(Dated: December 22, 2022)

In this work we report a detailed ESR spectroscopic study of the single-crystalline samples of the van der Waals compounds $M_2P_2S_6$ ($M_2 = \text{Mn}_2, \text{MnNi}, \text{Ni}_2$), performed at an excitation frequency of 9.56 GHz, in a broad range of temperatures above the magnetic order, and at different orientations of the magnetic field with respect to the sample. Analyzing temperature and angular dependences of the resonance field and of the linewidth of the $M_2P_2S_6$ compound we have observed a significant change of the spin dynamics from the dominance of the 3D-like fluctuations close to the magnetic order to a relative increase of the 2D-like spin fluctuations at higher temperatures. Such a behavior, which is opposite to the development of the low-D signatures in the previously studied $\text{Cr}_2\text{Ge}_2\text{Te}_6$ compound, can be explained by the difference in the type of magnetic order in $\text{Mn}_2P_2S_6$ and $\text{Cr}_2\text{Ge}_2\text{Te}_6$. On the other hand, $\text{MnNiP}_2S_6$ compound exhibits angular dependences of the linewidth typical for the system with 3D-like spin correlations in the whole measurement temperature range, however the 2D-like correlations can be seen in the temperature dependences of the resonance field and the linewidth. $\text{Ni}_2P_2S_6$, in turn, does not show any 2D signatures. This suggests that varying the Ni content in $(\text{Mn}_{1-x}\text{Ni}_x)_2P_2S_6$ one can control the exchange interaction, possibly also in the third dimension.

I. INTRODUCTION

Within the recent years layered magnetic van der Waals (vdW) materials attracted considerable attention in the field of fundamental science as well as in the applied research due to their natural tendency to exhibit a low dimensional behavior. By virtue of the vdW interaction which does not build up chemical bonds and thus only weakly couples atomic layers together, even in a bulk vdW material such low dimensionality is often strongly pronounced in physical properties [1]. This enables these materials to demonstrate new fundamental physical phenomena and, therefore, opens a possibility for their application in next-generation spintronic devices [2–6].

Particularly interesting subfamily of these compounds is represented by the transition metal (TM) triphosphates $M_2P_2S_6$ where $M$ stands for a TM ion [7, 8]. Here the crystallographic $ab$-plane hosts the spins of $M$ ions, which are arranged on a two-dimensional (2D) honeycomb spin lattice [9]. Due to the high flexibility of the choice of the $M$ ion, it is possible to control the magnetic properties, which, in turn, allows realization of different Hamiltonians in the $M_2P_2S_6$ family. For instance, if a system with $M = \text{Mn}$ can be described by the Heisenberg antiferromagnetic exchange with an easy-axis magnetic anisotropy term [10–14], which stabilize the antiferromagnetic order at $T_N \approx 77 \text{K}$, then in the case of $M = \text{Fe}$ the antiferromagnetism is found to be of the Ising type [10, 15, 16]. A compound with $M = \text{Ni}$ exhibits a more complex behavior, which possibly can be explained by the anisotropy of the Heisenberg exchange of the XXZ type [10, 12, 13, 16–18]. In this case the magnetic order sets in at $T_N \approx 158 \text{K}$, which is the highest in this series. Interestingly, in our previous work we have shown that $\text{Ni}_2P_2S_6$ exhibits a 3D-like spin dynamics rather then 2D-like in both magnetically ordered and paramagnetic states, which could be the result of a significant interlayer coupling [19]. Since low-dimensionality in layered vdW materials is the key property, the study of its signatures and understanding of its dependence on the sample composition are very important.

In this work we present the results of a detailed X-band $(\nu = 9.56 \text{GHz})$ electron spin resonance (ESR) spectroscopic study of single crystalline samples of $\text{Mn}_2P_2S_6$, $\text{MnNiP}_2S_6$, and $\text{Ni}_2P_2S_6$ carried out in a broad range of temperatures above the magnetic order. The ESR method, enabling a direct access to the electronic spin system, was recently successfully applied for studies of several magnetic van der Waals compounds providing important insights into the peculiarities of their spin dynamics [4, 20–34]. Here we show that signatures of the low dimensionality, seen in the characteristic angular dependence of the ESR linewidth, are present only in the $\text{Mn}_2P_2S_6$ compound. Interestingly, this material shows a development of the 2D behavior upon increasing temperature starting from the temperature $T \sim 150 \text{K}$ and up to the room temperature, which is opposite to the development of the low-D signatures in $\text{Cr}_2\text{Ge}_2\text{Te}_6$ [23], which is also a layered van der Waals magnet, however, with the ferromagnetic order stabilizing at a temperature.

