Received xxxxxxx; accepted xxxxxxx

Abstract. We present infrared and radio continuum observations of S 201 star forming region. A massive star cluster is observed in this region, which contains different classes of young stellar objects. The near-infrared colour-colour and colour-magnitude diagrams are studied to discuss the nature of these sources. We have discovered the knots of molecular hydrogen emission at 2.122 \textmu m in the central region of S 201. These knots are clearly seen along the diffuse emission in north–west direction which are probably the obscured Herbig-Haro objects. High sensitivity and high resolution radio continuum images from GMRT observations at 610 and 1280 MHz show an interesting arc-shaped structure due to the interaction between the HII region and the adjacent molecular cloud. The ionization front at the interface between the HII region and the molecular cloud is clearly seen by comparing the radio, molecular hydrogen and Br\gamma images. The emission from the carriers of Unidentified Infrared Bands in the mid-infrared 6–9 \textmu m (possibly due to PAHs) as extracted from the Midcourse Space Experiment survey (at 8, 12, 14 and 21 \textmu m) is compared with the radio emission. The HIRES processed IRAS maps at 12, 25, 60, and 100 \textmu m, have also been used for comparison. The spatial distribution of the temperature and the optical depth of the warm dust component around S 201 region, has been generated from the mid-infrared images.
1. Introduction

The high mass star forming region S 201, corresponding to the radio source W 5A, is at a distance of 2.3 kpc from the Sun (Mampaso et al. 1987). The S 201 region is coincident with an IRAS source (IRAS 02593+6016) with increasing spectrum from 12 to 100 $\mu$m. The IRAS fluxes lead to a luminosity of $\sim 1.1 \times 10^4 L_\odot$ (Zinchenko et al. 1997) for this source. The HII region S 201 is part of an extended complex of gas and dust stretched in the east-west direction and it is bordered on the west by the molecular cloud IC 1848 identified with the radio source W 5.

Earlier observations of S 201 region in the infrared wavelengths (Kleinmann et al. 1979, Thronson et al. 1984, Mampaso et al. 1989, Carpenter et al. 1993) and the radio (Felli et al. 1987, Fich 1993, Omar et al. 2002) have shown an interesting structure presumably due to the interaction between the HII region and the adjacent molecular cloud (Martin & Barrett 1978). The radio source has a bright, arc-shaped edge on one side and a smoothly decreasing surface brightness distribution on the opposite side as seen in the VLA observations at 2 and 6 cm (Felli et al. 1987). They modeled this configuration in terms of a three-dimensional electron distribution produced by the ionizing radiation of an early-type star located outside a spherical molecular cloud and found that an O9 zero age main sequence (ZAMS) star placed at a distance of 0.38 pc from a molecular cloud of 0.42 pc radius allows a good fit to the their data.

We have started a near-infrared (NIR) and radio continuum observational programme of study of regions of massive star formation. This is our first paper in this series. In this paper we study the Galactic star forming region S 201 in the infrared and the radio wavelengths with the aim of identifying the stellar populations in the directions of the IRAS source (IRAS 02593+6016). This paper combines new NIR observations from Telescopio Infrarosso del Gornergratm (TIRGO) & Telescopio Nazionale Galileo (TNG) telescopes, Italy with mid-infrared (MIR) data (8-21 $\mu$m) from Midcourse Space Experiment (MSX) and radio continuum observations at 610 & 1280 MHz from Giant Metrewave Radio Telescope (GMRT), India.

In Sect. 2, we present the broad- and narrow-band NIR observations, as well as complementary MIR and radio continuum observations. Sect. 3 deals with the results and the discussion and we summarize our conclusions in Sect. 4.
2. Observations and data reduction

2.1. NIR observations

2.1.1. Broad-band images

The broad-band (JHK) NIR observations were carried out on 23 December 2000 using the Arcetri NIR camera (ARNICA) mounted on the 1.5m f/20 infrared telescope TIRGO. ARNICA is equipped with a NICMOS3 \(256 \times 256\) HgCdTe detector. The plate scale at TIRGO was \(0.96''/\text{pixel}\) and the mean PSF was approximately \(1.5''-1.8''\) (FWHM) during the observations.

