Coherent dipole–dipole coupling between two single Rydberg atoms at an electrically-tuned Förster resonance

Sylvain Ravets, Henning Labuhn, Daniel Barredo, Lucas Béguin, Thierry Lahaye and Antoine Browaeys

Resonant energy transfers, the non-radiative redistribution of an electronic excitation between two particles coupled by the dipole–dipole interaction, lie at the heart of a variety of phenomena, notably photosynthesis. In 1948, Förster established the theory of fluorescence resonant energy transfer (FRET) between broadband, nearly-resonant donors and acceptors. The $1/R^6$ scaling of the energy transfer rate, where $R$ is the distance between particles, enabled widespread use of FRET as a ‘spectroscopic ruler’ for determining nanometric distances in biomolecules. The underlying mechanism is a coherent dipolar coupling between particles, as recognized in the early days of quantum mechanics, but this coherence has not been directly observed so far. Here we study, spectroscopically and in the time domain, the coherent, dipolar-induced exchange of excitations between two Rydberg atoms separated by up to 15 μm, and brought into resonance by applying an electric field. Coherent oscillation of the system between two degenerate pair states then occurs at a frequency scaling as $1/R^5$, the hallmark of resonant dipole–dipole interactions. Our results not only demonstrate, at the fundamental level of two atoms, the basic mechanism underlying FRET, but also open exciting prospects for active tuning of strong, coherent interactions in quantum many-body systems.

The possibility to tune at will coherent interactions in many-body systems by changing external parameters is one of the key tools enabling quantum simulation. For instance, in ultracold quantum gases, such tuning can be achieved by magnetically-induced Feshbach resonances. Rydberg atoms are another promising platform for the quantum simulation of complex many-body problems, owing to the strong interactions associated with their large principal quantum numbers. They have proved to be an efficient tool for characterizing non-radiative exchange of energy in resonant collisional processes, studying collective effects and engineering quantum states of matter. The observation of Rydberg blockade between individual atoms, where the strong interaction between Rydberg states inhibits multiple excitations within a blockade stripe, opens the way towards the development of Rydberg quantum simulators. An appealing tool for those applications is the possibility to tune the strength of the interactions by external electric fields using Förster resonances. So far, owing to inhomogeneities in the atomic ensembles used in experiments, only indirect evidence for the coherent character of the interaction has been obtained.

Here, we study a system of two single atoms at a Förster resonance. We first perform a spectroscopic measurement of the energies of the two-atom states as a function of the applied electric field, and observe directly the avoided crossing between pair states induced by the dipole–dipole interaction. The splitting at resonance is observed to scale as $1/R^3$ as a function of the distance $R$ between the atoms. In a second experiment, we prepare the system in a given pair state away from resonance, and switch to resonance for a controlled time, revealing the coherent oscillation between the two degenerate pair states induced by the dipolar interaction. These results open the way to real-time tuning of interactions for quantum simulation with Rydberg atoms.

Two atoms located at positions $\mathbf{R}_i$ and $\mathbf{R}_j$ interact through the dipole–dipole interaction

$$\hat{V}_{dd} = \frac{1}{4\pi\varepsilon_0} \left( \hat{\mathbf{r}}_{ij} \cdot \hat{\mathbf{r}}_{ij} - 3(\hat{\mathbf{r}}_{ij} \cdot \hat{\mathbf{n}})(\hat{\mathbf{r}}_{ij} \cdot \hat{\mathbf{n}}) \right),$$

where $\hat{\mathbf{r}}_{ij}$ is the electric dipole moment of atom $i$ ($i=1,2$), $R = |\mathbf{R}_i - \mathbf{R}_j|$ and $n = R/R$. When the two atoms are prepared in the same state, $\hat{V}_{dd}$ usually has no effect to first order, as the average value of the dipole moment vanishes in an atomic eigenstate. Second-order perturbation theory gives rise to an energy shift of the atom pair, which results in the van der Waals interaction $U_{vdW} \propto R^{-6}$. However, resonance effects between two Rydberg atoms can occur when two pair states are degenerate, and in this case the dipolar interaction manifests itself at first order. Such a resonance, called a ‘Förster resonance’ in analogy with the FRET mechanism at work in photochemistry, can be achieved using small electric fields to Stark-tune the energy of the pair states.

