ABSTRACT
We present a neural network autoencoder structure that is able to extract essential latent spectral features from observed spectra and then reconstruct a spectrum from those features. Because of the training with a set of unpeculiar spectra, the network is able to reproduce a spectrum of high signal-to-noise ratio that does not show any spectral peculiarities even if they are present in an observed spectrum. Spectra generated in this manner were used to identify various emission features among spectra acquired by multiple surveys using the HERMES spectrograph at the Anglo-Australian telescope. Emission features were identified by a direct comparison of the observed and generated spectra. Using the described comparison procedure, we discovered 10,364 candidate spectra with a varying degree of $H\alpha/H\beta$ emission component produced by different physical mechanisms. A fraction of those spectra belongs to the repeated observation that shows temporal variability in their emission profile. Among emission spectra, we find objects that feature contributions of a nearby rarefied gas (identified through the emission of [NII] and [SII] lines) that was identified in 4004 spectra, which were not all identified as having $H\alpha$ emission. Positions of identified emission-line objects coincide with multiple known regions that harbour young stars. Similarly, detected nebular emission spectra coincide with visually-prominent nebular clouds observable in the red all-sky photographic composites.

1 INTRODUCTION
The identification of peculiar stars, whose spectra contain emission lines, is of interest to a wide field of stellar research. Spectral complexity of such stars brings insight into the ongoing physical processes on and around the star. Emission features in stellar spectra might adversely impact the quality of stellar parameters and abundances determined by automatic data analysis pipelines that are configured to produce the best results for most common stellar types. Examples of how these features might compromise spectroscopic measurements when we assume that a star is not peculiar
include the determination of effective temperature (Cayrel et al. 2011; Amarsi et al. 2018; Giribaldi et al. 2019), computation of stellar mass (Ness et al. 2016; Bergemann et al. 2016), and the effects of self broadening on line wing formation (Barklem et al. 2000; Allard et al. 2008). Highly accurate measurement of the hydrogen absorption profiles are needed in those cases. Any deviations in the line shapes from model predictions would produce misleading results. We would therefore like to know if the investigated line is modified by additional, unmodelled physical process or spectral reduction process. Stars with evident emission lines populate a wide variety of regions on the HR diagram. Because of possible overlaps between different stellar types, detailed photometric (especially in the infrared region where warm circumstellar dust disc can be identified) and spectroscopic observations are needed for an accurate physical explanation of the observed features. An examples of such work is presented in Munari et al. (2019), who performed detailed a multi-band photometric study of an emission-line star, originally discovered on objective prism plates. The detailed photometric time-series study described in that work, together with observations of the star’s infrared excess, led to the star VES 263 being identified as a massive pre-main-sequence star and not a semi-regular AGB cool giant as classified previously. In a similar way, Lancaster et al. (2020) performed an analysis of the stellar object V* CN Cha, which had previously been identified as an emission star. By studying a long photometric time-series of the star, they concluded that the object was most likely a symbiotic binary star system whose emission was lined to a long-duration, low-luminosity nova phase.

Numerous different physical processes that can contribute to the complex shapes of the Hz emission profile are given by Reipurth et al. (1996); Jones et al. (2011); Silaj et al. (2014); Ignace et al. (2018), who compare observations with expected physical models. Following the classification scheme introduced by Kogure & Leung (2007), emission-line stars are predominately observed in close binaries, earliest-type, latest-type, and pre-main sequence stars. For systems in which mass accretion is occurring, the examination of emission lines can allow the mass accretion rate onto the central star to be estimated (White & Basri 2003; Natta et al. 2004). The procedure involves measuring simple indices (such as the equivalent width and broadening velocity) of the emission lines in the star’s spectrum.

