November 10, 2018

Abstract. We present a detailed study of the scaling behavior of correlation functions and AC susceptibility relaxations in the aging regime in three dimensional spin glasses. The agreement between simulations and experiments is excellent confirming the validity of the full aging scenario with logarithmic corrections which manifest as weak sub-aging effects.

PACS. 75.10.Nr Spin-glass and other random models – 75.40.Gb Dynamic properties – 75.40.Mg Numerical simulation studies

1 Introduction

There is a great interest in the understanding of dynamical effects in spin glasses. These include magnetization relaxation, aging and temperature change protocols \cite{1,2,3,4,5}. The study of these effects may clarify the nature of spatial effects and coarsening phenomena in spin glasses, an issue which remains still poorly understood.

In this paper we present a detailed study of magnetization relaxation phenomena and aging effects in three dimensional Edwards-Anderson spin glasses. Our primary goal is to check the validity of the full $t/t_w$ scaling behavior in correlation functions as well as identifying possible sources of corrections to that behavior by comparing to experimental data. Dynamical experiments in spin glasses include magnetic relaxation and AC measurements. Here we will focus our attention on correlation function and AC susceptibility relaxations. The advantage of studying correlations is that these are easy to evaluate numerically being also tightly related to thermoremanent magnetization relaxation experiments. On the other hand, AC relaxations can be directly compared to experimental results and, to the best of our knowledge, no results appeared on this point in the literature.

There exist many works on simulations in the literature \cite{6,7,8,9} studying correlations or remanent magnetization relaxations and this part of the topic that we investigate here is certainly not new. What has never been considered in detail in the past and merits further investigation is the explicit comparison between simulations and experiments. Having the experimental results in mind we have tried to apply the same scaling plots used by the experimentalists to our numerical data. This may serve as a valuable guide to better understand what properties are generic to spin glasses and what coarsening scenario accounts for the collected experimental data.

Magnetic relaxation (or correlation function) and AC experiments give equivalent information, the advantage of using AC experiments is that they constitute a very sensitive tool to detect dissipative processes. When measuring correlations the external timescale $t_w$ is fixed by the time elapsed after quenching below $T_c$ while in AC experiments the external timescale is fixed by the inverse of the frequency of the AC field. In a full scaling scenario, in the first class of experiments the relevant scaling variable is $t/t_w$ while in the second class it is $\omega t$. In what follows we check the validity of this simple scaling behavior identifying possible sources of corrections.

2 The model and the observables

The Edwards-Anderson model \cite{10} is defined by the following Hamiltonian

$$\mathcal{H} = - \sum_{\langle i,j \rangle} J_{ij}\sigma_i\sigma_j - h \sum_{i=1}^{V} \sigma_i ,$$

(1)

where the indices $i, j$ run from 1 to $V$, the $\sigma_i$ are Ising spins ($\sigma_i = \pm 1$) and the pairs $(i, j)$ identify nearest neighbors.
in a three dimensional lattice. The exchange couplings \( J_{ij} \) are taken from a random distribution. The simplest choice is a Gaussian distribution with zero average and finite variance,

\[
P(J) = \left(\frac{1}{2\pi}\right)^{\frac{3}{2}} \exp\left(-\frac{J^2}{2}\right) . \tag{2}
\]

This model displays a spin glass transition at finite temperature \( T_c \approx 0.95 \) \cite{13,12}. A Monte Carlo step corresponds to a sweep over \( V \) randomly chosen spins of the lattice. Monte Carlo simulations of (1) use random updating of the spins with the Metropolis algorithm. Dynamical experiments use very large lattices (typical sizes are in the range \( L = 20 - 100 \)) with negligible finite-size effects for the largest sizes \( (L = 64 \) for magnetization relaxation experiments and \( L = 100 \) for AC experiments). Correlation function simulations have been done on a special purpose machine APE100 \cite{13} for sizes \( 64^3 \) and averaged over 10 samples. AC experiments were done for a single sample on a Linux cluster of PC’s for size \( L = 100 \).