In this work, we use the states $|p\rangle = |61P_{3/2}, m_f = 1/2\rangle$, $|d\rangle = |59D_{3/2}, m_f = 3/2\rangle$ and $|f\rangle = |57F_{3/2}, m_f = 5/2\rangle$ of $^{87}$Rb. The Förster defect $\Delta_0 = (E_p - E_d)/\hbar$, in the absence of an electric field, is only 8.5 MHz ($\hbar$ is Planck’s constant). Using the differential Stark effect between $|dd\rangle$ and $|pp\rangle$, they can be brought to exact resonance by applying an electric field $E_{\text{elas}} \simeq 32 \text{ mV cm}^{-1}$ (Fig. 1b). The small electric fields at play ensure that we work in a regime of induced dipoles (even for the highly polarizable $f$ state), as opposed to the rigid dipoles obtained for larger electric fields. At resonance, the eigenstates of the interacting system are $|\pm\rangle = (|dd\rangle \pm |pp\rangle)/\sqrt{2}$, where $|pp\rangle = (|pp\rangle + |dp\rangle)/\sqrt{2}$. If the system is initially prepared in $|dd\rangle$, it thus oscillates between the two degenerate electronic states $|\pm\rangle$. This is observed as a spectroscopic ruler for determining nanometric distances in biomolecules, as a ‘spectroscopic ruler’ for determining nanometric distances in biomolecules. The underlying mechanism is a coherent dipolar coupling between particles, as recognized in the early days of quantum mechanics, but this coherence has not been directly observed so far. Here we study, spectroscopically and in the time domain, the coherent, dipolar-induced exchange of excitations between two Rydberg atoms separated by up to 15 μm, and brought into resonance by applying an electric field. Coherent oscillation of the system between two degenerate pair states then occurs at a frequency scaling as $1/R^5$, the hallmark of resonant dipole–dipole interactions. Our results not only demonstrate, at the fundamental level of two atoms, the basic mechanism underlying FRET, but also open exciting prospects for active tuning of strong, coherent interactions in quantum many-body systems.

The possibility to tune at will coherent interactions in many-body systems by changing external parameters is one of the key tools enabling quantum simulation. These results open the way to real-time tuning of interactions for quantum simulation with Rydberg atoms.

Two atoms located at positions $\mathbf{R}_i$ and $\mathbf{R}_j$ interact through the dipole–dipole interaction

$$\hat{V}_{dd} = \frac{1}{4\pi\varepsilon_0} \left( \hat{\mathbf{r}}_{ij} \cdot \hat{\mathbf{r}}_{ij} - 3(\hat{\mathbf{r}}_{ij} \cdot \hat{\mathbf{n}})(\hat{\mathbf{r}}_{ij} \cdot \hat{\mathbf{n}}) \right),$$

where $\hat{\mathbf{r}}_{ij}$ is the electric dipole moment of atom $i$ ($i=1,2$), $R = |\mathbf{R}_i - \mathbf{R}_j|$ and $n = R/R$. When the two atoms are prepared in the same state, $\hat{V}_{dd}$ usually has no effect to first order, as the average value of the dipole moment vanishes in an atomic eigenstate. Second-order perturbation theory gives rise to an energy shift of the atom pair, which results in the van der Waals interaction $U_{vdW} \propto R^{-6}$. However, resonance effects between two Rydberg atoms can occur when two pair states are degenerate, and in this case the dipolar interaction manifests itself at first order. Such a resonance, called a ‘Förster resonance’ in analogy with the FRET mechanism at work in photochemistry, can be achieved using small electric fields to Stark-tune the energy of the pair states.