In recent years, multiple dedicated photometric and spectroscopic surveys (e.g. Witham et al. 2008; Mathew et al. 2008; Matijević et al. 2012; Nakano et al. 2012; Drew et al. 2014; Aret et al. 2016; Nikoghosyan et al. 2016), and exploratory spectral classifications of large unbiased all-sky spectroscopic observational datasets (e.g. Kounotk & Wehmeyer 1999; Reid & Parker 2012; Traven et al. 2015; Nikoghosyan et al. 2016; Hou et al. 2016; Traven et al. 2017) have been performed, each finding from hundreds to tens of thousands of interesting emission-line stars. Some of these surveys provide a basic physical classification in addition to an emission detection. Therefore they can be used as source lists for further in-depth studies of individual stars.

If a star is engulfed in a hot rarefied interstellar medium or stellar envelope, emission features of the forbidden lines (the most commonly studied of which are the [NII] and [SII] lines) could be observed in its spectrum, providing an insight into the temperature, density, intrinsic movement, and structure of its surrounding interstellar environment (Bohuski 1973; Raju et al. 1993; Escalante & Morisset 2005; Damiani et al. 2016, 2017).

Focusing on spectroscopic data, procedures for the detection of emission lines can roughly be separated into two categories. Simpler procedures searching for obvious emitters above the global continuum (Traven et al. 2015; Nikoghosyan et al. 2016; Hou et al. 2016; Nikoghosyan et al. 2016) and more complex procedures, where the observed spectrum is compared to an expected stellar spectrum of a normal star (Zerjal et al. 2013). The reference spectra in the latter case can be generated using exact physics-based stellar modelling or data-driven approaches. Of these, the data-driven approaches can be separated into supervised and unsupervised generative models. We would like to know if the investigated line is a normal star (Zerjal et al. 2013). The reference spectra in two categories. Simpler procedures searching for obvious emitters above the global continuum (Traven et al. 2015; Nikoghosyan et al. 2016; Hou et al. 2016; Nikoghosyan et al. 2016) and more complex procedures, where the observed spectrum is compared to an expected stellar spectrum of a normal star (Zerjal et al. 2013). The reference spectra in the latter case can be generated using exact physics-based stellar modelling or data-driven approaches. Of these, the data-driven approaches can be separated into supervised and unsupervised generative models. where, for the later, it is not required to provide an estimate of the stellar parameters for a given spectrum in advance. To predict a reliable model using supervised models, we must determine the correct stellar labels of an emission star in advance. This can pose a serious limitation if the strongest lines in the acquired spectrum can be populated by an emission feature, which happens for Gaia and RAVE spectra (Zerjal et al. 2013). In light of the future publication of Gaia RVS spectra as part of Gaia DR3 for hundreds of million of stars, it is thus important to develop tools to identify emission-line stars, as we aim to do in this study via GALAH spectra.

The paper is structured in the following order. We begin with the description of the used spectroscopic data in Section 2. In Section 3 we explain our analysis pipeline whose main components are the generation of reference spectra (Section 3.1) and identification of multiple emission features (Sections 3.3 and 3.4). The temporal variability of detected emissions is analysed in Section 4. The results are discussed and summarised and discussed in Section 5.

2 DATA

The spectroscopic data used in this study was taken from the main GALactic Archaeology with HERMES (GALAH) survey (De Silva et al. 2015), the K2-HERMES survey (Wittenmyer et al. 2018), the TESS-HERMES survey (Sharma et al. 2018), and the dedicated HERMES open clusters survey (De Silva et al. in preparation) and the HERMES Orion star forming region (Ko et al. in preparation) survey. All of the spectra were acquired by the High Efficiency and Resolution Multi-Element Spectrograph (HERMES, Barden et al. 2010; Sheinis et al. 2015), a multi-fibre spectrograph mounted on the 3.9-metre Anglo-Australian Telescope (AAT) at the Siding Spring Observatory, Australia. The spectrograph has a resolving power of $R \sim 28,000$ across four wavelength ranges ($4713 - 4903 \, \text{Å}$, $5648 - 5873 \, \text{Å}$, $6478 - 6737 \, \text{Å}$, and $7585 - 7887 \, \text{Å}$), also referred to as blue, green, red, and infrared spectral arms. Of the four, we use only the first (blue) and the third (red) in our study, as they cover the wavelength regions where interesting Balmer and forbidden emission lines can be seen and detected.