Relaxation measurements are done applying a uniform magnetic field and measuring the decay of the thermoremanent magnetization (hereafter denoted by TRM), or equivalently, the growth of the zero-field cooled (ZFC) magnetization. The typical experiment consists in the following. A sample is fastly quenched below the spin glass transition temperature for a time \( t_w \) (i.e. the waiting time). Then a uniform small magnetic field \( h \) is applied and the growth of the magnetization measured,

\[
\chi_{ZFC}(t_w, t_w + t) = \frac{1}{V} \sum_{i=1}^{V} \sigma_i(t_w + t) . \tag{3}
\]

Another quantity of interest related to the magnetization which can be numerically investigated is the two-time correlation defined by

\[
C(t_w, t_w + t) = \frac{1}{V} \sum_{i=1}^{V} \sigma_i(t_w)\sigma_i(t_w + t) . \tag{4}
\]

The interest of studying correlations instead of zero-field cooled magnetizations is that they yield the same dynamical information. Indeed in the stationary regime they are related through the fluctuation-dissipation theorem (FDT)

\[
\chi_{ZFC}(t) = \frac{1 - C(t)}{T} . \tag{5}
\]

In AC experiments an oscillating magnetic field \( h(t) = h_0 \cos(2\pi\omega t) \) of frequency \( \omega = \frac{1}{t_p} \), where \( P \) is the period, is applied to the system and the magnetization measured as a function of time

\[
M(t) = M_0 \cos(2\pi\omega t + \phi) , \tag{6}
\]

where \( M_0 \) is the intensity of the magnetization and \( \phi \) is the dephasing between the magnetization and the field. The origin of the dephasing is dissipation in the system which prevents the magnetization to follow the oscillations of the magnetic field. From the magnetization one can obtain the in-phase and out-of-phase susceptibilities defined as

\[
\chi' = \frac{M_0 \cos(\phi)}{h_0} = \frac{2}{h_0} \int_0^P M(t) \cos(2\pi\omega t) dt , \tag{7}
\]

\[
\chi'' = \frac{M_0 \sin(\phi)}{h_0} = \frac{2}{h_0} \int_0^P M(t) \sin(2\pi\omega t) dt . \tag{8}
\]

The dephasing \( \phi \) measures the rate of dissipation in the system and is given by

\[
\tan(\phi) = \frac{\chi''}{\chi'} . \tag{9}
\]

In numerical simulations the in-phase and out-of-phase susceptibilities are computed by averaging the right-hand side in Eqs. (7,8) over several periods \( P = \frac{1}{\omega} \). This means a very large measurement time for low frequencies for both experiments and simulations.

In the numerical simulations (both in DC or AC experiments) the intensity of the probing fields cannot be arbitrarily small because of the weakness of the signal in comparison to other source of fluctuations such as finite-size effects (which induce finite-volume statistical fluctuations for extensive quantities, like the susceptibility). Consequently, the intensities of the probing magnetic fields used in numerical simulations are much larger than the corresponding experimental ones (between 50 and 500 times larger). As we will comment later, we do not believe that this leads to conflicting results between simulations and experiments. As soon as one checks that measurements are done within the linear response regime then the intensity of the probing field should not be crucial. Actually the values of the intensity of the fields usually employed in numerical simulations of TRM experiments are well known to satisfy linear response \cite{14,15}. Note that, in general, similar difficulties are encountered when analyzing data in both numerical simulations and real experiments, the main difference is the absolute magnitude of the time scales one can explore in the two cases (up to microseconds in simulations and between seconds and days in experiments).

### 3 TRM and correlation function relaxations

In order to study time scaling in a wide times range (especially in the aging \( t \gg t_w \) regime) experimentalists have measured the decay of the TRM \cite{3}, which is strictly related to the zero-field-cooled one through \( M_{ZFC} = M_{FC} - M_{TRM} \), where the field-cooled magnetization is practically constant in the glassy phase.