We observed the field in the direction of the IRAS source 02593+6016 in the three standard J (1.25 \(\mu m\), \(\Delta \lambda = 0.3 \mu m\)), H (1.6 \(\mu m\), \(\Delta \lambda = 0.3 \mu m\)), and K (2.2 \(\mu m\), \(\Delta \lambda = 0.4 \mu m\)) broad-band filters. A large number of dithered sky frames were obtained (by shifting the telescope a few arcmin off the source in north-west-south-east directions) in all the filters for sky subtraction and for making flat frames. Total on-target integration times were 60 s, 24 s, and 24 s in the J, H, and K bands, respectively. The photometric calibration was obtained by observing the standard stars AS03 & AS09 (Hunt et al. 1998) in all three bands. Fig. 1 shows the J, H, and K band images of S 201 region. The JHK images show the presence of diffuse emission near the center of the images, with an apparent concentration of embedded stars, suggesting the presence of a young cluster (see Sect. 3).

Data reduction was done using IRAF\(^1\) software tasks. All the NIR images went through standard pipeline procedures like sky-subtraction and flat-fielding. Accurate photometry was performed on the point sources detected in each of the three bands using the DAOPHOT (Stetson 1987) routines in IRAF software. Absolute position calibration was achieved using the coordinates of a number of stars from the USNO2.0 catalogue. The completeness limits of the images were evaluated by adding artificial stars of different magnitudes to the images and determining the fraction of stars recovered in each magnitude bin. The recovery rate was greater than 90% for magnitudes brighter than 17, 16 and 15.5 in the J, H and K bands, respectively. The observations are complete (100%) to the level of 15.5, 14.5 and 14 magnitudes in J, H and K bands, respectively. The average photometric error in all colours is \(\pm 0.07\) mag.

We checked our photometry with the data from 2MASS (The Two Micron All Sky Survey). The 2MASS All Sky Point Source Catalogue\(^2\) provides J, H & K\(_s\) magnitudes for each source. The 2MASS K\(_s\) filter is centered at 2.17 \(\mu m\) and has a bandpass of 0.32 \(\mu m\). Fig. 2 shows the comparison between TIRGO and 2MASS magnitudes in J, H & K bands.

---

\(^1\) IRAF is distributed by the National Optical Astronomy Observatories, which is operated by the Association of Universities for Research in Astronomy, Inc. under contract to the National Science Foundation.

\(^2\) http://www.ipac.caltech.edu/cgi-bin/gator/nph-dd
filters. We see a good linear relation between the two systems, with the slopes between 0.9–0.97 and the dispersions that increase with the magnitude.

2.1.2. Narrow-band images

The images through narrow-band filters including the molecular hydrogen ($\text{H}_2$ $v = 1 - 0 S(1)$) transition (2.122 $\mu$m, FWHM = 0.032 $\mu$m), the Br$\gamma$ line (2.169 $\mu$m, FWHM = 0.035 $\mu$m), and continuum K (Kcont at 2.275 $\mu$m, FWHM = 0.039 $\mu$m), were obtained on 13 November, 2002 at 3.58m TNG telescope at La Palma using the Near-Infrared Camera Spectrometer (NICS). NICS is the TNG infrared (0.9–2.5 $\mu$m) multimode instrument which is based on a HgCdTe Hawaii 1024x1024 array (Baffa et al. 2001). The image scale was 0.25$''$/pixel and the mean PSF was approximately 1.3$''$ (FWHM). Total integration time was of 90 s in all three filters. The images were analysed in a similar process as those from TIRGO. To identify the pure line emission ($\text{H}_2$ $v = 1 - 0 S(1)$ and Br$\gamma$) one needs to subtract the continuum. That is done by subtracting the K continuum image from H$_2$ and Br$\gamma$ images after aligning and PSF matching.

