations on the transect. For data analysis the Nile perch samples from the small and large trawlers were combined.

**Biotic data and stomach examination**

Total length (TL) of Nile perch was measured to the nearest cm (digits ending at ≥ 0.5 were rounded to the nearest cm above). Depending on the size of the catch, stomach contents of all Nile perch ≤ 20 cm TL, or of a sub-sample, were analysed, while all fish > 20 cm TL were all analysed. When using a large trawler identification of stomach contents was performed on board, immediately after each haul. In case of the small trawler, fish were kept on ice and analysis was performed in the laboratory on the same day. The entire stomach of each fish was removed. Before opening the stomach, its fullness was estimated at five levels; 0, 25, 50, 75 and 100%. The prey items were identified to the lowest possible taxonomic level. Small prey items like zooplankton and midge larvae that could only be observed with the aid of a microscope were discarded in this study, as we were mainly interested in the contribution of haplochromines and other large prey items to the diet. Moreover, Katunzi et al. (2006) showed that they were relatively unimportant prey types for Nile perch at the research transect (their station 3). Zooplankton was only eaten by fish < 5 cm TL (frequency of occurrence < 15%), and midge larvae mainly by fish < 10 cm (frequency of occurrence < 30%).

The frequency of occurrence of each food item was expressed as the percentage of fish containing that food item out of the total number of fish containing food. Volume per food type was estimated for each fish separately as a percentage of the total volume of food it had ingested and then a correction on volume per food type was made for the percentage of fullness of the stomach. This implied that the sum of the volume percentages of all food types, together with the empty part added up to 100%.

For calculating frequencies of occurrence and volume percentages of prey items, fish with empty stomachs were discarded and those filled less than 25% were discarded for calculating volume percentages. In total, 1073 fish (2.5-114 cm TL) from 2006 and 2008 with food in their stomachs were used for calculating frequencies of occurrence of prey items, whereas 1070 were used for volume
percentages. Fish were grouped into size classes of 5 cm. The minimum number of individuals per length class was 11 (46-50 cm TL) and maximum number was 242 (11-15 cm TL).

**Comparison with data collected in 1988/89**

For a comparison of Nile perch diets in 2006/2008 with those in 1988/89, we used fish up to 30 cm TL, as this was the size range studied by Katunzi et al. (2006). From the latter study we only used Nile perch containing food (n = 1392) that were collected at station 3 (12-16 m deep), whereas from the present study we used Nile perch containing food (n = 639) from the deeper stations of the transect (F, G, H and I; 9.5-13 m), as these stations roughly overlapped with station 3 in Katunzi et al. (2006). Data collected by Katunzi et al. (2006) for 1 cm classes of Nile perch were lumped as 5 cm classes to make them comparable with those in the present study.

**Data analysis**

A Pearson correlation coefficient was calculated between the percentages of empty stomachs and fish size classes (5 cm) for all stations combined. The Jonckheere-Terpstra test was used to test for trends of prey items among size classes. A Chi-Square test was used for testing if differences in frequencies of occurrence of food items between 1988/89 and 2006/2008 were significant. Sequential Bonferroni corrections were applied in case of repeated tests. Statistical tests were performed with SPSS 17.0 for Windows.

**RESULTS**

**Frequency of occurrence of prey items**

On average, 28.4 ± 11.5% of all studied stomachs were empty. The average percentage of empty stomachs was positively correlated with Nile perch length class (Pearson correlation coefficient, \( R = 0.868; P = 0.001; n = 11 \)). The average percentage of empty stomachs in Nile perch from 1 to 30 cm was 21.1 ± 8.7%.