$\ast$ These authors contributed equally to this work.
$T_C \approx 61 - 66$ K. The MnNiP$_2$S$_6$ compound exhibits angular dependences of the linewidth typical for the system with 3D-like spin correlations in the whole measurement temperature range, however the 2D-like correlations can be seen in the temperature dependences of the resonance field and the linewidth. Ni$_2$P$_2$S$_6$, in turn, does not show any 2D signatures. Bearing in mind the sensitivity of the characteristic angular dependence of the linewidth to the short-wavelength antiferromagnetic fluctuations, our finding suggests that an increase of the Ni content in (Mn$_{1-x}$Ni$_x$)$_2$P$_2$S$_6$ increases the exchange interaction, which is possibly extended to the third dimension, i.e., along the direction normal to the crystallographic ab-plane.

II. EXPERIMENTAL DETAILS

Single crystals of Mn$_2$P$_2$S$_6$, MnNiP$_2$S$_6$ and Ni$_2$P$_2$S$_6$ studied in this work were grown using chemical vapor transport method. Details of their growth, crystallographic, compositional and static magnetic characterization are described in Refs. [12, 16]. Note, that the experimental value $x_{exp}$ in (Mn$_{1-x}$Ni$_x$)$_2$P$_2$S$_6$ for the nominal MnNiP$_2$S$_6$ compound is found to be $x_{exp} = 0.45$, considering an uncertainty of approximately 5% [12]. The ESR measurements were carried out at a microwave frequency of $\nu = 9.56$ GHz using Bruker X-band ESR-spectrometer. The magnetic field $H$ was swept from 0 to 9 kOe. Samples were placed in a $^4$He-gas flow cryostat (Oxford Instruments) allowing temperature measurements between 4 and 300 K. The experimental setup was equipped with a goniometer for angular dependent measurements. All samples were placed in a He-gas flow cryostat (Oxford Instruments) allowing temperature measurements between 4 and 300 K. The experimental setup was equipped with a goniometer for angular dependent measurements. All the recorded spectra are field derivatives of the microwave power absorption.

The measured spectra consist of a single line which have been fitted with the field derivative of the Dysonian function [35, 36]:

\[ \frac{dD}{dH} = \frac{dD_+}{dH} + \frac{dD_-}{dH} ; \quad x_\pm = 2 \frac{H \mp H_{res}}{\Delta H} ; \]
\[ \frac{dD_\mp}{dH} \propto \frac{2}{\Delta H} \left( \frac{1 - x_\mp^2}{(1 + x_\mp^2) \Delta H} \sin(\phi) - \frac{2x_\mp}{(1 + x_\mp^2) \Delta H} \cos(\phi) \right). \]  

Here, $D$ is the Dysonian line shape function where $\mp H_{res}$ is the resonance field, negative or positive, $\Delta H$ is the full width at half maximum. The first term in brackets in Eq. (1) is the dispersion part of the spectra and the second term is the absorption part of the spectra. The contribution with the negative resonance field $\frac{dD_-}{dH}$ is necessary to correctly fit broad lines. Parameter $\phi$ represents the instrumental mixing effect of absorption and dispersion parts. In the cases of Mn$_2$P$_2$S$_6$ and MnNiP$_2$S$_6$ a very good fit of the Eq. (1) to the measured data showed that the mixing was negligible ($\phi = 0$). Therefore, the line shape was Lorentzian, i.e., given by the pure absorption term in Eq. (1). From the fit, $\Delta H$ and $H_{res}$ values were obtained.

For a precise alignment of the sample in the magnetic field parallel to the ab-plane and perpendicular to the ab-plane, the angular dependence of the resonance field $H_{res}(\theta)$ and the linewidth $\Delta H(\theta)$ was used.