Fig. 3 shows the H$_2$, Br$\gamma$, H$_2$ continuum subtracted (reveal the pure H$_2$ line emission), and Br$\gamma$ continuum subtracted images.

2.2. Mid-infrared data from MSX

The MSX images in A (8.3 $\mu$m), C (12.13 $\mu$m), D (14.65 $\mu$m), and E (21.34 $\mu$m) bands (Price et al. 2001) for the region around S 201 have been used to estimate the spatial distribution of warm interstellar dust, its temperature and optical depth. The MSX A and C bands with $\lambda(\Delta\lambda)$ corresponding to 8.28(3.36) and 12.13(1.72) include several Unidentified Infrared emission Bands (UIBs) at 6.2, 7.7, 8.7, 11.3, and 12.7 $\mu$m. Using a scheme developed by Ghosh & Ojha (2002), the emission in these UIBs, probably due to the Polycyclic Aromatic Hydrocarbons (PAHs), have been extracted from the MSX images by correcting for the underlying thermal continuum from the interstellar dust.

2.3. Mid- and far-infrared data from IRAS

The data from the IRAS survey in the four bands (12, 25, 60, and 100 $\mu$m) for the region around S 201 were HIRES processed (Aumann et al. 1990) at IPAC. The HIRES processed maps in all the four IRAS bands are shown in Fig. 4. These maps have also been used to generate the maps of dust colour temperature and optical depth.

2.4. GMRT Radio continuum observations

The ionized gas within and around the HII region associated with S 201 has been mapped at high angular resolution using the Giant Metrewave Radio Telescope (GMRT) array.
The radio continuum observations have been carried out in two frequency bands, viz., 610 & 1280 MHz on 04 January, 2002 and 28 September, 2002, respectively. The sources 3C48 and 3C147 were used as the primary flux calibrators for 610 & 1280 MHz observations, respectively, while the source 0432+416 was used as a secondary calibrator for both the observations. The GMRT antennas and their configurations are discussed in detail by Swarup et al. (1991).

Data reduction was done in classic AIPS. Bad data (dead antennas, interference, spikes, etc.) were identified and flagged using UVFLG & TVFLG. Images of the field were formed by Fourier inversion and cleaning (IMAGR). The initial images were improved by self-calibration (CALIB) in both phase and amplitude.

Figs. 5 & 6 show the radio continuum images of S 201 region generated from the GMRT observations at 1280 & 610 MHz respectively. The radio continuum images have a resolution of 4.5″×2.5″ at 1280 MHz, and 8.7″×5.7″ at 610 MHz. The images have an rms of 42 µJy beam$^{-1}$ at 1280 MHz, and 47 µJy beam$^{-1}$ at 610 MHz. The total flux densities are 0.68 Jy & 0.77 Jy at 1280 MHz & 610 MHz, respectively.

3. Results and discussion

3.1. The embedded cluster

Inside a ~ 3.5′×3.4′ field centered on IRAS 02593+6016 source, 114 stars are found to be common to all the three JHK bands and 153 stars are common to the HK bands alone, with magnitude errors less than 0.2. Fig. 7 shows a colour-colour (CC) diagram for the 114 stars detected in the JHK bands. The solid and broken heavy curves represent the unreddened main sequence dwarfs and giant branch (Koornneef 1983) and the parallel dashed lines are the reddening vectors for early and late type stars (drawn from the base and tip of the two branches) that encloses reddened main sequence objects. The dotted line indicates the locus of T-Tauri stars (Meyer et al. 1997). We have assumed that $A_J/A_V = 0.282; A_H/A_V = 0.175$ and $A_Ks/A_V = 0.112$ (Rieke & Lebofsky 1985).

Most of the sources have colours of reddened photospheres but some of the stars lying outside the region of reddened main sequence objects (right of the reddening line for early type stars) are mostly young stellar objects (YSOs) with intrinsic colour excess. By de-reddening the stars (on the CC diagram) that fell within the reddening vectors encompassing the main sequence stars, we found visual extinction ($A_V$) towards each star. The individual extinction values range from 0 to 18 magnitudes with the average foreground extinction of $A_V \sim 5$ mag. The stars lying on the left side of the reddening band are mostly foreground stars as supported by their low values of $A_V$.