The shrimp *C. nilotica* and haplochromine cichlids were the most common prey types in Nile perch (Table 6.1). With increasing size of Nile perch, the frequency of occurrence of shrimps decreased significantly (98-0%; Jonckheere-Terpstra test, \( P \leq 0.001; n = 1073 \)), whereas that of haplochromines increased
Diet change in Nile perch

significantly (0-60%; Jonckheere-Terpstra test, \( P \leq 0.001; n = 1073 \)). Dagaa was eaten by a relatively small proportion of all size-classes of Nile perch. Juveniles of its own species were found in low proportions of Nile perch \( \geq 11 \) cm TL. For dagaa and juvenile Nile perch the frequency of occurrence increased significantly with Nile perch size (Jonckheere-Terpstra test, \( P \leq 0.001; n = 1073 \) for both prey types), especially for the size classes \( \geq 26 \) cm TL, reaching maxima of about 20% in fish \( > 50 \) cm (Table 6.1). Other fish taxa were rather rare in the Nile perch diet and mainly comprised juvenile *Oreochromis niloticus* (Linnaeus) and *Barbus* spp. A relatively large percentage of Nile perch contained fish remains that could not be further identified as they were too far digested (Table 6.1). The frequencies of unidentifiable fish also increased significantly with Nile perch size (Jonckheere-Terpstra test, \( P = 0.011; n = 1073 \)). The highest frequencies (10-11%) of dragonfly nymphs (Odonata) and molluscs were occurring in the intermediate size classes (Table 6.1). Two large fish (one of 46-50 cm and one \( \geq 51 \) cm) contained crab and plant remains in their stomachs, listed as *other prey*.

**Table 6.1** Frequency of occurrence (percentages) of prey types in Nile perch per 5 cm length class in the Mwanza Gulf in 2006 & 2008 (\( n = \) number of fish with food).

| Size class (cm, TL) | 1-5 | 6-10 | 11-15 | 16-20 | 21-25 | 26-30 | 31-35 | 36-40 | 41-45 | 46-50 | 51+ |
|---------------------|-----|------|-------|-------|-------|-------|-------|-------|-------|-------|-----|
| \( n \)             | 44  | 205  | 242   | 201   | 110   | 81    | 65    | 46    | 26    | 11    | 42  |
| Odonata             | 0   | 1    | 4     | 10    | 11    | 7     | 11    | 4     | 4     | 0     | 2   |
| Molluscs            | 0   | 0    | 3     | 2     | 5     | 10    | 11    | 7     | 0     | 0     | 0   |
| Shrimps             | 98  | 80   | 71    | 62    | 32    | 26    | 11    | 0     | 0     | 0     | 0   |
| Dagaa               | 2   | 1    | 1     | 2     | 4     | 5     | 9     | 4     | 15    | 9     | 21  |
| Nile perch          | 0   | 0    | 1     | 1     | 2     | 2     | 6     | 11    | 4     | 18    | 19  |
| Haplochromines      | 0   | 12   | 19    | 25    | 51    | 57    | 57    | 85    | 73    | 64    | 60  |
| Other fish          | 0   | 0    | 0     | 1     | 2     | 0     | 0     | 0     | 9     | 5     | 0   |
| Unidentified fish   | 0   | 10   | 14    | 13    | 26    | 36    | 35    | 20    | 27    | 27    | 45  |
| Other prey          | 0   | 0    | 0     | 0     | 0     | 0     | 0     | 0     | 9     | 2     | 0   |

**Volume percentages of food items**

With the volume percentage method, similar results as with the frequency of occurrence were obtained (Table 6.2). Shrimps dominated the diet (40-86%) in Nile perch up to 20 cm TL, whereas haplochromines dominated (33-46%) in Nile perch from 21 cm onwards. The contribution of juvenile Nile perch to the diet increased slowly with predator length, but was never more than 9%; the unidentifiable fish species reached a maximum of 12% in size class 46-50 cm TL.
Insects, molluscs, dagaa and other fish taxa never contributed more than 9% to the diet of each size class. The volume percentages of other prey were negligible.