III. THEORETICAL FRAMEWORK

In the canonical theories describing the implications of the electron spin dynamics in low-dimensional magnets on the characteristics of the ESR response, that are reviewed, e.g., in Ref. [37], the spin system is parameterized by the Hamiltonian comprising the Zeeman interaction $H_Z$, the isotropic Heisenberg exchange $H_{iso}$, and the weaker anisotropic magnetic couplings such as the dipole-dipole (d-d) $H_{d-d}$ interaction and the symmetric anisotropic exchage (pseudo-dipolar) interaction $H_{aniso}$:

\[ H_Z = g\mu_B \sum_i H \cdot S_i ; \]
\[ H_{iso} = J \sum_{i \neq j} S_i \cdot S_j ; \]
\[ H_{d-d} = \sum_{i < j} g^2 \mu_B^2 \left[ \frac{S_i \cdot S_j}{r_{ij}^3} - \frac{3(S_i \cdot r_{ij})(S_j \cdot r_{ij})}{r_{ij}^5} \right] ; \]
\[ H_{aniso} = \sum_{i \neq j} S_i \cdot A \cdot S_j . \]

Here, $J$ is the isotropic exchange constant and $A$ is the tensor of the symmetric anisotropic exchange. Under the ESR resonance conditions the circular polarized microwaves of the frequency $\omega_0$ couple to the transverse magnetization $M_T$ of the electron spin ensemble precessing at the Larmor frequency $\omega_L = \omega_0$ which causes absorption of electromagnetic energy. If only isotropic interactions (2) and (3) were present, the absorption line would be a delta function since both $H_Z$ and $H_{iso}$ commute with $M_T$, i.e., $M_T$ is a conserved quantity under these conditions. In contrast, anisotropic interactions (4) and (5) do not commute with $M_T$ causing broadening of the ESR signal. Usually, its width can be treated as a sum of two contributions [38, 39]:

\[ \Delta H = \Delta H(T) + \Delta H(T \rightarrow \infty) . \]

$\Delta H(T \rightarrow \infty)$ in Eq. (6) stands for the angle and temperature independent part corresponding to the linewidth in the infinite temperature limit, whereas $\Delta H(T)$ is the temperature and angular dependent contribution. It is a product of two terms, the $T$-dependent and isotropic part which incorporates the spin dynamics and the angular part which reflects the symmetry of the spin lattice and the symmetry of the interactions.

Specifically, assuming a dipolar-like symmetry of the anisotropic part of the interaction, $\Delta H(T)$ can be expressed in terms of the spectral densities of the spin correlation functions $\Gamma(\omega)$ at low frequencies $\omega < J/\hbar$ as...
Here, $\omega_d$ is the dipolar coupling constant, the first term in brackets is the contribution from the secular part of the d-d interaction that connects the $S_1$ and $S_2$ states for which the total magnetization $M_z = \sum S_z$ does not change ($\Delta M_z = 0$), while the second and the third terms are due to the nonsecular part of the d-d interaction with $\Delta M_z = \pm 1$ and $\Delta M_z = \pm 2$, respectively. \cite{40} all weighted by the respective geometrical coefficients $F_{0.1.2}$ \cite{41}.

The specific type of the angular part of Eq. (7) depends on the details of the spin fluctuation spectrum. In the layered spin systems with strong interlayer couplings the spin self-correlation function decays rapidly on the timescale of $J^{-1}\hbar$. At such short times spin fluctuation modes with all wave vectors $q$ contribute to the fluctuation spectrum and summing the geometrical coefficients in Eq. (7) over all wave vectors yields the angular dependence of the type $\Delta H(T) \propto (\cos^2 \theta + 1)$, where $\theta$ is the angle between the field vector $\mathbf{H}$ and the normal to the spin plane \cite{38, 41}. If the spin planes are decoupled, correlations can retain for much longer time manifesting in a long diffusive tale of the spin self-correlation function at $t > J^{-1}\hbar$ for both FM and AFM type of intra-plane exchange. Since the low $q$ modes have the longest lifetimes they dominate in this regime. For $q \to 0$ the geometrical coefficients in Eq. (7) simplify to \cite{41, 42}:

$$
F_0^2 = (3 \cos^2 \theta - 1)^2,
$$
$$
F_1^2 = \sin^2 \theta \cos^2 \theta,
$$
$$
F_2^2 = \sin^4 \theta.
$$

Since the secular part of the d-d interaction makes the dominant contribution to the linewidth (first term in Eq. (7)), its angular dependence acquires roughly the form $\Delta H(T) \propto (3 \cos^2 \theta - 1)^2$ \cite{41}.