In this work, we use the states $|p\rangle = |61P_{3/2}, m_f = 1/2\rangle$, $|d\rangle = |59D_{3/2}, m_f = 3/2\rangle$ and $|f\rangle = |57F_{3/2}, m_f = 5/2\rangle$ of $^{87}$Rb. The Förster defect $\Delta_0 = (E_p - E_d)/\hbar$, in the absence of an electric field, is only 8.5 MHz ($\hbar$ is Planck’s constant). Using the differential Stark effect between $|dd\rangle$ and $|pp\rangle$, they can be brought to exact resonance by applying an electric field $E_{\text{elas}} \simeq 32 \text{ mV cm}^{-1}$ (Fig. 1b). The small electric fields at play ensure that we work in a regime of induced dipoles (even for the highly polarizable $f$ state), as opposed to the rigid dipoles obtained for larger electric fields. At resonance, the eigenstates of the interacting system are $|\pm\rangle = (|dd\rangle \pm |pp\rangle)/\sqrt{2}$, where $|pp\rangle = (|pp\rangle + |dp\rangle)/\sqrt{2}$. If the system is initially prepared in $|dd\rangle$, it thus oscillates between the two degenerate electronic states $|\pm\rangle$.
configurations with a frequency given by the dipolar coupling $2\sqrt{2}C_\delta/R^3$ (where $C_\delta = \langle dd|V_{\text{df}}|pf\rangle$). In particular, after half a period of interaction, the system has evolved to the entangled state $|pf\rangle$.

Our experimental set-up has been described previously\textsuperscript{26,27}. We trap two single laser-cooled atoms in optical tweezers separated by a controlled distance $R$ of a few micrometres (Fig. 1c). A set of eight independent electrodes allows us to apply a controlled electric field $F$ aligned with the internuclear axis\textsuperscript{31}. A 3 G magnetic field, also aligned along $z$, is used to split the Zeeman sublevels. We optically pump the atoms in the ground state $|g\rangle = \left| 5S_{1/2}, F = 2, m_F = 2 \right\rangle$ (with an efficiency $>90\%$), which we couple, with an effective Rabi frequency $\Omega$, to the Rydberg state $|d\rangle$ using a two-photon transition (using two lasers of wavelengths 795 nm and 474 nm, with $\pi$ and $\sigma^+$

Figure 1 | Principle of the experiment. a, The pair states $|dd\rangle$ and $|pf\rangle$ are coupled by the dipolar interaction at a Förster resonance. b, Stark effect of the pair states. In the absence of coupling, the two pair-state energy levels (dotted lines) vary when an external electric field $F$ is applied, and cross each other for $F=F_{\text{res}}$. The coupled system (solid lines) undergoes an avoided crossing at resonance (vertical dashed line). c, Experimental set-up. Two individual $^{87}\text{Rb}$ atoms are trapped in microscopic optical tweezers separated by a distance $R$. Eight independent electrodes allow the application of a tunable electric field $F$ along the internuclear axis $z$. d, Structure of the coupled levels at resonance. We scan the excitation laser (blue arrow) to perform a two-atom excitation process. The coupled system (solid lines) undergoes an avoided crossing at resonance (vertical dashed line). A representative error bar (one standard error in the measurement of $P_{nf}$) is shown. A double Gaussian (solid line) is fit to the data. Double-logarithmic plot of the splitting $\Delta E$ between the peaks, at resonance, as a function of $R$. Error bars are one standard deviation in the determination of $\Delta E$ in the fit by a double Gaussian. The solid line shows a fit by a power law, giving an exponent $-3.2 \pm 0.2$.

Figure 2 | Spectroscopy at the Förster resonance. a, Two-atom excitation spectrum where the population of doubly-Rydberg-excited states, $P_{nf}$, is plotted as a function of $\delta$ and $F$, showing the avoided crossing between the resonant pair states. The white dashed line indicates the position of the Förster resonance. b, Spectrum $P_{nf}(\delta)$ at resonance for $R=8.1\mu m$. A representative error bar (one standard error in the measurement of $P_{nf}$) is shown. A double Gaussian (solid line) is fit to the data. The detuning between the laser frequency and the position of $|dd\rangle$ in the absence of interactions (grey horizontal line) is denoted by $\delta$. Independent electrodes allows us to apply a controlled electric field $F$ aligned with the internuclear axis $z$. A 3 G magnetic field, also aligned along $z$, is used to split the Zeeman sublevels. We optically pump the atoms in the ground state $|g\rangle = \left| 5S_{1/2}, F = 2, m_F = 2 \right\rangle$ (with an efficiency $>90\%$), which we couple, with an effective Rabi frequency $\Omega$, to the Rydberg state $|d\rangle$ using a two-photon transition (using two lasers of wavelengths 795 nm and 474 nm, with $\pi$ and $\sigma^+$