From the numerical simulations point of view the best quantity one can look at for checking time scaling is the autocorrelation function \( C(t_w, t_w + t) \). It has much less fluctuations than any response to an external field. Moreover over in the quasi-equilibrium regime where the fluctuation-dissipation theorem (FDT) holds, it gives exact information on the zero-field-cooled susceptibility via

\[
\chi(t_w, t_w + t) = \frac{1 - C(t_w, t_w + t)}{T} . \tag{10}
\]
In the aging regime the connection between correlation and susceptibility is less trivial. However in the limit of small perturbing field and large times, where a generalization of the FDT seems to hold, a relation between correlation and susceptibility can still be established. Then, in general, concerning time scaling, we can safely assume that the autocorrelation functions decay as the TRM do.

In this section we try to understand which is the best scaling for the \( C(t_w,t_w+\tau) \) data. The measurements have been taken on 10 samples of a 64\(^3\) system, at a temperature \( T = 0.5 \), with waiting times ranging up to \( t_w = 10^8 \) and measuring times up to \( t = 10^6 \). We have considered two different experimental situations, that is with or without an external magnetic field after time \( t_w \) (the evolution up to time \( t_w \) being always with no field), in order to check whether such a small perturbation may change the dynamical scaling. The external field intensity \( h = 0.1 \) has been chosen such that the system is in the linear response regime. If the magnetic field would be applied during all the experiment we do not expect any sensible difference with the \( h = 0 \) case.

In Fig. 1 we show the correlation functions data, with and without the external magnetic field. As the time goes on the effect of the magnetic field seems to accumulate and the differences become larger. Note however that, for any given waiting time \( t_w \), the correlation curve presents the two well known regimes \( [11] [13] \): the quasi-equilibrium one \( (t < t_w) \) and the aging one \( (t > t_w) \).

Because we are mainly interested in the scaling in the aging regime, we have tried, as the simplest analysis, to collapse the \( t > t_w \) data using \( t/t_w^\mu \) as the scaling variable. The results are shown in Fig. 2 and they clearly show that a value of \( \mu \) smaller than 1 is needed in order to collapse the data in the large times limit. Note also that the presence of an external field seems to decrease sensibly the value of \( \mu \). The errors on the estimation of \( \mu \) are of the order of \( 10^{-2} \).

This numerical result may suggest the presence of a sub-aging regime in the EA model [19] and it could be interpreted as one more similarity with real spin glasses, where \( \mu = 0.97 [3] \). However a more careful analysis shows that the correlation functions are perfectly compatible with a full aging, that is \( t/t_w \) scaling. In Fig. 3 we present the results of such an analysis, which has been done following the one performed on experimental TRM data in reference [3].

Few comments are in order. The best values for the \( A \) and \( \alpha \) parameters seem to be similar to the experimental ones \((A = 0.1 \text{ and } \alpha = 0.02)\). However, because of the lack of a quantitative criterion for data collapsing, the best collapse is very often subjective. In this case we have found that, in order to obtain a good data collapse, the \( \mu \) parameter must be fixed to 1 or very close to it. On the other hand, the \( A \) and \( \alpha \) parameters are strongly correlated (with a correlation coefficient close to -1) and they can be changed by a quite large amount without affecting the data collapse. Then the errors on these parameters are large. In Fig. 3 we show the collapse for parameters values being more or less in the center of the confidence region. We have also tried to collapse both sets of data \((h = 0 \text{ and } h = 0.1)\) with the same parameters, but it was impossible to obtain any reasonable data collapse.