If the spins interact predominantly antiferromagnetically, lowering the temperature would result in a 3D long-range AFM order of the layered spin system at a finite $T_N$ due to the residual interlayer coupling, or the substantial magnetic anisotropy. An enhancement of the short-wavelength AFM spin fluctuations at the ordering $q$-vector by approaching $T_N$ on expense of the long-wavelength ($q \to 0$) fluctuations would result in the change of the type of the angular dependence from $(3 \cos^2 \theta - 1)^2$ towards $(\cos^2 \theta + 1)^2$ \cite{41}. In contrast, in the case of the ferromagnetic interaction, the $(3 \cos^2 \theta - 1)^2$ type of dependence may become even more pronounced by approaching the magnetic phase transition due to the enhancement of the long-wavelength FM spin fluctuations.

IV. EXPERIMENTAL RESULTS

A. Mn$_2$P$_2$S$_6$

X-band spectra of Mn$_2$P$_2$S$_6$ at various temperatures for magnetic field applied parallel and perpendicular to the crystallographic ab-plane are shown in Fig. 1(a) and Fig. 1(b), respectively. As can be seen in the figures, approaching the ordering temperature $T_N \sim 77$ K \cite{12} the intensity of the spectra drastically reduces and the linewidth increases due to the growing correlations and the opening of the antiferromagnetic (AFM) excitation gap at low temperatures \cite{14, 20, 22}, as expected for the magnetically ordered materials. The disappearance of

![Fig. 2](image-url)  
**FIG. 2.** Mn$_2$P$_2$S$_6$: Temperature dependence of the linewidth at $\nu = 9.56$ GHz for $\mathbf{H} \parallel$ ab-plane (closed circles) and $\mathbf{H} \perp$ ab-plane (closed squares). The respective temperature dependence of the resonance field is shown in the inset. Differently colored temperature ranges indicate four regimes of the spin dynamics discussed in Sec. IV A.
the ESR signal in this case can be used for the estimation of $T_N$.

In Fig. 2, the temperature dependence of the linewidth and the resonance field, obtained according to Sec. II (Eq. (1)), are shown for both orientations $H \parallel ab$-plane and $H \perp ab$-plane. With decreasing temperature the $H_{\text{res}}$ value for $H \parallel ab$ orientation (inset in Fig. 2) remains practically constant down to a temperature of about 100 K, then there is a shift of the line due to the development of the AFM spin correlations, static on the ESR time scale. For the $H \perp ab$ configuration the line shift is visible in the whole measurement temperature range. As for the linewidth, for the $H \perp ab$ orientation it decreases with lowering the temperature down to approximately 100 K and below this temperature it starts strongly increasing towards the ordering temperature. For the $H \parallel ab$ orientation, above 200 K the linewidth remains constant. With further lowering the temperature it slightly decreases down to approximately 100 K and demonstrates an increase below 100 K similar to the $H \perp ab$ orientation.