About 12% of the sources (within 0.43 pc radius around the position of the IRAS source) detected in J, H & K bands show an infrared excess (H-K > 1, J-H > 1, $A_V \sim 8$–14). These YSOs are shown as star symbols in Fig. 7 and they are concentrated close
to the center of the embedded young stellar cluster. The most massive O6–O8 type star is located S-W of the cluster and is surrounded by at least two massive stars of spectral types earlier than B2, both of them showing an infrared excess (see Fig. 8).

Fig. 8 shows the H-K vs K colour-magnitude (CM) diagram for all the sources detected in HK bands. The vertical solid lines (from the left to the right) represent the main sequence curve reddened by 0, 20 and 40 magnitudes, respectively. We have assumed a distance of 2.3 kpc to the source to reproduce the main sequence data on this plot. The horizontal slanting lines in Fig. 8 trace the reddening zones for each spectral type. However, it should be noted that the spectral types inferred from the CM diagram are only upper limits when the stars present infrared excess. YSOs with an infrared excess found from CC diagram (Fig. 7) are shown as star symbols. However, it is important to note that even those stars not shown with a star symbol may represent YSOs with intrinsic colour excess, since these stars detected in the H and K bands are not detected in the J band due to their very red colours. The three massive and luminous stars discussed earlier are located at the top of the CM diagram (K < 11.8).

Following the method described in Testi et al. (1999) we estimated the number of stars in the central regions of the cluster, within 40″ (0.4 pc), from the most massive star in the cluster (#2). We found an excess of ~ 38 objects above the background with K band magnitude less than 15.5, corresponding to our 90% completeness level. The corresponding stellar volume density in the inner region of the cluster would then be ~ 10^2 stars/pc^3, on the low side compared to the typical densities of objects around early Herbig Be stars in the survey of Testi et al. (1999). However, to make a sensible comparison we need to estimate the lowest mass object that can be probed with our observations, which can be estimated following the method outlined in Testi et al. (1998). Assuming the distance of 2.3 kpc, an age in the range 0.5–1 Myr, and an extinction in K band between 0 and 1 mag (up to A_V ~ 10), the derived magnitude limit corresponds to M ~ 0.5 M_☉ (using Palla & Stahler (1999) pre-main sequence evolutionary tracks)), which is significantly higher than most of the limits in Testi et al. (1999).

3.2. Comparison of infrared and radio continuum observations

The radio maps from GMRT at 1280 and 610 MHz (Figs. 5 & 6) display a striking cometary morphology with sharp boundaries toward the N–NE, and diffuse emission extending toward S–SW (an angular diameter of approximately ~ 4′). This kind of morphology is produced by the winds and shocks from the massive stars in the vicinity of the molecular clouds, which are expected to compress the nearmost edges of nearby clouds and develop the cometary structure (Bachiller et al. 2002). Three bright near-infrared sources are present within the radio nebulosity. One of the sources (id#1 in Fig. 1) with NIR excess (H-K > 1) is very close to the radio peak suggesting the spectral type
of B1 in the H-K vs K CM diagram. This source is also coincident, within errors, with the H$_2$O maser position present in the region (Blair et al. 1980). The brightest infrared source (id#2: K=10.24, H-K = 1.40, J-H = 2.66) deeply embedded in the cloud ($A_V$ $\sim$ 22), is located $\sim$ 26$''$ ($\sim$ 0.29 pc) west of the radio peak. The projected distance of source #2 from the cloud is approximately 33$''$ (0.37 pc). The colour and IR luminosity of this source indicate that it is an O6–O8 type star. The position of #2 coincides with the “secondary peak” detected by Felli et al. (1987) in the radio and also seen in the GMRT radio images (see Figs. 1 & 5).

