Integrated photonics has enabled much progress towards quantum technologies. Many applications, e.g., quantum communication, sensing, and distributed cloud quantum computing, require coherent photonic interconnection between separate on-chip subsystems. Large-scale quantum computing architectures and systems may ultimately require quantum interconnects to enable scaling beyond the limits of a single wafer, and towards multi-chip systems. However, coherently connecting separate chips remains a challenge, due to the fragility of entangled quantum states. The distribution and manipulation of entanglement between multiple integrated devices is one of the strictest requirements of these systems. Here, we report the first quantum photonic interconnect, demonstrating high-fidelity entanglement distribution and manipulation between two separate photonic chips, implemented using state-of-the-art silicon photonics. Path-entangled states are generated on one chip, and distributed to another chip by interconverting between path and polarization degrees of freedom, via a two-dimensional grating coupler on each chip. This path-to-polarization conversion allows entangled quantum states to be coherently distributed. We use integrated state analyzers to confirm a Bell-type violation of $S=2.638\pm0.039$ between the two chips. With further improvements in loss, this quantum photonic interconnect will provide new levels of flexibility in quantum systems and architectures. © 2014 Optical Society of America

1. Introduction

Further progress towards quantum communication [1, 2], sensing [3] and computing [4, 5] will greatly benefit from a “quantum photonic interconnect” (henceforth QPI): an inter-/intra-chip link—e.g. in optical fiber or free-space—capable of coherently distributing quantum information and entanglement between on-chip sub-systems within a single complete quantum system. The significance of quantum interconnectivity was first highlighted by Kimble [1]. Here we study a chip-based interconnect solution, which will be essential in many future applications and provide substantial architectural flexibility. Secure quantum key distribution and quantum communications [6–8], and distributed and even cloud quantum computing [9–11], for example, will require interconnected on-chip subsystems in practice. Precise quantum sensing will gain more flexibility and versatility from on-chip generation and measurement of entanglement, with the interaction with the sample occurring remotely, in a different medium or location (e.g. chip, fiber, and free-space [12–14]). Quantum computing will greatly benefit from this QPI through architectural simplifications [15–17]; easier integration of materials, and platforms optimized for the performance of sources [18, 19], single [20, 21] and detection [22, 23], and such as optical delays and memories. Ultimately, large-scale integrated quantum systems and devices may even exceed the area of a single wafer or require interconnects for architectural reasons.

A QPI must coherently and robustly transmit a qubit state $a\ket{0}+b\ket{1}$ between subsystems [1], in which the relative phase information must be maintained, as in classical coherent optical communication protocols [33]. The quantum photonic interconnect must be capable of coherently interconverting between the preferred encodings in the platforms and media through which it connects [1, 34]. Perhaps, the most demanding requirement for a quantum interconnect is the preservation of high-fidelity qubit entanglement throughout manipulation, conversion, and transmission processes within the full chip-based system. Path-encoding [20–25] in two waveguides is the most common and natural choice for the encoding of qubits on-chip. However, encoding qubits in two separate free-space or fiber links needs sub-wavepacket path-length matching, and fast active phase stabilization. Polarization [6–10], spatial-mode [35, 36], or time-bin [37] encoding is typical for off-chip qubit transmission and distribution. For example, the state of polarization is robust in free-space, and in optical fiber (birefringence-induced fluctuation can be actively corrected on slow time scales [38]). Already there have been demonstrations of many important features of
Our chip-to-chip QPI system is shown schematically in Figs. 1(a) and (b). This system generates path-entangled states on chip-A and coherently distributes one entangled qubit to chip-B, via an optical fiber link.

A filtered 50-mW continuous-wave pump ($\lambda=1555.5$ nm) is coupled into chip-A and split into two paths using a multimode interference coupler (MMI) with a 50/50 splitting ratio [44] (Fig. 1(d)). Each path is connected to a photon-pair source. One photon pair is produced in superposition between these two sources, which, after post-selection on measuring a coincidence, yields the photon-number entangled state $|\psi\rangle = (|0\rangle + |1\rangle)/\sqrt{2}$, when $\theta_0$ equals to $(n+1/2)\pi$ or $n\pi$ for an integer $n$, with the subscripts referring to signal or idler photons.