The combined dataset consist of 669,845 successfully reduced stellar spectra, of which a small fraction are repeated observations. All acquired spectra were homogeneously reduced to one dimensional spectra, continuum normalised,
GALAH: emission-line stars

3 DETECTION AND CHARACTERIZATION

The first attempts to discover H\(\alpha\)/H\(\beta\) emission spectra in GALAH survey observations were performed by Traven et al. (2017), who use the unsupervised dimensionality reduction technique t-SNE (van der Maaten 2013) to group morphologically similar spectra. As the amplitude and shape of the observed emission can vary substantially depending on the astrophysical source, Traven et al. (2017) presumably detected only a portion of the strongest emitters. One of the reasons for this is the manual classification of data clumps determined by the clustering algorithm. In the case of weak emissions in an investigated clump (performed manually by the operator), an expressed emission feature must be strong enough to be visually perceived when looking at a spectrum. To broaden the range of detectability to include spectra with marginal levels of emission as well, a more sophisticated and partially supervised procedure must be employed.

To expand the search, our methodology uses additional prior knowledge about the expected wavelength locations of interesting emission spectral lines. The prior wavelengths are used to narrow down the interesting wavelength regions during the comparison between the spectrum of a possibly peculiar star and an expected (reference) spectrum of a star with similar physical parameters and composition.

Figure 2. Prediction accuracy of the blue and red arm autoencoders at different training epochs. The prediction error is computed as a sum of all absolute differences between the input and output data set (see Equation 2). Shown are training (solid line) and validation curves (dashed line) which do not show any strong model over-fitting on the training set. The curves indicate that both autoencoders learned in a similar way because the same optimiser was used. The blue arm model has a bit higher loss and shows slower learning because of a greater spectral complexity and lower signal to noise ratio in that wavelength region.
3.1 Spectral modelling using autoencoders

A reference or a synthetic spectrum of a normal, non-emissive star, can be produced by a multitude of physically-based computational stellar models (Kurucz 1993; Munari et al. 2005; de Laverny 2012) or supervised generative data-driven approaches (Ness et al. 2015; Ting et al. 2019), whose common weakness is the need for prior knowledge of at least an approximate stellar parameters of an analysed stars used by the data-driven algorithm.

As some of our spectra do not have determined stellar parameters or they are flagged with warning signs that indicate different reduction and analysis problems (missing infrared arm, various reduction issues, bad astrometric solutions, SME did not converge etc.), we focused on an unsupervised spectral modelling to produce our set of reference spectra. Given the large size of available training data set, we chose to use an autoencoder type of an artificial neural network (ANN) that is rarely used to analyse astronomical data. Its current use ranges from data denoising (Qin et al. 2015; Li et al. 2017; Pan & Li 2017; Shen et al. 2019; Li et al. 2019) to unsupervised feature extraction and feature based classification (Yang & Li 2017; Shen et al. 2019; Li et al. 2019) to unsupervised generative approaches (Ness et al. 2015; Ting et al. 2019), whose role is to reconstruct a normal non-peculiar spectrum by extraction of a few relevant spectral features. Additionally, because of the low number of extracted features, our decoded output spectrum is a smoothed and denoised version of an input spectrum.

A visual representation of the described architecture is shown in Figure 1. The shape of the decoding structure of the autoencoder is the same, except in a reverse order. The Parametric Rectified Linear Unit (PReLU, He et al. 2015) activation function defined as

\[
f(x) = \begin{cases} 
  x, & \text{if } x > 0 \\
  ax, & \text{if } x \leq 0
\end{cases}
\]

is used for all nodes of the network, with the exception of the final output layer that uses a linear (i.e. identity) activation function. The \(x\) denotes one spectrum flux value in the first layer and one latent feature in the remaining layers. The free parameter \(a\) in Equation 1 is optimised during the training phase.