Table 6.2 Nile perch diet composition (mean volume percentages) per 5 cm length class in the Mwanza Gulf in 2006 and 2008 (n = number of fish of which the stomach fullness was > 25%).

| Size class (cm, TL) | 1-5 | 6-10 | 11-15 | 16-20 | 21-25 | 26-30 | 31-35 | 36-40 | 41-45 | 46-50 | 51+ |
|--------------------|-----|------|-------|-------|-------|-------|-------|-------|-------|-------|-----|
| n                  | 44  | 205  | 242   | 200   | 109   | 81    | 64    | 46    | 26    | 11    | 42  |
| Odonata            | 0   | 0    | 2     | 5     | 3     | 1     | 1     | 1     | 1     | 0     | 0   |
| Molluscs           | 0   | 0    | 1     | 1     | 1     | 2     | 1     | 1     | 0     | 0     | 0   |
| Shrimps            | 86  | 64   | 48    | 40    | 15    | 7     | 6     | 1     | 0     | 0     | 0   |
| Dagaa              | 2   | 1    | 1     | 2     | 2     | 3     | 0     | 3     | 1     | 2     |     |
| Haplochromines     | 0   | 8    | 15    | 18    | 33    | 37    | 34    | 46    | 43    | 34    | 34  |
| Nile perch         | 0   | 0    | 0     | 1     | 1     | 1     | 2     | 4     | 6     | 9     | 7   |
| Other fish         | 0   | 0    | 0     | 0     | 1     | 0     | 0     | 0     | 0     | 0     | 2   |
| Unidentified fish  | 0   | 9    | 6     | 5     | 12    | 11    | 6     | 4     | 9     | 11    | 12  |
| Other prey         | 0   | 0    | 0     | 0     | 0     | 0     | 0     | 0     | 1     | 0     |     |
| Empty              | 11  | 18   | 27    | 30    | 33    | 38    | 47    | 44    | 39    | 34    | 42  |

Comparison of data collected in 1988/89 and 2006/2008

The proportion of Odonata in the diet of Nile perch was independent of time period for all size classes, except for Nile perch of 11-15 cm, where the proportion was higher in 2006/2008 (Fig. 6.1; Chi-Square, $P = 0.009$). For the other size classes the difference in the frequency of occurrence of Odonata was not significant (Chi-Square, $P$ ranging from 0.102 to 0.777). However, all other food items showed striking differences amongst both periods. In 2006/2008, Nile perch up to 20 cm TL ate shrimps more frequently than in 1988/89 (Chi-Square, $P \leq 0.009$), whereas the reverse was true for Nile perch of 21-30 cm TL (Chi-Square, $P \leq 0.004$; Fig. 6.1). After Bonferroni corrections the frequencies of occurrence of dagaa in Nile perch from 16-30 cm TL were strikingly lower in 2006/2008 than in 1988/89 (Chi-Square, $P = 0.032-0.191$ for size range 1-15 cm and $P \leq 0.006$ for size range 16-30 cm; Fig. 6.1). Moreover, for Nile perch ranging from 1–30 cm TL, in1988/89, the frequency of occurrence of dagaa increased significantly with Nile perch size (Jonckheere-Terpstra test, $P \leq 0.001$; $n = 1392$), but this was not the case in 2006/2008 (Jonckheere-Terpstra test, $P = 0.373$; $n = 639$). In 1988/89 juvenile Nile perch were present in 25-30% of the stomachs of their conspecifics larger than 6 cm, whereas in 2006/2008 this had declined to less than 3% (Fig. 6.1; Chi-Square, $P \leq 0.001$ for all Nile perch classes between 6 and 30 cm).
Fig. 6.1 Frequency of occurrence of the main prey types of Nile perch up to 30 cm TL (per 5-cm size class) in 1988/89 (n = 1392) and 2006/2008 (n = 639): (a) shrimps, (b) dagaa, (c) Odonata nymphs, (d) haplochromines, (e) Nile perch. For 2006/2008 only Nile perch were used collected at stations F, G, H and I, which approximately cover station 3 sampled by Katunzi et al. (2006) in 1988/1989.
In 1988/89 haplochromines were virtually absent in sub-littoral waters in the northern part of the Mwanza Gulf and consequently also absent in Nile perch stomachs. Molluscs were not encountered in the diet of Nile perch from 1988/89. The average percentage of empty stomachs in Nile perch from 1 to 30 cm in 2006-2008 (21.1 ± 8.7%) was similar to that found during the non-haplochromine diet regime (viz. 21.2 ± 5.6%) in 1988/89 by Katunzi et al. (2006).