In Fig. 3 we use the scaling variable \( \log(t + t_w) - \log(t_w) \), even if \( t/t_w \) would be the most natural one when full aging holds. Our choice is dictated by the need for a comparison with the collapse of experimental data shown in Fig 3.b of reference [3]. There the scaling variable \( [(t + t_w)^{1-\mu} - t_w^{1-\mu}]/(1 - \mu) \) is used, which tends to \( \log(t + t_w) - \log(t_w) \) in the \( \mu \to 1 \) limit. It is well known that the goodness of a data collapse may depend on the scales chosen for presenting the data. In the present case, in the scaling variable \( \log(t + t_w) - \log(t_w) \) we have better collapses than in the variable \( t/t_w \), because large times are “compressed”. Note however that both scaling variables give very good collapses of our data, the same being true for the experimental data [21]. Anyhow it is worth to note that the use of the scaling variable \( t/t_w \) for checking full aging and \( [(t + t_w)^{1-\mu} - t_w^{1-\mu}]/(1 - \mu) \) for checking sub-aging makes the life harder to the full aging scenario. This without considering the fact that there could be additional logarithmic corrections to the full \( t/t_w \) scaling [11].

We conclude that it is not easy to obtain precise quantitative information in order to distinguish the full aging from the sub-aging scenario. Moreover the presence of an external magnetic field, which on a first simple analysis seems to change the scaling, is in fact irrelevant for the scaling and it only changes a little bit the fitting parameters.

### 3.1 A small note on the ZFC susceptibility scaling

The scaling of the zero-field cooled susceptibility has been already studied in the past, both directly [3] or via the fluctuation-dissipation relation which links it to the correlation functions scaling [17]. Here we do not repeat this.
kind of analysis. We simply would like to present some new data regarding the ZFC's susceptibility scaling.

Indeed very recently Bernardi et al. have proposed the following scaling for the ZFC susceptibility [21]

$$\chi_{ZFC}(t_w, t_w + t) = \tilde{\chi}(R(t_w), L(t))$$

where both length scales grow in an algebraic fashion

$$R(\tau) \propto L(\tau) \propto \tau^{\alpha T}$$

with an exponent linear in the temperature, like for the off-equilibrium correlation length [8,22,9]. We found that numerical data obtained with very large simulations are not compatible with the proposed scaling (see Fig. 4).

Our numerical experiments are performed in the following way. For any given temperature $T_1$ (which takes 3 values in our case $T_1 = 0.3, 0.5, 0.7$), we start the simulation from a random configuration and we let evolve the system at temperature $T_1$ for a number of MCS $t_w$, such that $t_w^{T_1} = A$ where $A$ is a constant that we fixed to $A = 10^{1.5}$. At this time we switch on a small perturbing field, we move the temperature to $T_2 = 0.5$ and then we measure the response of the system (ZFC susceptibility). From this kind of experiment we have obtained many interesting information on the spin glass low temperature dynamics which have been published elsewhere [24]. Here we used again this kind of experiment in order to verify the scaling (11) proposed in Ref. [21].

By construction we have that in all the three experiments the length $R(t_w)$ is the same and the $L(t)$ is related to $t$ by the same law, because after time $t_w$ we always make

Fig. 2. Best scaling in the aging regime ($t > t_w$) for the data presented in Fig. 1.

Fig. 3. Full aging ($\mu = 1$) data collapse for the correlations functions presented in Fig. 1. Note that the use of a logarithmic scale improves the quality of data collapsing.

Fig. 4. ZFC susceptibilities after a particular experiment (see text). If the scaling in Eq.(11) would be correct, data in the figure should collapse.
evolve the system at the same temperature. Then if the scaling (1) would hold, we should find a good data collapse in Fig. 2, which is not true. This behavior can be explained by observing that after the thermalization time $t_w(T)$ the three experimental situations are not identical: they have developed a similar correlation length, nevertheless the actual configuration is different and the response to an external perturbation differs.

In Ref. [21] the authors find a perfect agreement to the scaling (1). However it must be noted that they use temperatures in a small range, $T \in [0.5, 0.7]$, which corresponds to the two uppermost curves in Fig. 2 which indeed almost coincide. Violation to the scaling (1) can be seen only at lower temperatures, which where not used in Ref. [21].