If the network learns a physics-based generative model of a stellar spectrum, information contained in the extracted features should be related to real physical parameters, such as \(T_{\text{eff}}\), \(\log g\), \([\text{Fe/H}]\), and \(v \sin i\), or their mathematical combinations.

To train our autoencoder, we created a set of presumably normal spectra (with no emission features), resampled to a common wavelength grid (\(\Delta \lambda\) equal to 0.04 and 0.06 Å for the blue and red arm) whose coverage is slightly wider than the range of an individual HERMES arm to account for variations in wavelength span because of radial velocity. Observations that did not completely fill the selected range were padded with continuum value of 1. To be classified as normal, spectra must suffice the following selection rules: signal to noise ratio (SNR) in the green arm must be greater than 30, a spectrum must not contain any known reduction issues.
Figure 4. Correlation between extracted latent features and physical parameters. Scatter plots between different features are colored by the GALAH physical parameters of original spectra. Points in the lower triangle are colored by their $T_{\text{eff}}$ and in upper triangle by their log g. Associated colour mappings are given below the figure (for the lower triangle) and on its right side (for the upper triangle). Presented are results for the red arm autoencoder.

Presented are results for the red arm autoencoder.

After we applied these quality cuts, we were left with 482,900 spectra, of which last 10% were used as an independent validation set during the training process. Before the training, normalised spectra were inverted ($1 - \text{normalised flux}$), which sets the continuum level to a value of 0. The inversion improved the model stability and decreased the required number of training epochs.

The described autoencoder was trained with the Adam optimisation algorithm (Kingma & Ba 2014) for 350 epochs. At every epoch all training spectra were divided into multiple batches of 40,000 spectra, whose content is randomised at every epoch. A batch is a subset of data that is independently used during a training process. Such splitting and randomisation of training spectra into batches decreases the probability of model over-fitting. To enable the selection of

(red_flag = 0 in Kos et al. 2017) and have valid spectral parameters ($\text{flag_sp} < 16$ in Buder et al. in preparation). Although choosing $\text{flag_sp} = 0$ returns the spectra with the most trustworthy parameters, we choose to use this higher cutoff in $\text{flag_sp}$ to filter out only the strangest spectra and not to produce a set of spectra with well defined parameters. Spectra with $0 < \text{flag_sp} < 16$ include objects with bad astrometric solution, unreliable broadening, and low SNR that are still useful for our training process. From Traven et al. (2017); Buder et al. (2018) and Cotar et al. (2019), we know that some GALAH spectra display peculiar chemical composition or consist of multiple stellar components, therefore we removed all identified classes with the exception of stars classified as hot or cold that are actually treated as normal spectra in our case. Even such a rigorous filtering approach can miss some strange spectra.
the best network model, it was saved after the end of every
training epoch.

The loss score minimised by the Adam optimiser, shown in
Figure 2, was computed as a mean absolute error (MAE)
between the input observed and decoded spectra defined as:

$$\text{loss}_{\text{MAE}} = \frac{1}{NR_d} \sum_{n=1}^{N} \sum_{i=1}^{n_d} |f_{\text{enc},n,i} - f_{\text{obs},n,i}|,$$  \hspace{1cm} (2)

where \(N\) represent the number of all spectra, \(n_d\) the number
of wavelength bins in each spectrum, \(f_{\text{enc},n,i}\) the flux value
of a decoded spectrum at one of the training epochs, and
\(f_{\text{obs},n,i}\) the flux value of a normalised observed spectrum.
Such a loss function gives lower weight to gross outliers in
comparison to the mean squared error (MSE). At the same
time, outputs are closer to a median spectrum of spectra
with a similar appearance and less affected by remaining
peculiar spectra in the training set.