In order to get insights on the linewidth anisotropy at different temperatures (Fig. 2) we have measured angular dependence of the ESR spectra at various temperatures. The obtained dependences of the linewidths are presented in Fig. 3. At a temperature of 80 K which is close to the AFM transition, $\Delta H(\theta)$ is proportional to the $(\cos^2(\theta) + 1)$ dependence, where $\theta$ is the angle between the applied magnetic field and the direction normal to the $ab$-plane, i.e., the spin plane. As explained in Sec. III, such an angular dependence is typical for spin systems arranged in three-dimensional lattices with a noticeable anisotropic coupling [37, 41], or in two-dimensional lattices with a significant interlayer coupling, which renders them quasi-three-dimensional. At a temperature of 100 K the $\Delta H(\theta)$ dependence is very weak. At higher temperatures of 200 and 300 K $\Delta H(\theta)$ has a characteristic minimum close to the angle of $\theta = 55^\circ$, which is a signature of the low-dimensionality of the spin system (Sec. III). These two dependences can be fitted with additional contribution of the form proportional to $(3\cos^2(\theta) - 1)^2$, which is accounted for in the phenomenological total angular dependence of the linewidth $\Delta H(\theta) = C_2(\cos^2(\theta) + 1) + C_4(3\cos^2(\theta) - 1)^2 + C_0$ (solid lines in Fig. 3). Note, that this simplified equation does not provide precise weights of different contributions, but rather serves as an indicator of the prominence of the 2D correlations. As a result, we observe, that at 300 K the contribution to the angular dependence of the linewidth due to low-dimensionality is stronger than that at 200 K. Interestingly, such an evolution of the angular dependence of the ESR linewidth with changing temperature was observed in Mn$_2$P$_2$Se$_6$ compound by Okuda et al. [20], which supports our finding.

Thus, the $\Delta H(T, \theta)$ dependences presented in Figs. 2 and 3 enable to determine four regimes of the spin dynamics highlighted in Fig. 2: (i) $T < T_N$ – long-range magnetic order; (ii) $T_N < T < \sim 100$ K – strong dominance of the quasi-static on the ESR time scale correlations of a 3D-like character; (iii) $\sim 100$ K $< T < \sim 150$ K almost isotropic regime, representing a crossover from 3D- to 2D-like dynamics; (iv) $T > \sim 150$ K growing prominence of the correlations of a 2D-like character.

In addition to the angular dependence of the linewidth $\Delta H(\theta)$, the angular dependence of $H_{\text{res}}$ at various temperatures was measured. At all temperatures it is given by $H_{\text{res}}(\theta) \propto \cos^2(\theta)$ (Fig. 4). Interestingly, even at the highest measurement temperature, the resonance fields still show a pronounced angular dependence, which suggests a g-factor anisotropy [14] and a presence of static on
the ESR time scale local magnetic fields due to 2D correlations seen in the angular dependence of the linewidth at these temperatures. The latter is also suggested by the gradual increase of the resonance field with decreasing temperature measured for the \( \mathbf{H} \perp ab \) configuration (inset in Fig. 2).

### B. MnNiP\(_2\)S\(_6\)

Characteristic X-band ESR spectra of MnNiP\(_2\)S\(_6\) for a wide range of temperatures are presented for both \( \mathbf{H} \parallel ab \) and \( \mathbf{H} \perp ab \) orientations in Fig. 5(a) and Fig. 5(b), respectively. Similarly to the Mn\(_2\)P\(_2\)S\(_6\) sample, the temperature of the vanishing of the ESR signal can be used for the estimation of the ordering temperature for this particular sample. As a result we get a value of \( T_N \), which is equal to or less than \( \sim 60 \) K. It agrees well with the value of \( T_N \sim 57 \) K obtained from the measurement of the temperature dependence of the susceptibility \( \chi \) at \( H = 1000 \) Oe for the \( \mathbf{H} \perp ab \) configuration, performed on the same sample [43].

The linewidth evolution with temperature for two magnetic field orientations observed for the MnNiP\(_2\)S\(_6\) compound is somewhat different from the one observed for Mn\(_2\)P\(_2\)S\(_6\) (Fig. 6). A shallow minimum for both orientations \( \mathbf{H} \parallel ab \) and \( \mathbf{H} \perp ab \) occurs at \( T \sim 175 \) K, which is higher than that for Mn\(_2\)P\(_2\)S\(_6\). Upon further reduction of temperature the linewidth increases likely due to the growing 2D correlations. Note that the linewidth at each temperature is several times larger than in the case of the pure Mn\(_2\)P\(_2\)S\(_6\) compound.

The inset of Fig. 6 shows the temperature evolution of \( H_{\text{res}} \) for MnNiP\(_2\)S\(_6\). The rapid decrease of \( H_{\text{res}} \) before reaching the ordering temperature is related to the development of AFM spin correlations, static on the ESR time scale. At temperatures higher than \( 90 \) K, \( H_{\text{res}} \) for both orientations of the magnetic field progressively changes as a function of temperature. This could be due to the static on the ESR timescale fields, resulting from the short range 2D correlations present up to the highest measurement temperature of \( 300 \) K.