The signal qubit is manipulated and measured on the same chip (chip-A) by a single qubit measurement stage $A(\theta_{0A}, \theta_{0B})$. This consists of a thermo-optically driven Mach-Zehnder interferometer with an additional thermal phase shifter (Fig. 1(d)). The path-encoded idler qubit is directed to an on-chip path-to-polarization converter (PPC). This device, described in more detail in the next section, coherently interconverts the qubit from an on-chip path encoding to an in-fiber polarization encoding. After transmission across the fiber link, chip-B reverses this process, converting the polarization-encoded qubit back to on-chip path encoding, via a second PPC. There, it is measured by a second single qubit measurement stage $B(\theta_{0A}, \theta_{0B})$ (Fig. 1(b)). In our experiment, the QPI consists of the fiber link bracketed by these two PPCs.

The polarization in the fiber can drift over time due to changes in environmental conditions (stress, vibrations, temperature, etc.). Due to the relatively short length of fiber used in this experiment (10 m), the fiber link was used without any control of its environment, other than to fix it to our optical table. Longer links may need active phase (i.e., polarization) compensation and control [38].
Fig. 2. Interconversion of polarization-encoding and path-encoding. (a) Initial arbitrary polarization-encoded states $\alpha|H\rangle + \beta|V\rangle$ ($|H\rangle$ and $|V\rangle$ are two orthogonally polarized states) were prepared by using a set of bulk optic polarizer (P), half-wave plate (HWP), and quarter-wave plate (QWP). A fiber-based polarization controller was used to compensate polarization rotation in the single mode fiber. The PPC interconverted the polarization-encoded states into on-chip path-encoded states $\alpha|0\rangle + \beta|1\rangle$, where $|0\rangle$ and $|1\rangle$ denote path states in two waveguides. The path-encoded states were then analyzed using the integrated analyzer $B(\theta_{\text{pc}}, \phi_{\text{pc}})$ to implement state tomography. The Bloch sphere representation of, (b) ideal polarization-encoded states $|H\rangle$, $|V\rangle$, $|D\rangle$, $|A\rangle$, $|B\rangle$, and $|L\rangle$ in bulk optics (red points), and (c) measured path-encoded states $|0\rangle$, $|1\rangle$, $|+\rangle$, $|-\rangle$, $|+\rangle$, and $|-\rangle$ on chip (blue points). The density matrix representation of all these states is provided in Supplement. Indicated fidelity represents the mean over the six measured states. (d) Reconstructed process matrix $\chi$ of the PPC using the quantum process tomography.

After configuring the measurements on the two chips, photon pairs were detected by two fiber-coupled superconducting nanowire single photon detectors (SNSPDs) with $\sim 50\%$ efficiency and $\sim 800$ Hz dark counts [45], after passing through relatively narrow 1.2-mm spectral band-pass filters. Finally, photon coincident events were recorded using a time interval analyzer. At the output of chip-A, $\sim 500$ photon pairs per second were measured, dropping to $\sim 12$ pairs per second after the idler photon had additionally traversed the QPI and chip-B. Ultimately, signal and idler photons had experienced 18 dB and 34 dB total attenuation, respectively.

B. Path-polarization interconversion

The PPC converts the two orthogonal polarization modes of the fiber into the fundamental transverse-electric (TE) modes of two on-chip waveguides. The stronger confinement of the TE mode in our silicon waveguide geometry ($500\text{nm} \times 220\text{nm}$) facilitates more efficient nonlinear optical photon-pair sources [39], and a higher integration density. Accordingly, we designed the PPC to couple into the TE mode of the silicon waveguide.

Our PPC is implemented using a 2D grating coupler (see Fig.1(e)), essentially formed by superposing two 1D grating couplers at right angles [40, 41]. In this way, the polarization state of the SMF fiber-transmitted photon is determined by the waveguide on-chip state, and vice versa, achieving path-polarization interconversion. Further