After examining the decoded outputs at different epochs
in comparison with known normal and peculiar spectra, we
decided to use the model produced after 150 training epochs.
After that, overall improvements of the model are minor,
which increases the model opportunity to over-fit on a low
number of peculiar spectra. After closer inspection of the
last epoch, we found indications of over-fitting on known
emission stars, which further confirms the validity of choosing
less longer trained model (with greater prediction loss) and
rejects the need for a longer model training.

To decrease the complexity of a dense neural network
and reduce the required training time, two independent auto-
tencoders were trained, separately for the blue and red
HERMES spectral arms.

After the training and model selection were completed,
al available 669,845 spectra were run through the same au-
toencoder to produce their high SNR reference spectra. An
element of four such spectra is shown in Figure 3.

### 3.2 Latent features

To test the idea of extracted scalar latent features being
connected to physical parameters, and to inspect how an au-
toencoder structure actually orders spectra, we colour coded
values of latent features by unflagged physical parameters
connected to physical parameters, and to inspect how an au-
toencoder to produce their high SNR reference spectra. An
example of four such spectra is shown in Figure 3.

#### 3.3 Hα and Hβ emission characterization

The detection of emission components in spectra is based on
a spectral difference \(f_{\text{diff}}\), computed as:

$$f_{\text{diff}} = f_{\text{obs}} - f_{\text{ref}},$$ \hspace{1cm} (3)

where \(f_{\text{obs}}\) and \(f_{\text{ref}}\) are the observed spectrum and the gen-
erated reference spectrum respectively. The result of a com-
puted difference \(f_{\text{diff}}\) for an emission spectrum is shown in
the top panel of Figure 5. Ideally, this computation would
enhance only mismatch between both spectra, with inclu-
sion of spectral noise, if both represent a star with the same
stellar physical parameters. During the initial processing, we
found out that some observed spectra have slight normali-
sation problems, therefore we re-normalised them prior to
difference computation. As the targeted reference spectrum
\(f_{\text{ref}}\) is known and has a continuum level close to a median
value of similar stars in the training set, we first compute a
spectral ratio \(f_{\text{div}}\), defined as:

$$f_{\text{div}} = \frac{f_{\text{obs}}}{f_{\text{ref}}}.$$ \hspace{1cm} (4)

The resulting ratio can be viewed as a proxy for a remoral-
isation curve that would bring \(f_{\text{obs}}\) to the same continuum
level as \(f_{\text{ref}}\), but would at the same time cancel out any
spectral differences between them. To avoid the later, we
fitted \(f_{\text{div}}\) with a 3rd degree polynomial with a symmetrical

![Figure 5. Panels show two different wavelength regions of \(f_{\text{diff}}\)
for the same star. The top panel is focused on the Hα and [NII]
nebular lines, while the second panel focuses on [SII] lines. Rest
wavelengths of both nebular doublets are given by the green
dash-dotted vertical lines. Their fitted locations, affected by a
gas cloud movement, are given by the red dashed vertical lines.
The EW(Hα) integration range is bounded by the central black
dashed vertical lines on the top panel.]
2-sigma clipping, run for five iterations. We used the polynomial fit to renormalise $f_{\text{obs}}$.

To get the first identification of an emission features, we calculate the equivalent width (EW) of the spectral difference in a $\pm 3.5$ Å range around the investigated Balmer Hα and Hβ lines. The selected range (shown in Figure 5) is wide enough to encompass emission profile of all spectra, with the exception of a few ones, which have very broad and structured profiles. We kept the width narrow to reduce the effect of spectral noise and nearby sky emission lines (see Section 3.5). The correlation between measurements of both equivalent widths is shown in Figure 6 from which it is evident that the Hβ emission feature is not as strong as the Hα feature, but comparable to it.