The angular dependence of the linewidth \( \Delta H(\theta) \) for MnNiP\(_2\)S\(_6\) reveals a pure \((\cos^2(\theta) + 1)\) type at all measured temperatures (Fig. 7). This suggests a strong dominance of the three-dimensional spin correlations seen in the ESR linewidth in the whole measurement temperature range, which is in contrast to the Mn\(_2\)P\(_2\)S\(_6\) compound. Since nevertheless, signatures of the two-
dimensionality are observed in the temperature dependence of the resonance field and the linewidth, the absence of the characteristic $(3 \cos^2(\theta) - 1)^2$ dependence in the angular dependence of the linewidth is possibly due to an increased isotropic exchange interaction (Sec. III), which could be induced by the Ni ions present in MnNiP$_2$S$_6$.

The angular dependences of $H_{res}$ for MnNiP$_2$S$_6$ at four temperatures are presented in Fig. 8. At higher temperatures of 300 and 200 K they can be well fitted by the $H_{res}(\theta) \propto \cos^2(\theta)$ dependence, whereas at lower temperatures of 100 and 80 K the $H_{res}(\theta)$ dependences progressively deviate from $\sim \cos^2(\theta)$, suggesting a more complicated type of magnetic order possessing a symmetry which is different from an easy-axis biaxial AFM in Mn$_2$P$_2$S$_6$.

C. Ni$_2$P$_2$S$_6$

X-band ESR spectra of Ni$_2$P$_2$S$_6$ were measured for both $\mathbf{H} \parallel ab$ (Fig. 9(a)) and $\mathbf{H} \perp ab$ (not shown) orientations at temperatures above $T_N$. The spectra were fitted with the function given in Eq. (1). In contrast to the Mn$_2$P$_2$S$_6$ and MnNiP$_2$S$_6$ cases, here the obtained fits show some deviations from the measured spectra. The deviations are resulting likely from the extremely small intensities and the large linewidths of the ESR lines in the case of the Ni$_2$P$_2$S$_6$ sample. The linewidth at any temperature is larger than that in Mn$_2$P$_2$S$_6$ and MnNiP$_2$S$_6$ compounds. The small intensity increases the signal to noise ratio, and the linewidth, that is larger than the resonance field results in the violation of the resonance condition, which might cause the distortion of the line shape. Nevertheless, the dependence of the linewidth as a function of temperature resulting from the fit can be used for the comparison with the other samples, however, one has to bear in mind large error bars. As can be seen in Fig. 9(b), close to $T_N$ the ESR linewidth of Ni$_2$P$_2$S$_6$ increases with decreasing temperature, which is visible for both magnetic field orientations, $\mathbf{H} \parallel ab$ and $\mathbf{H} \perp ab$. Taking into account the error bars, the difference between the linewidth measured for different directions of the magnetic field is quite small, which, together with results of the study of the high frequency/field ESR on this compound [19], allows to conclude on the absence of the signatures of 2D-like spin fluctuations in Ni$_2$P$_2$S$_6$ compound.

V. DISCUSSION

Comparing Mn$_2$P$_2$S$_6$, MnNiP$_2$S$_6$ and Ni$_2$P$_2$S$_6$ samples, first of all, it is found that the ESR linewidth in the paramagnetic state above $T_N$ progressively increases with increasing the Ni content. In contrast to Mn$^{2+}$ with the half filled 3d electronic shell, and a small admixture of the excited state $^4P_{3/2}$ into the ground state $^6S_{5/2}$, the ground state of the Ni$^{2+}$ ion in the octahedral environment [9] is a spin triplet with the higher lying orbital multiplets, admixed through the spin-orbit coupling [44]. Such a second-order spin-orbit coupling effect enhances a sensitivity of the Ni spin ($S = 1$) to the small differences in the local environment. As has been shown in Ref. [19], due to the sizable interaction of Ni spins, causing the exchange narrowing effect, variation of the local environment should yield a change of the effective $g$-factor value. The disorder, resulting from stochastic mixing of two
magnetically inequivalent ions in MnNiP$_2$S$_6$ compound, therefore, could explain the increase of the linewidth. However, if such disorder would play a major role in the determination of the linewidth, then the largest linewidth should be observed in the MnNiP$_2$S$_6$ compound, which is not the case. Another possible source of the broadening of the line is the anisotropy of the exchange interaction (Sec. III). In the case of symmetric anisotropic exchange (Eq. 5), the linewidth is proportional to $A^2/\langle|J|\rangle$ [45, 46], where $A \propto (\Delta g/g)^2 J$ [47], yielding:

$$
\Delta H \propto \left(\frac{\Delta g}{g}\right)^4 J
$$

(11)

Here $\Delta g = |g-2|$ is the deviation of the average g-factor from the free electron spin only value caused by the spin-orbit coupling. According to Ref. [19], in the Ni$_2$P$_2$S$_6$ compound $\Delta g$ amounts to $\sim 0.166$. In Mn$_2$P$_2$S$_6$ one can try to estimate $\Delta g$ from the resonance fields for $H \parallel ab$ and $H \perp ab$ at 300 K, assuming that the shift of the resonance field is given only by the spin-orbit coupling effect, which likely would give an overestimated value. In this case for Mn$_2$P$_2$S$_6$ $\Delta g$ is about $\sim 0.016$, which is comparable to the values found in other Mn doped diophosphates [48, 49]. Similar estimation of the g-factor shift for MnNiP$_2$S$_6$ compound yields a value of 0.019. The observed general trend of increasing $\Delta g$ with increasing Ni content suggests that the anisotropy of the exchange interaction might have a substantial contribution to the linewidth in the paramagnetic state [Eq. (11)].

Interestingly, this is not the only effect that Ni substitution has on the spin dynamics of the title compounds. In the Ni$_2$P$_2$S$_6$ compound three-dimensionality of the spin lattice is suggested by the small anisotropy of the linewidth and by the results reported in Ref. [19]. The MnNiP$_2$S$_6$ compound does not show signatures of the 2D-correlations in the angular dependences of the linewidth in the whole measurement temperature range, although such correlations can be seen in the temperature dependence of the resonance field and the linewidth. The pure Mn compound Mn$_2$P$_2$S$_6$ shows signatures of the 2D-like spin dynamics in the angular dependence of the linewidth. However, they become visible only at high temperatures, i.e., far away from the ordering temperature. This, first, suggests that the magnetic order itself is of a 3D nature, provided by the magnetic anisotropy and the non-zero inter-plane interaction, which was also observed in, e.g., layered vdW magnetic topological insulators [34]. In order to suppress this interaction, it is apparently necessary to increase the temperature. This behavior is opposite to the one, which is found in another representative of magnetic vdW materials, Cr$_2$Ge$_2$Te$_6$ [23]. There an enhancement of the 2D-like spin fluctuations was observed upon decreasing the measurement temperature, and was found strongest in the paramagnetic state close to the magnetic ordering temperature. Such a contrasting behavior in Cr$_2$Ge$_2$Te$_6$ and Mn$_2$P$_2$S$_6$ is likely related to the difference in the type of magnetic order, being easy-axis ferromagnetic in the former [23], and easy-axis antiferromagnetic (with some anisotropy in the $ab$-plane) in the latter case [14, 22], respectively. As is explained in Sec. III, in the case of a 3D long-range AFM order an enhancement of the short-wavelength AFM spin fluctuations at the ordering $q$-vector by approaching $T_N$ on expense of the long-wavelength ($q \to 0$) fluctuations hinders the observation of the 2D spin dynamics in the angular dependence of the linewidth [41]. In contrast, the case of the ferromagnetic interaction, the 2D correlations may become even more pronounced by approaching the magnetic phase transition due to the enhancement of the long-wavelength FM spin fluctuations.