It is interesting to revisit the model of Felli et al. (1987) after the results of our new near-infrared observations. Their modeling of the VLA observations was based on the assumption of a single star providing all the ionizing photons, while our observations clearly reveal a rich cluster within the radio continuum emission. The estimated spectral types from CM diagram and the total Lyman continuum photons (using the table in Panagia 1973) for the five bright stars within the young cluster are shown in Table 1. The most massive star (#2) alone provides more than 90% of the total Lyman continuum supply rate, explaining the success of the model based on a single source of the ionizing radiation. It is also interesting to note that our observations confirm the suggestion by Felli et al. (1987) of the co-location of the massive star responsible for the ionization of the nebula and the secondary peak of radio emission.

The quadrupole transition ($v = 1 - 0$ $S(1)$) of molecular hydrogen at 2.122 $\mu$m is an excellent tracer of shock emission and photo-dissociation regions (PDRs). In particular, in PDRs the molecular hydrogen emission traces the first neutral layer beyond the ionization front, a typical, well studied case is that of the PDR at the interface between the Orion Nebula and the Orion molecular cloud (the Orion Bar, see Walmsley et al. 2000). In fact, the model of Felli et al. (1987) implicitly predicts that a PDR should be located at the interface between the ionized and molecular gas, to the east of the arc-shaped feature in the radio continuum maps. Our near-infrared narrow band images fully support this picture, as we detect diffuse H$_2$ emission where the PDR region should be located (see Fig. 9). Additionally, in the north-east corner of the image we detect an H$_2$ knot reminiscent of Herbig-Haro objects.

The continuum subtracted Br$\gamma$ image displays a morphology very similar to the radio continuum maps, with a bright, arc-shaped edge on one side and a smoothly decreasing surface brightness distribution on the opposite side and a peak coinciding exactly with the radio continuum one (Figs. 3 & 10). The similar morphology between the Br$\gamma$ and radio continuum maps indicates that there are no steep extinction gradients across the S 201 region.

The ionization front at the interface between the HII region and the molecular cloud is clearly seen by comparing the radio, molecular hydrogen and Br$\gamma$ images (Figs. 3, 5

3.3. Spatial distribution of Unidentified Infrared emission Bands (UIBs) around S 201 region

The MSX surveyed the entire Galactic plane within |b| ≤ 5° in four mid-infrared spectral bands centered at 8.28, 12.13, 14.65 and 21.34 μm, with image resolution of 20′′ (Price et al. 2001). We have used the scheme developed by Ghosh & Ojha (2002) to extract the contribution of Unidentified Infrared emission Bands (UIBs) from the mid-infrared MSX images of S 201 region in the four bands. The scheme models the observations with a combination of thermal emission (gray body) from interstellar dust and the UIB emission from the gas component, under reasonable assumptions. The spatial distribution of emission in the UIBs with an angular resolution ∼ 20′′ (intrinsic to MSX survey) has been extracted and is shown in Fig. 11.

The UIBs emission map has been compared with the GMRT observations at 1280 MHz in Fig. 12. The positions of the peaks and other morphology (along N-S to E-W) compare rather well between the UIBs and the radio emission maps though we see a strong extended component of UIBs emission along S-E as compared to the radio emission.

3.4. Dust optical depth and temperature maps

3.4.1. From MSX

The MSX maps were used to obtain maps of warm dust temperature and optical depth (Ghosh & Ojha 2002). Since the range of frequencies covered by the MSX bands is limited, we assume a power law dependence of the dust emissivity on frequency of the form $\epsilon_\lambda \propto \lambda^{-1}$. The optical depth and dust temperature maps have been presented in Fig. 13.

The positions of the peaks of the optical depth and temperature are different. The optical depth map is morphologically similar to the UIBs intensity map and the peaks
in the two coincide indicating presence of the high densities near the embedded sources. However, the temperature map shows a more extended distribution with decreasing temperature gradient toward S to S-W. The temperature map peaks close to the boundary of UIBs emission toward west (48″ or 0.5 pc from the UIBs emission peak).