polarizations, respectively). The readout of the states of the atoms is performed by shining resonant light at 780 nm on the atoms, giving a fluorescence signal only if the atom is in \(|g\rangle\) (an atom in a Rydberg state, be it \(|p\rangle\), \(|f\rangle\), or \(|r\rangle\), is lost from the trap during the sequence). Repeating the same sequence \(\sim 100\) times allows us to reconstruct the four populations \(P_{gg}, P_{pp}, P_{gf}\), and \(P_{fr}\), where \(r\) stands for any of the Rydberg states \(p, d\), and \(f\), which we cannot discriminate directly with our loss-based detection scheme), with a typical uncertainty in the measurement of \(P_r\) on the order of \(\pm 0.05\) (see representative error bars in Figs 2b and 3b).

We first fix \(R = 8.1\) μm and perform a spectroscopic measurement to find the electric field \(F_{res}\) corresponding to the Förster resonance. Our laser system couples \(|gg\rangle\) to \(|dd\rangle\) (but not to \(|pf\rangle\) or \(|gp\rangle\)), via the states \(|dg\rangle\) and \(|gd\rangle\). Thus \(|gg\rangle\) is partially coupled to the states \(|+\rangle\) and \(|-\rangle\) at resonance. For increasing values of \(F\), we scan the laser detuning \(\delta\) (defined with respect to the transition \(|gg\rangle\) to \(|dd\rangle\)), see Fig. 1d) and measure the probability \(P_{fr}\) for both atoms to be in a Rydberg state (Fig. 2a). For \(F = 0\), we observe a single line centred at \(\delta/(2\pi) \approx -5\) MHz, corresponding to the attractive van der Waals interaction between the two atoms out of resonance. For \(F \approx 20\) mV cm\(^{-1}\), a repulsive branch appears in the spectrum, a signature of the interaction between \(|dd\rangle\) and \(|pf\rangle\). Increasing the field even further allows scanning across the avoided crossing until only one peak is visible again. We reach the Förster resonance (smallest splitting between the two peaks) at \(F_{res} = 32 \pm 4\) mV cm\(^{-1}\), where we observe two symmetric peaks corresponding to \(|\pm\rangle\). The spectra also show further small structures in addition to the two main peaks. However, to extract the interaction energy in a simple way, we fit the spectra by two Gaussians with a splitting \(\Delta E\) between the two peaks (Fig. 2b).

We then measure the evolution of the spectra at resonance when varying the distance \(R\). When \(R\) increases, the splitting between the peaks decreases. Figure 2c is a double-logarithmic plot of \(\Delta E\) versus \(R\). The data show a power-law behaviour of exponent \(-3.2\pm 0.2\), consistent with the expected \(C_{3i}/R^3\) law. We measure \(C_{3i} = 2.1 \pm 0.1\) GHz μm\(^2\), where the error is statistical. Systematic effects are an overall \(-5\%\) uncertainty in our calibration of \(R\), a small bias in the determination of \(\Delta E\) due to the choice of double Gaussian functions to fit the data and possible residual light-shifts in the two-photon spectroscopy. To estimate the bias introduced by our choice of fit function, we fitted simulated spectra, obtained by solving the optical Bloch equations, by double Gaussians. The extracted splitting underestimates by \(\sim 10\%\) the actual splitting \(\Delta E\).) Theoretical calculations\(^{25}\) give \(C_{3i,th} \approx 2.54\) GHz μm\(^2\).