**DISCUSSION**

Obviously, shrimps and haplochromines were the key preys of Nile perch in the northern part of the Mwanza Gulf in 2006/2008. In Nile perch up to 20 cm the dominant prey items were shrimps and in the larger size classes they were haplochromines. Though unidentified fishes also contributed significantly to the frequency of occurrence of prey types, their contribution to the volume percentages was much smaller (Tables 6.1, 6.2). Moreover, it should be noted that most likely a major part of the unidentified fishes were haplochromines that were too far digested to be identified. During a survey in the entire Tanzanian sector of the lake in November 2006, it was found that shrimps dominated in the diet of Nile perch < 50 cm TL by contributing 54% by volume, whereas haplochromines made up 41% of the diet of Nile perch > 50 cm TL (Ngupula & Mlaponi 2010). Our data indicate that in the northern part of the Mwanza Gulf the switch from shrimps to haplochromines as dominant prey occurred already at the size of about 20 cm TL. Similar results were found in 1999-2002 by Budeba & Cowx (2007) for their zone A, which included the Speke Gulf, the Mwanza Gulf and the offshore area between Kome Island and Ukerewe Island. In the other two zones (zone B near Musoma and zone C covering the south-western part of the Tanzanian waters) haplochromines only became the dominant prey in Nile perch > 50-60 cm TL. As there is no information on haplochrome and shrimp densities in these areas, the cause of this delayed switch is not clear.

In September 1986, when haplochromine catches in the Mwanza Gulf had decreased to ca 60 kg h⁻¹ (from ca 1500 kg h⁻¹ in the 1970s), haplochromines still were the most frequently occurring prey (> 60%) in Nile perch of 15–40 cm TL (Mkumbo & Ligtvoet 1992). Between June 1987 and August 1988, when haplochromines had virtually vanished from the trawl catches (Goudswaard et al. 2008), the frequency of occurrence of haplochromines in Nile perch of 15–40 cm
Diet change in Nile perch

TL had decreased to less than 5% (Mkumbo & Ligtvoet 1992). Finally, in the period of September 1988 to September 1989, no haplochromines at all were found in Nile perch up to 30 cm TL (Fig. 6.1; Katunzi et al. 2006). The shift from haplochromines to shrimps as the main prey between 1986 and 1989 in the Mwanza Gulf was clearly due to the decline of the haplochromines (Witte et al. 1992b; Goudswaard et al. 2008) and the concomitant increase of shrimps (Goudswaard et al. 2006).

Katunzi et al. (2006) found that in 1988/89 at station 3 in the Mwanza Gulf, Nile perch up to 30 cm TL, in addition to shrimps (the most common prey), fed on juvenile Nile perch (≤ 5 cm TL), and with lower frequency on dagaa. However, it appeared that in seasons with high abundance of shrimps, juvenile Nile perch and dagaa were neglected, even if their abundance was high. Though the biomass of dagaa increased in the lake during the past decade (Tumwebaze et al. 2007; Witte et al. 2009b), their contribution to the Nile perch diet in 2006/2008 was much lower than in 1988/89 and never exceeded 3% by volume percentage (Table 6.2). Our current observations suggest that Nile perch > 20 cm TL prefer haplochromines over shrimps. From 40 cm TL onwards, no shrimps at all were present in the diet, whereas during the second half of the 1980s, when haplochromines were absent, shrimps were eaten by Nile perch up to 60 cm TL (Ogutu-Ohwayo 1990b; Mkumbo & Ligtvoet 1992) and in the Nyanza Gulf (Kenya) even by fish of more than one metre (Hughes 1986; Ogari & Dadzie 1988). Concordantly, the frequency of occurrence of shrimps in the diet of Nile perch up to 30 cm TL did not show a trend across size classes in 1988/89 when haplochromines were absent, but a significant negative trend was found after the recovery of the haplochromines in 2006/2008 (Fig. 6.1).