3.4.2. From HIRES

We have used HIRES maps to generate maps of the dust colour temperature \(T(12/25)\) & \(T(60/100)\), and optical depth \(\tau_{12} \& \tau_{100}\) around S 201 region. The intensity maps at 12, 25, 60 and 100 \(\mu m\) (Fig. 4) were spatially averaged before computing \(T(12/25), \tau_{12}, T(60/100), \) and \(\tau_{100}\) in a manner similar to that described by Ghosh et al. (1993) for an emissivity law of \(\epsilon_\lambda \propto \lambda^{-1}\). The dust optical depth and temperature maps are presented in Fig. 14.

3.4.3. Comparison between MSX and HIRES maps

A comparison of the \(\tau_{10}\) maps generated from the higher angular resolution MSX maps (Fig. 13a) and that based on IRAS HIRES maps at 12 and 25 \(\mu m\) (the best resolution among the 4 bands) is in order. The latter has been presented in Fig. 14a, which is scaled to 10 \(\mu m\) by \(\lambda^{-1}\) emissivity law to make the comparison with MSX \(\tau_{10}\) map. The peak optical depth and the effective FWHM for the central maximum are \(2.13 \times 10^{-4}\) and \(54''\) respectively for the map based on MSX. The corresponding values from the IRAS–HIRES maps are \(6.6 \times 10^{-5}\) and \(60''\).

These derived values are in reasonable agreement considering the fact that they are based on instruments with very different angular resolutions. The difference in the peak values of \(\tau_{10}\) may be a result of two effects, viz., beam dilution and a clumpy interstellar medium.

The peak dust column density implied by the optical depth map at 100 \(\mu m\) (Fig. 14b), is much higher than that implied by the \(\tau_{10}\) map from MSX data (Fig. 13a). This is not surprising, since the former has main contribution from the cooler component of dust grains (\(T < 80\) K) lying in the larger outer envelope of the cloud. Only the dust grains very close to the exciting source can contribute to \(\tau_{10}\) map.

Compared to MSX, the HIRES maps at 60 and 100 \(\mu m\) trace the distribution of colder dust (35–55 K). However, the hot spot due west and a cooler plateau due east can be seen in the two maps (Figs. 13b & 14c), which shows the similar sense of temperatures between the MSX and HIRES (\(T(12/25))\).

4. Conclusions

A detailed radio and infrared study of an embedded young stellar cluster associated with the Galactic star forming region S 201 is presented here. The colour-colour and colour-
magnitude diagrams have been constructed to identify young stellar objects and estimate their spectral types. The high sensitivity and high angular resolution radio continuum maps based on the GMRT observations at 610 and 1280 MHz have been generated. These radio maps show interesting morphological details, including an interesting arc-shaped structure highlighting the interaction between the HII region and the adjacent molecular cloud. Three luminous infrared sources have been identified which are located within the radio nebulosity. The spatial distribution of temperature and optical depth of the interstellar dust component in the S 201 region, has been presented based on the mid- and far-infrared measurements from the MSX and IRAS (HIRES) missions.

We have detected a compact embedded star cluster located within the ionized nebula responsible for the radio continuum emission. The cluster has richness similar to the clusters surrounding early type Herbig Be stars; the most luminous member is consistent with an O6–O8 zero age main sequence star. Our analysis confirms that this single star is responsible for most of the Lyman continuum emission required to sustain the ionized radio nebula, with all the other cluster members contributing at most 10% of the ionizing photons. This explains the reason for the success of the model of Felli et al. (1987) (which assumed a single massive star for excitation), in explaining the radio continuum morphology of S 201. Our observations also confirm the position of this massive star as well as the location of the molecular cloud being eroded by the ionizing radiation. The PDR at the interface between the ionized gas and the molecular cloud is traced to the west of the bright arc-shaped feature in radio continuum and Brγ, by the diffuse H2 emission detected in our narrow-band near-infrared images.