We now study the coherence properties of the system at resonance using a sequence (Fig. 3a) reminiscent of pump–probe spectroscopy. We prepare the system in the state \(|dd\rangle\) using a π-pulse of 200 ns, which transfers each atom from \(|g\rangle\) to \(|d\rangle\). To start in a pure \(|dd\rangle\) state, we perform the excitation in the van der Waals regime above resonance \((F \approx 64\) mV cm\(^{-1}\)), where the Förster defect is \(\Delta(F) \approx h \times 100\) MHz and where interactions are weak. We then turn on the resonant interaction for a variable duration \(T\), by rapidly switching (risetime below 10 ns) the field to \(F_{res}\). During this time, the two-atom system oscillates between \(|dd\rangle\) and the entangled state \(|pf\rangle\), with a frequency \(f_{osc} = \Delta E/h = 2\sqrt{2C_{3i}}/(hR^3)\) given by the dipolar coupling. We then apply a deexcitation π-pulse identical to the first one to read out the state of the system. The deexcitation pulse couples the \(|dd\rangle\) component of the system back to \(|gg\rangle\). At the end of the sequence we measure the probability \(P_{gs}\) to be back in \(|gg\rangle\), thus indirectly measuring the population left in \(|dd\rangle\) after the pulse...
The oscillations between two states are a direct proof of the coherent nature of the coupling underlying Förster energy transfer, and also allow a more accurate determination of the interaction energy than the spectroscopic method described above. We fit the oscillation by a damped sine wave to extract the oscillation frequency \( f_{osc} \). Figure 3c shows a double-logarithmic plot of the values of \( f_{osc} \) as a function of \( R \). The data shows a power-law behaviour of exponent \(-3.0 \pm 0.1\), again in excellent agreement with the expected \( R^{-3} \) behaviour. The measured \( C_3 = 2.39 \pm 0.03 \text{ GHz mm}^{-1} \) is also close to the theoretical value.

The observed damping of the oscillations comes mainly from dephasing, arising from two effects. First, shot-to-shot fluctuations in the distance \( R \) (on the order of \( \delta R \approx 170 \text{ nm} \)), due to the finite temperature of the atoms in the tweezers, give rise to dephasing, as the oscillation frequency \( f_{osc} \), or \( \lambda / R \), is slightly different for each realization. This effect dominates at short distances; for instance, for \( R > 9 \mu m \), the corresponding spread \( \Delta f_{osc} \) or \( \Delta \lambda / R \) is slightly different for each realization. Second, the voltages applied to the electrodes also fluctuate from shot to shot by a few mV, inducing fluctuations in \( F \) and thus in the detuning \( \Delta F \) from resonance (by a factor of a MHz for our parameters). This has negligible impact for small \( R \), but appreciably contributes to the damping for large \( R \), where the dipolar interaction is weaker. In principle, both sources of damping can be strongly decreased by technical improvements in the set-up, using colder atoms as demonstrated recently\(^{26,31} \) and more stable voltage sources.

Our results open exciting prospects for real-time tuning of interactions in systems of Rydberg atoms, in particular to switch on and off Ryberg blockade on nanosecond timescales. As an illustration, in the above experiment, when switching \( F \) from 64 mV cm\(^{-1} \) (away from resonance) to 32 mV cm\(^{-1} \) (on resonance), the blockade shift between two atoms separated by \( R = 10 \mu m \) varies from \( U = U_{\text{RRW}} \approx \hbar \times 0.2 \text{ MHz} \) (van der Waals regime) up to \( U = \Delta E / 2 \approx \hbar \times 4 \text{ MHz} \) (\( C_4 / R^4 \) regime). If the pair of atoms initially in \( |gg \rangle \) were driven with a Rabi frequency \( \Omega / 2 \approx 1 \text{ MHz} \), one would observe a strong blockade in the second case, whereas blockade would be almost totally suppressed in the first situation. This means that, simply by changing the value of the electric field by a few mV cm\(^{-1} \), we obtain a twenty-fold enhancement of the interaction, and the blockade radius is increased by a factor \( \sim 2 \) in real time, a feature hard to achieve by other means.

A natural extension of this work will consist in measuring the angular dependence of resonant interactions\(^{29} \), in view of tailoring even further the interactions between the two particles. Extending our results beyond two particles, to few-body\(^{32} \) and many-body systems\(^{15,16,23} \), will enable the study of transport of excitations and generation of entanglement in fully controlled many-body systems.