Previously, the critical behavior of Mn$_2$P$_2$S$_6$ both in the magnetically ordered state at $T < T_N$ and also above $T_N$ was studied by nuclear magnetic resonance (NMR) spectroscopy [50–53] and neutron scattering [11, 54, 55]. Regarding the paramagnetic state at $T > T_N$, which is in the focus of the present work, the static critical behavior probed by the temperature dependent measurements of the $^{31}$P NMR Knight shift [52, 53] and by the analysis of the magnetic correlation length by the neutron scattering [54] suggests a 2D character of the spin correlations in Mn$_2$P$_2$S$_6$. This is also supported by the observation of the broad maximum of the static susceptibility at $T \approx 118 K > T_N$ [12], expected for the 2D systems [37, 56]. The dynamic critical behavior assessed by the analysis of the temperature dependence of the $^{31}$P spin-lattice relaxation in Mn$_2$P$_2$S$_6$ implied the mean-field behavior. On the other hand, the dynamical critical neutron scattering indicates that the critical dynamics is completely confined in the $ab$ planes above $T \approx 105 K$ described at best with the 2D anisotropic Heisenberg model with a crossover to the 3D Heisenberg behavior by approaching $T_N$ [54]. This is consistent with the above discussed angular dependence of the ESR linewidth in Mn$_2$P$_2$S$_6$ showing a qualitatively similar crossover.

The absence of such 2D signatures in the angular dependence of the ESR linewidth of the MnNiP$_2$S$_6$ compound, and the absence of any 2D correlations in Ni$_2$P$_2$S$_6$ suggest that an increase of the Ni content in (Mn$_{1-x}$Ni$_x$)$_2$P$_2$S$_6$ enhances the isotropic exchange interaction, possibly also in the third dimension, i.e., along the $c$-axis. Indeed, a recent study of the magnetic dynamics of Ni$_2$P$_2$S$_6$ with inelastic neutron scattering reveals from the analysis of the spin wave dispersion a substantially stronger interlayer exchange interaction as compared to Mn$_2$P$_2$S$_6$ [57]. At first glance one would expect that the increased exchange interaction as a function of Ni content should also increase the ordering temperature $T_N$ in (Mn$_{1-x}$Ni$_x$)$_2$P$_2$S$_6$. However, this is not the case as the smallest $T_N$ is found in the MnNiP$_2$S$_6$ compound [12, 13]. Such a suppression of $T_N$ despite a stronger magnetic exchange could be explained by the increased disorder due to the stochastic mixing of the magnetically inequivalent Mn and Ni ions, and by the competition of two different types of order in pure Mn$_2$P$_2$S$_6$ (out-of-plane Néel type AFM) and Ni$_2$P$_2$S$_6$ (in-plane zigzag type AFM) [13].
VI. CONCLUSION

In summary, we have performed a detailed ESR spectroscopic study of the single-crystalline samples of the van der Waals compounds Mn$_2$P$_2$S$_6$, MnNiP$_2$S$_6$ and Ni$_2$P$_2$S$_6$, the members of the family of TM triphosphates. The measurements were carried out at an excitation frequency of 9.56 GHz, in a broad range of temperatures above the magnetic order, and at different orientations of the magnetic field with respect to the sample. By analyzing the temperature dependence of the resonance field and of the linewidth of the Mn$_2$P$_2$S$_6$ compound, we determined several regimes of the spin dynamics. Interestingly, the angular dependence of the ESR linewidth measured at high temperatures $T > \sim 150$ K showed signatures which are characteristic for the 2D spin correlations. In contrast to the previously studied magnetic vdW compound Cr$_2$Ge$_2$Te$_6$ [23], Mn$_2$P$_2$S$_6$ shows a development of the 2D behavior upon increasing temperature, which we attribute to the difference in the type of magnetic order in these compounds. The MnNiP$_2$S$_6$ compound, on the other hand, shows signatures of 2D correlations only in the temperature dependence of the magnetic order due to the increase of the exchange interaction, possibly also in the third dimension. Understanding of the details of such compositional dependence of the magnetic exchange calls for theoretical modeling.

[43] Note, that various studies have reported different values of $T_N$ for MnNiP₂S₆ compound, for instance it amounts to 12 K in [58], 38 K in [12], 41 K in [59] and 42 K in [13]. Such a variation in $T_N$ could be due to a stochastic distribution of Mn and Ni ions on the 4g Wyckoff sites of the crystal structure, and due to small variations of the real Mn/Ni content.