Acknowledgements. We thank the staff of the GMRT that made the radio observations possible. The GMRT is run by the National Centre for Radio Astrophysics of the Tata Institute of Fundamental Research. It is a pleasure to thank the Arcetri and TNG technical staff and the TNG operators for their assistance during the NICS observing runs. We also thank the TIRGO team, especially Filippo Mannucci, for nice scheduling and service observing at the Gornergrat.

This paper is based on observations made with the Italian Telescopio Nazionale Galileo (TNG) operated on the island of La Palma by the Centro Galileo Galilei of the CNAA (Consorzio Nazionale per l’Astronomia e l’Astrofisica) at the Spanish Observatorio del Roque de los Muchachos of the Instituto de Astrofisica de Canarias.

This publication makes use of data products from the Two Micron All Sky Survey, which is a joint project of the University of Massachusetts and the Infrared Processing and Analysis Center/California Institute of Technology, funded by the National Aeronautics and Space Administration and the National Science Foundation. IPAC is thanked for providing HIRES processed IRAS data.

This research made use of data products from the Midcourse Space Experiment, the processing of which was funded by the Ballistic Missile Defense Organization with additional support from NASA Office of Space Science. This research has also made use of the NASA/IPAC
Infrared Science Archive, which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with National Aeronautics and Space Administration.

DKO was supported by the JSPS (Japan) through a fellowship during which some part of this work was done. We thank Francesco Palla for providing us with their PMS grids.

**Fig. 1.** TIRGO J, H & K band images (clockwise from the top left) of S 201 region. North is the top and east to the left. The total integration times are 60 s in J, 24 s in H, and 24 s in K bands. The abscissa and the ordinates are in B1950.0 epoch. The bottom left figure shows the TIRGO K band image overlayed by GMRT radio contours (see §3.2 for discussion).

**Fig. 2.** Comparison between TIRGO and 2MASS magnitudes in J, H & K bands. The continuous lines show the linear fit to the magnitudes. The slopes to the linear fits range from 0.9 to 0.97 between the two systems in the three filters.

**Fig. 3.** H$_2$, Br$_\gamma$, continuum subtracted Br$_\gamma$, and continuum subtracted H$_2$ line images of the central region ($\sim 88'' \times 88''$) of S 201 (clockwise from the top left). Notice also the presence of H$_2$ knots near the center and upper left corner of the image (bottom left figure). North is the top and east to the left. The total integration time is 90 s in all the filters. The abscissa and the ordinates are in B1950.0 epoch.

**Fig. 4.** The HIRES processed IRAS maps for S 201 region in the four bands (clockwise from the top left) – (a) 12 $\mu$m with peak = 21 Jy/sq. arcmin, (b) 25 $\mu$m with peak = 122 Jy/sq. arcmin, (c) 60 $\mu$m with peak = 622 Jy/sq. arcmin, and (d) 100 $\mu$m with peak = 415 Jy/sq. arcmin. The isophot contour levels in 12 $\mu$m are 95, 90, 80, 70, 60, 50, 40, 30, 20 & 10 %, in 25 & 60 $\mu$m are 95, 90, 80, 70, 60, 50, 40, 30, 20, 10, 5 & 2.5 %, and in 100 $\mu$m are 95, 90, 80, 70, 60, 50, 40, 30, 20, 10 & 5 % of the respective peaks. The abscissa and the ordinates are in B1950.0 epoch.

**Fig. 5.** GMRT high resolution map of S 201 at 1280 MHz. The resolution is 4.5×2.5 arcsec$^2$ along PA = -23°, and the rms noise in the map is 42 $\mu$Jy beam$^{-1}$.

**Fig. 6.** GMRT high resolution map of S 201 at 610 MHz. The resolution is 8.7×5.7 arcsec$^2$ along PA = -14°, and the rms noise in the map is 47 $\mu$Jy beam$^{-1}$.