In Lake Kyoga, where the upsurge and decline of the Nile perch occurred about a decade earlier than in Lake Victoria (Ogutu-Ohwayo 1990a, 2004), a similar pattern was observed as in the Mwanza Gulf; shrimps were more important than haplochromines in the diet of Nile perch < 20 cm and of 20-59 cm TL in 1978-1980. However, in 1991-1993, haplochromines dominated in the diet of Nile perch of these two size classes, as well as in the size class of 60-100 cm TL (Ogutu-Ohwayo 2004).

In Lake Nabugabo, where shrimps appeared to be absent, dagaa and juvenile Nile perch were the main prey types before the mid-1990s, when haplochromines
were extremely rare in the lake (Ogutu-Ohwayo 1993; Schofield & Chapman 1999). After the mid-1990s, when haplochromines were resurging in Lake Nabugabo, the diet of the Nile perch changed and in 2000 and 2007 it was dominated by haplochromine cichlids (Paterson & Chapman 2009). Notably, the shift from invertebrates to fish occurred at a smaller size (between 10 and 15 cm TL) in case of haplochromines than in case of dagaa and juvenile Nile perch (between 30 and 35 cm TL; Paterson & Chapman 2009). This agrees with our observations in the Mwanza Gulf, where in 1988/89 shrimps were eaten more frequently than fish by Nile perch up to at least 30 cm TL, while in 2006/2008 haplochromines became the most frequently eaten prey from 21 cm onwards. In conclusion it seems that haplochromines are the preferred prey of Nile perch that are large enough to feed on them.

Between 1987 and 1989, when haplochromines had virtually vanished from the Mwanza Gulf (Witte et al. 1992b; 2007a), cannibalism became important in Nile perch ≥ 5 cm TL (Mkumbo & Ligtvoet 1992; Katunzi et al. 2006), whereas it strongly decreased after resurgence of the haplochromines. Also in other parts of Lake Victoria and in Lake Kyoga, Nile perch began feeding on their young only when haplochromine species were depleted (Ogutu-Ohwayo 1993). Hopson (1972) stated that cannibalism in Lake Chad may have resulted partly from the scarcity of preferable prey items. During the past years there has been some worry that the resurging haplochromines may do harm to the Nile perch stocks by feeding on Nile perch eggs and larvae (Kolding et al. 2008). Though this may be the case (Goudswaard et al. 2008), the data of our study indicate that the preference of Nile perch for haplochromines instead of for their own young, reduces cannibalism. This may counterbalance the loss of eggs and larvae or even enhance rates of recruitment of Nile perch, which is of great importance for a sound fishery.
CONCLUSION
Based on a modelling study by Kaufman & Schwarz (2002), indicating that Nile perch prefer and grow fastest on a haplochromine prey base, it has been suggested that conservation of biodiversity and fishery sustainability may not have to be antitheses in the management of Lake Victoria (Balirwa et al. 2003). The observed reduction of cannibalism by Nile perch when haplochromines are available seems to support this suggestion.

Since haplochromines are now taken as a by-catch in the dagaa fishery, management measures in dagaa fishery should take haplochromines into account. If the recovery of the haplochromine cichlids will continue, high dependence of the Nile perch on haplochromines and low rates of cannibalism, may contribute to another round of the Nile perch success in Lake Victoria.

ACKNOWLEDGEMENTS
We would like to thank the following organisations that funded this study: the Netherlands Foundation for the Advancement of Tropical Research (WOTRO; grants W 87-189, W 84-488, WB84-587), the Netherlands Organization for International Cooperation in Higher Education (NUFFIC), the International Foundation for Sciences (IFS), the Schure Beijerinck-Popping Fonds and the section DPO of the Netherlands Ministry of Foreign Affairs. We are also grateful to the crew members of the small trawler; Mhoja Kayeba, Mohamed Haruna and Rajabu Machage, the master fishermen; Raphael Mamelela and Gabriel Mbaya of the larger trawlers (R.V. Lake Victoria Explorer and M.V. Mdiria) and all other crew members for making sampling successful.