Fig. 3. Entanglement fringes. (a) $\chi$-classical interference (cyan) and $\lambda/2$-quantum interference (red) fringes measured on the chip-A. Bright light was measured (normalized) at port D1, and coincidences were collected (accumulated 20s) between ports D1 and D2. The $\theta_{\text{pc}}$ was rotated to produce the fringes, when $A(\theta_{\text{pc}}, \theta_{\text{ss}})$ was set as the Hadamard gate. Photons are bunched or anti-bunched when $\theta_{\text{pc}}$ is $\pi n$ and $(n+1/2)\pi$, (b) and (c) Entanglement correlation fringes for the Bell states $|\Phi^+\rangle$ and $|\Phi^-\rangle$ after distributed across the two chips. Coincidences were collected (accumulated 30s) between ports D1 and D3. The $\theta_{\text{ss}}$ on chip-B was continually rotated ($\theta_{\text{ss}} = 0$) to obtain the fringes, as $A(\theta_{\text{pc}}, \theta_{\text{ss}})$ on chip-A was projected onto $|\langle 1\rangle, |0\rangle, |-\rangle, |+\rangle$ basis by setting the $\theta_{\text{ss}}$ to $0, \pi/2, \pi, 3\pi/2$ and $2\pi$. The indicated visibility represents the mean over all four fringes. Error bars are given by Poissonian statistics, and accidental coincidences are subtracted.

To verify the PPC coherent mapping, we prepared arbitrary bright-light polarization states using bulk optical components and coupled them into the on-chip receiver (see Fig.2(a)). The PPC allowed us to convert the polarization states into path-encoded states, which we analyzed on-chip performing quantum state tomography [34, 46]. We prepared a set of six polarization states $\rho_{\text{pol}}$ in bulk optics, and measured the corresponding on-chip path states $\rho_{\text{pc}}$; these states are respectively shown as Bloch (or Poincare) vectors in Figs. 2(b) and (c). We provide the full density matrix data of these states in the Supplement; these data correspond directly with the plotted Bloch vectors. The overlap between the input states and measured states can be described by the state fidelity, which is defined as $F_{\text{state}}(\rho_{\text{pol}}, \rho_{\text{pc}}) \leq 1$. We find a mean state fidelity of the six states of $98.82\%$. We also fully quantify the PPC process using a quantum process tomography [34]. This can be mathematically described by a process matrix $\chi$ defined by $\rho_{\text{pol}} = \sum_{i,j} (E_{ij}\rho_{\text{pol}} E_{ij}^\dagger)/\sum_{i,j} \text{Tr}(E_{ij}^\dagger E_{ij})$. We find a mean process fidelity of the six states of $98.82\%$.
9824±0.82%, defined as $F_{\text{cross}} = \frac{1}{2} |\langle \Phi^+ | D_1 \rangle |^2$, where $\chi_{\text{ideal}}$ is the ideal process matrix with unit $(I, I)$ component, $X$, $Y$, and $Z$ amplitudes of the matrix $\chi$ represent the probabilities of a bit-flip or phase-flip error in the PPC interconversion. The process fidelity is directly related to the device cross-talk, which we estimate as 18dB (98.4%). PPC designs with improved cross-talk (and loss) have been demonstrated [47, 48].

C. Entanglement correlation fringes

Our first observation of entanglement distribution between the two chips took the form of nonlocal fringes. We configured the chip-A to produce entangled photons. These photons were collected at ports D1 and D2 and routed to the detectors. Through a continual scanning of $\theta_{\text{v}}$, we observed $\lambda/2$ (classical) and $\lambda/4$ (quantum) interference fringes with a high visibility (defined as $V = 1 - N_{\text{off}}/N_{\text{on}}$) of 9999±0.01% and 9936±0.17%, respectively (Fig. 3(a)). The high visibility of this phase-doubled fringe is a dear evidence of the high-quality photon-number entanglement produced inside the chip-A [22,12]. These high visibilities arise from well-balanced MMI couplers [44] and from a good spectral overlap between the two sources within the narrow bandwidth of the signal and idler filters. The photon-number entangled state evolves into the path-entangled Bell states $|\Phi^+\rangle^*$ or $|\Phi^+\rangle^*$, depending on the setting of $\theta_{\text{v}}$ (as described previously).

The entangled-photons were then separated and distributed, with the signal qubit kept on chip-A and the idler sent via the QPI to chip-B. We measured correlation fringes across the two chips by continuously varying $\theta_{\text{v}}$, and setting $\theta_{\text{v}}$ variously at $0$, $\pi/2$, $\pi$, and $3\pi/2$, while collecting coincidences between ports D1 and D3, Fig. 3(b) and Fig. 3(c) respectively show these fringes for the two Bell states $|\Phi^+\rangle^*$ and $|\Phi^+\rangle^*$. These experimental results are in good agreement with the theoretical model $\cos[(\theta_{\text{v}} \pm \delta\theta)/2]/2$ [49], with a small phase offset due to device calibration. These fringes exhibit a mean visibility of 97.63±0.39% and 96.85±0.51%, respectively, above the quantum threshold of $1/\sqrt{2}$ (71%) required to violate the Bell inequality [50]. These data show that entanglement is produced on chip-A and faithfully transferred to chip-B.