**Fig. 7.** Colour-Colour diagram for the 114 sources detected in JHK bands in S 201 region. The locii of the main sequence and giants branch are shown by the solid curve (dwarf) and broken heavy curve (giants) taken from Koornneef (1983). The three parallel dashed straight lines follow the reddening vectors taken from Rieke & Lebofsky (1985). Crosses on the dashed lines are separated by $A_V = 5$ mag. The dotted line represents the locus of T-Tauri stars (Meyer et al. 1997). The star symbols represent YSOs with intrinsic colour excesses within 0.43 pc radius around the center of the cluster. Three bright stars within the cluster are represented by #1, #2 & #3 (see Fig. 1 & §3).
Fig. 8. Colour-Magnitude diagram for the 153 sources detected in HK bands. Stars represent the YSOs identified from Fig. 7. The vertical solid lines from left to right indicate the track of main sequence dwarfs at 2.3 kpc reddened by 0, 20 and 40 magnitudes, respectively. The intrinsic colours are taken from Koornneef (1983). Slanting horizontal lines identify the reddening vectors (Rieke & Lebofsky 1985). The symbols are same as shown in Fig. 7.

Fig. 9. Continuum-subtracted molecular hydrogen emission at 2.122 μm around S 201 region. The contour plot shows the 1280 MHz radio continuum emission from GMRT. Notice also the presence of knots near the center and upper left corner of the image. The abscissa and the ordinates are in B1950.0 epoch.

Fig. 10. Continuum-subtracted Brγ image of S 201 region. The contour plot shows the 1280 MHz radio continuum emission from GMRT. The abscissa and the ordinates are in B1950.0 epoch.

Fig. 11. The spatial distribution of total radiation in Unidentified Infrared emission Bands (UIBs) for the region around S 201, as extracted from the MSX images. Contour levels are drawn at 5, 10, 20, 30, 40, 50, 60, 70, 80, 90, 95 and 99% of the peak intensity of $4.11 \times 10^{-5} \text{W m}^{-2} \text{sr}^{-1}$. The abscissa and the ordinates are in B1950.0 epoch.

Fig. 12. The emission in UIBs (grey scale) in the mid-infrared (6–9 μm). The contours show the radio emission at 1280 MHz as measured by GMRT. The abscissa and the ordinates are in B1950.0 epoch.

Fig. 13. (a) The spatial distribution of dust optical depth ($\tau_{10}$ at 10 μm) for the S 201 region, as extracted from the MSX images. The contour levels are at $\tau_{10} = 0.1 \times 10^{-4}$, $0.2 \times 10^{-4}$, $0.4 \times 10^{-4}$, $0.8 \times 10^{-4}$, $1.2 \times 10^{-4}$, $1.6 \times 10^{-4}$ & $2.0 \times 10^{-4}$. The peak value in this map is $2.13 \times 10^{-4}$. (b) The spatial distribution of dust temperature and the contours correspond to the temperatures 130, 120, 110, 90, 70, 50 & 30 K. The abscissa and the ordinates are in B1950.0 epoch.
Fig. 14. (a) The dust optical depth ($\tau_{10}$) distribution from the HIRES 12 and 25 $\mu$m maps, scaled to 10 $\mu$m by $\lambda^{-1}$ emissivity law. The contours represent 95, 90, 80, 70, 60, 50, 40, 30, 20, 10, 5 & 2% of the global peak value of $6.63 \times 10^{-5}$. (b) The dust optical depth ($\tau_{100}$) distribution from the HIRES 60 and 100 $\mu$m maps for the region around S 201 assuming a dust emissivity law of $\epsilon_{\lambda} \propto \lambda^{-1}$. The contours represent 95, 90, 80, 70, 60, 50, 40 & 30 % of the global peak value of $3.05 \times 10^{-3}$. (c) The dust temperature ($T(12/25)$) distribution and the contours are drawn from 140, 145 to 215 K in step of 10 K (from left to right in the figure). The peak value in this map is 230 K and occurs at the extreme right position (RA = 02:58:56.4, DEC=+60:15:38) of the map. (d) The dust temperature ($T(60/100)$) distribution and the contours correspond to the temperatures 55, 50, 45, 40 & 37 K. The abscissa and the ordinates are in B1950.0 epoch.