4 AC susceptibility relaxations

Let us briefly remind how these experiments are usually done. The system is quenched to a low temperature (ranging between 0.6 and 0.9 times the value of $T_c$) and the AC susceptibility is recorded. Typical values of the frequency of the AC field are between 0.1 and 1 Hertz. The amplitude of the probing AC field is of order $10^{-2}$ to $10^{-1}$ Oersteds deep inside the linear response regime. The AC susceptibility is then recorded as a function of time and relaxation is observed on time scales of order $\omega t \sim 1000 - 5000$ corresponding to several thousands of periods of the AC field. Measurements are then obtained averaging over several cycles of the AC field in order to obtain $\chi'$ and $\chi''$ with enough accuracy (10 cycles is a typical value).

Having in mind the experimental setup we have done the following experiment. Starting from a random configuration we have measured the AC susceptibility as a function of time for different frequencies of the AC magnetic field. The frequencies of the field are defined as $\omega = \frac{P}{t}$, where $P$ is the period of the oscillating field in Monte Carlo steps. The results for the in-phase and out-of-phase susceptibilities are shown in Fig. 3 at temperature $T = 0.6 \simeq 0.63 T_c$ and field periods $P = 50, 100, 500, 1000$. Each point in Eqs. (7) and (8) is obtained by averaging over 10 periods of the field. The curves can be very well fitted to a power law decays of the type $\chi(\omega, t) = \chi(\omega, \infty) + At^{-\alpha}$ but the exponents depend very much on the frequency. For the largest frequencies the exponent in both susceptibilities are compatible with a value smaller than 0.1 although it is difficult to establish its precise value. A similar difficulty is found in laboratory experiments.

To make evident the $\omega t$ scaling for the AC experiment we show in Fig. 4 the results of Fig. 2 plotted vs. $\omega t$. The values of the susceptibilities in the vertical scale have been shifted, by an arbitrary quantity to make them coincide. This procedure is exactly the same as done in experiments in the figure 2 of reference [3], showing the same qualitatively results. Note from Fig. 3 that the relaxation of the AC susceptibility on our time scale is as large as in real experiments, the relaxing signal being bigger for $\chi''$ than for $\chi'$. This explains why the study of $\chi''$ is usually preferred in laboratory experiments. For $\chi''$ the amount of

![Fig. 5. AC susceptibility for $L = 100, T = 0.6$ and frequencies $\omega = 1/P = 0.02$ (circles), 0.01 (squares), 0.002 (diamonds), 0.001 (crosses).](image)

![Fig. 6. AC susceptibility for $L = 100, T = 0.6$ and frequencies $\omega = 1/P = 0.02, 0.01, 0.002, 0.001$ plotted as a function of $\omega t$. Following Ref. [3], susceptibilities have been shifted on the vertical scale by arbitrary amounts to make them collapse.](image)
relaxation is nearly equal to the corresponding stationary ($\omega t \to \infty$) value.

5 Conclusions

In this paper we have made a detailed study of the dynamical scaling behavior of the correlation functions and AC susceptibilities in the aging regime for spin glasses. The study has been done applying the scaling behaviors preferred by the experimentalists and comparing them with the results obtained in numerical simulations of the three dimensional Edwards-Anderson model.

The general conclusion is that there is a full agreement between the experimental results measured for TRM decays and simulations for correlations. This agreement must be understood as the presence of an external field and they can be misinterpreted as a subaging scenario. We are not aware of any microscopic model displaying aging with full scaling without logarithmic corrections and it is possible (for not to say unavoidable) that such corrections are also present in the 3d Edwards-Anderson model. This fact explains the small subaging effects measured in both experiments and numerical simulations.

It is also interesting to see how the parameters obtained in the fits of the decay of the correlation function agree with the equivalent parameters for the TRM in experiments suggesting a universality in the dynamical scaling of relaxations which is well captured by the Edwards-Anderson model. A similar conclusion is obtained also for AC experiments which, in general, fulfill a good scaling behavior of the correlation functions and AC relaxations on a master curve, by appropriately shifting them by their stationary $\omega t$ scaling (with $\omega t \to \infty$) value.