D. Bell-CHSH measurement

A strict test of the existence and level of entanglement distributed between the two chips is the Bell-CHSH test (Clauser-Horne-Shimony-Holt) [51, 52]. The CHSH inequality is defined as:

$$S = |\langle A_1, B_1 \rangle + \langle A_1, B_2 \rangle + \langle A_2, B_1 \rangle - \langle A_2, B_2 \rangle| \leq 2$$

(1)

where $A_i$ and $B_i$ briefly denote the projectors $A(0, \theta_{\text{v}})$ and $B(0, \theta_{\text{v}})$ on two chips. Normalized correlation coefficients $(A_i, B_i)$ were measured when $\theta_{\text{v}}$ on the chip-A was chosen to be $(0, \pi/2)$ and $\theta_{\text{v}}$ on the chip-B was simultaneously chosen to be $(\pi/4, 3\pi/4)$. Full data of $(A_i, B_i)$ is provided in Table 1. Substituting them into equation (1), we obtained the directly measured $S_{\text{CHSH}}$ values of 2.638±0.039 and 2.628±0.041 for the two Bell states $|\Phi^+\rangle^*$ and $|\Phi^+\rangle^*$, respectively. These $S_{\text{CHSH}}$ parameters violate the Bell-CHSH inequality by 16.4 and 15.3 standard deviations, respectively, strongly confirming that the two photons after distribution are highly entangled. Moreover, we also estimate the maximally achievable $S_{\text{photon}}$ value of 2.761±0.011 and 2.739±0.015 for the $|\Phi^+\rangle^*$ or $|\Phi^+\rangle^*$ states, from the mean visibility of the entanglement correlation fringes (Fig. 3(b) and Fig. 3(c)) according to $S_{\text{photon}} = \sqrt{2 \times V}$ [50]. Fig. 4 illustrates the good agreement between $S_{\text{CHSH}}$ and $S_{\text{photon}}$, confirming the high-performance of the chip-to-chip QPI.

Table 1. Measured Bell-CHSH correlation coefficients.

| $\theta_{\text{v}}$, $\theta_{\text{v}}$ | $|\Phi^+\rangle^* \langle A_1, B_1 \rangle$ | $|\Phi^+\rangle^* \langle A_1, B_2 \rangle$ | $|\Phi^+\rangle^* \langle A_2, B_1 \rangle$ | $|\Phi^+\rangle^* \langle A_2, B_2 \rangle$ |
|------------------|-------------------------------|-------------------------------|-------------------------------|-------------------------------|
| $(0, \pi/4)$     | 0.601±0.021                   | 0.673±0.021                   | 0.673±0.021                   | 0.601±0.021                   |
| $(0, 3\pi/4)$    | −0.692±0.018                  | −0.589±0.023                  | −0.589±0.023                  | −0.692±0.018                  |
| $(\pi/2, \pi/4)$ | 0.692±0.019                   | 0.652±0.020                   | 0.652±0.020                   | 0.692±0.019                   |

between the $S_{\text{photon}}$ and $S_{\text{CHSH}}$ values. Firstly, $S_{\text{photon}}$ strictly provides an upper bound on $S_{\text{CHSH}}$, which is saturated only when the Bell-CHSH measurement projects align with the state in question, and when the detection efficiencies are the same for all measurements [53]. Miscalibration of the measurement projectors, or fluctuations in the fibre-chip coupling (see Supplementary Fig. 54) could both reduce $S_{\text{CHSH}}$.

3. Conclusion

We have now demonstrated high-fidelity entanglement generation, manipulation, interconversion, distribution, and measurement across two separate integrated photonic devices, achieving the first chip-to-chip quantum photonic interconnect. The use of path-polarization interconversion preserves coherence across the fully interconnected chip-fiber-chip system.