Alongside the equivalent widths of the residual components (EW(Hα) and EW(Hβ)), we also measured two additional properties of these lines, which give some insight into physical understanding of emission source. The broadening velocity of a line is described by its width at the 10% of the line peak (W10%(Hα) and W10%(Hβ)) expressed in km s$^{-1}$. The automatic measurement procedure first finds the highest point inside the integration wavelength range and then slides down on both sides of the peak until its strength drops below 10% of the peak flux value. The broadening velocity is defined as a width between those two limiting cuts. As the computation is done for every object in an unsupervised way, the results are meaningful only for the spectra with evident emission lines. In the case when a low broadening velocity is estimated (equivalent to a very narrow peak), the highest peak could be a residual sky emission line or a cosmic ray streak. By combining EW(Hα) and W10%(Hα), mass accretion could be estimated if emission is of a chromospheric origin.

The second index measured in the $f_{\text{diff}}$ spectrum, that roughly describes the shape and location of an emission feature, is the asymmetry index defined as:

$$\text{Asymmetry} = \frac{|\text{EW}_{\text{red}}| - |\text{EW}_{\text{blue}}|}{|\text{EW}_{\text{red}}| + |\text{EW}_{\text{blue}}|},$$

(5)

where $|\text{EW}_x|$ represents the equivalent width of the absolute difference $|f_{\text{diff}}|$ on the red and blue side of the central wavelength of the investigated Balmer line. By this definition, a line that is, as a whole, moved to the redward side would have this index equal to 1, whilst if it was moved to the blueward side, the index would instead equal −1. The distribution of the asymmetry index values for the most prominent and unflagged (see Section 3.8) emitters is shown in Figure 7, where a strong correlation between the asymmetry of Hα and Hβ lines is evident. As the Hβ line in most cases produces a much weaker or even no emission feature, its asymmetry is much harder to measure. That is evident in Figure 7 where its index is scattered around 0, except for the most asymmetric cases. The distribution of the Hα asymmetry is much more uniform outside the central symmetric region. From this index, we can roughly classify the source of the emitting component as a chromospheric origin would produce a centered component with an asymmetry index close to 0. Everything outside the central region in Figure 7, defined by the circle with a radius of 0.25, could be thought to be of an extra-stellar origin as lines are not perfectly aligned. The used thresholding radius value of 0.25 was defined by observing Figure 7 to encircle the main overdensity of almost symmetric emission profiles.

Figure 6. Correlation between equivalent widths of the Hα and Hβ emission components for our set of detected stars (defined as having $f_{\text{Ha, EW}} > 0.25$ Å) as black points. The remaining set of objects is shown with gray dots. All flagged objects and possible spectroscopic binaries are taken out for this plot. The green dashed linear line represent the one-to-one relation and the orange dash-dotted line identicates cases where the equivalent width of the Hβ is half of the Hα line.

Figure 7. Asymmetry index of objects with prominent emission lines in the integration range around investigated Hydrogen Balmer lines. Objects with index inside the green dashed circle are considered to have a symmetric emission contribution, which can be attributed to a chromospheric activity. Central circular region has a radius of asymmetric index 0.25.
3.4 Detection of nebular contributions

Due to the multiple possible origins of H emission lines (Kogure & Leung 2007), we also attempted to detect the extra-stellar nebular contributions of nearby rarefied gas. Its presence is expressed as forbidden emission lines in addition to the H emission. The spectral coverage of the HERMES red arm enables us to observe doublets of [SII] (6548.03 and 6583.41 Å), and [NII] (6716.47 and 6730.85 Å). Having usually a weak emission contribution that could possibly be blended with nearby absorption lines, they are most easily detected when we remove the expected reference spectrum from the observed one (resulting in \( f_{\text{diff}} \)). To automatically detect the emission strength and position of both doublets, we independently fitted two Gaussian functions with the same radial velocity shift for each element to \( f_{\text{diff}} \). Because the contributing medium is not necessarily physically related to the observed object, its radial velocity could be different, therefore it was treated as a free parameter in our fit. Two independent velocities, one for each of the two doublets, give us an indication of a spurious or unreliable fit component if their difference is large. To filter out outliers, we adopted a threshold of 15 km s\(^{-1}\) on their velocity difference. Some of the discarded outliers might be correct detections because few of the spectra show two or more peaks for each nebular line which might point to a contribution of multiple clouds with different radial velocities. Such cases are not fully accounted for by the fitting algorithm that only identifies the strongest emission.