Our system could be improved in several ways. The efficiency and fidelity [47, 48] of this interconversion process can be improved, and other off-chip encodings (e.g. orbital angular momentum [54, 55] or time bin [56]) may further enrich this quantum interconnectivity. The spiral photon-pair sources used here require no tuning to achieve spectral overlap, whereas optical microring resonators facilitate higher photon flux, produce spectrally uncorrelated photons [23, 57], and have a smaller footprint, but require careful tuning. Finally, the coupling fluctuations observed could be avoided by optically packaging the chip, enabling a more robust and portable chip-to-chip quantum system.

A robust QPI will facilitate new applications of quantum technology. This chip-to-chip quantum interconnectivity could be used for short-distance secret key sharing between bank and user, for example. Remote quantum sensing could be made possible by this system, allowing the quantum metrology of remote, possibly birefringent, analytes. Chip-to-chip interconnectivity would bring architectural flexibility to the design of linear optical quantum computers, potentially allowing quantum computation to be distributed over chip-based subsystems. In addition, the use of silicon technology allows large-scale integration [28, 58, 59] and compatibility with microelectronics and telecommunications infrastructure [60], and offers ability to monolithically integrate photon sources [19, 23], circuits [22, 28], and detectors [29, 30]. Our work opens the door to multi-chip integrated quantum photonic systems, capable of robustly distributing and transmitting quantum information among chips.
Appendix A: Devices design and fabrication.

Chip-A and chip-B respectively have a device footprint of 1.2 × 0.5 mm² and 0.3 × 0.05 mm². These devices were fabricated on the standard silicon-on-insulator wafer with a 220 nm silicon layer and a 2 μm buried silica oxide layer. The MMI couplers were designed as 2.8 μm × 27 μm to get a nearly balanced splitting ratio (Fig.1(d)). MMIs can offer a large bandwidth and large fabrication tolerance. We used the same MMIs design as Ref [22] and we both observed high-visibility classical and quantum interference, reflecting its excellent reproducibility. Spiraled waveguide sources with a 2 cm length were used to create photon-pairs. The 1D grating couplers consist of a periodic 315 nm silicon layer with a 630 nm pitch. The 2D grating couplers include 10 μm × 10 μm hole arrays with a 390 nm diameter and 605 nm pitch. Resistive heaters with a 50 μm length were designed and formed by a Ti/TiN metal layer. The devices were fabricated using the deep-UV (193 nm) lithography at LETI-ePIXfab. Silicon waveguides were 220 nm fully etched, while grating couplers were 70 nm shallow etched. The devices were covered with a 1.6 μm silica oxide layer.

Appendix B: Devices characteristics.

Optical accesses and electric accesses were independently controlled on two chips (Supplementary Fig. S1). Optical access was achieved using V-groove single modes fiber arrays with a 127 μm pitch. Fibers were tilted with an angle of θ=10–12 degrees to guarantee grating couplers work at the required wavelengths (Fig1). The waveguide crosser had a crosstalk of about -40 dB. The extinction ratio of the MZI structures was measured to be more than 30 dB, corresponding to MMIs with a 50%±1% reflectivity. The polarization extinction ratio of 1D and 2D grating couplers was measured to be larger than 20 dB and 18 dB, respectively. Excess loss of 1D and 2D grating couplers were about -48 dB and -7.6 dB at peak wavelengths, respectively (see Supplementary Fig.S2). We made estimation of losses from different contributors in the full system: -6 dB from off-chip filters, -6 dB from SNIPDs, -9.5 dB from 1D grating couplers, -15.2 dB from 2D grating couplers, -6 dB from demultiplexing MMIs, and -8 dB from MMIs loss and propagation loss in waveguide. Totally, signal and idler photons respectively experienced -18 dB and -34 dB attenuation. We tested several copies of the devices and they all exhibited similar performance.

All thermal-driven phase shifters were controlled using homemade electronic controllers. Wire bonding technology was used to contact heaters’ transmission lines. Optical power was recorded as a function of electric power added on heaters. The optical–electric power coupling was fitted and used to construct the mapping between the required states and electric power. Supplementary Fig.S3 shows the calibration results of chip-A’s and chip-B’s state analyzers. To avoid the influence of temperature variation, both two chips were mounted on temperature-stabilized stages. The pump light propagates collinearly with single photons, and we use this bright light to perform fiber realignment using piezo-electronic stacks, and to monitor that photon states are stable in time throughout the full system. Supplementary Fig.S4 shows the stability of the chip-to-chip system, which indicates path-encoded states on the two chips and polarization-encoded states in the fiber are both stable in time.