In the absence of additional fitting constraints, the routine might also find two noise peaks and lock onto them. Therefore, we put an arbitrarily selected detection threshold (0.05 of relative flux) on a minimum amplitude of the fitted forbidden lines to be counted as detected. The result from this fitting and analysis procedure is a number of successfully detected peaks per element and their combined equivalent widths (\( \text{EW([NII])} \) and \( \text{EW([SII])} \)), reported in the final published table (see Table A1). To filter out some possible miss-detection, we count a spectrum as having nebular lines when at least three nebular lines above the threshold were detected. The correlations for measured radial velocities and equivalent widths of identified objects with nebular emission are given in Figure 8 and 9 respectively.

The radial velocities of both doublets shown in Figure 9 give us a first impression that the gas dynamics of the elements in all observed clouds is nearly coincident, but elements are moving at slightly different velocities. This velocity offset, but in the opposite direction, was also observed by Damiani et al. (2016, 2017) who attributed it to the uncertainties in their adopted line wavelengths, that are slightly different to ours (less than 0.05 Å), causing the velocity points to be located either above or under the identity line in Figure 9. Additionally, the plot reveals that the majority of the gas clouds have a different radial velocity than stars behind or inside a cloud. As we are working with fully reduced normalised spectra, with inclusion of sky background removal, the detection procedure would, in the case of an ideal background removal, not detect emission due to nebular clouds. As the measured flux of the nebular contribution is very unlikely the same for object and because of the physical separation of the sky fibres (see next Section 3.5 and Kos et al. (2017)), the ideal cases are very rare. Similarly, the densities and the temperatures of such nebular clouds, extracted from corrected spectra could be influenced by the extraction pipeline and were therefore not performed in our case.

The strength of the identified lines, measured by their equivalent widths, is shown in Figure 8. This shows high a degree of correlation, where on average [SII] lines have lower strength than [NII] lines.
Figure 10. Sky emission lines are most evident after spectra subtraction in $f_{\text{mag}}$. Green vertical dashed lines represent expected locations of emission lines in the rest frame of an observed star. The middle sky line in this plot falls inside the actual Hα emission feature and changes its shape from single- to double-peaked and consequently modifies the measured equivalent width. Upper and lower thresholds for detection are given by the bold horizontal dashed lines. The number of detected under- and over-corrected sky lines in this order is given above the plot.

### 3.5 Identification of sky emission lines

Attributing a limited and relatively low number of the HERMES fibres to monitor the sky in hopefully star and galaxy free regions, imposes limitations to a quality of the sky background removal in the GALAH reduction pipeline (Kos et al. 2017). As the sky spectrum is sampled at 25 distinct locations over the whole 2° diameter field, it must be interpolated for all other fibre locations that are pointing towards stellar sources. Depending on the temporal and spatial variability of weather conditions, and possible nebular contributions, interpolation may produce an incorrect sky spectrum that is thereafter removed from the observed stellar spectra.

In most cases, this does not influence the spectral analysis, unless one of the strongest sky emission lines falls in a range of the analysed stellar line. For us, the most problematic sky emission line, which can alter the shape of the Hα profile, is located at 6562.7598 Å (our list of sky emission lines was taken from Hanuschik 2003). As it can get blended with a real emission feature of the Hα or simulate its presence, we try to estimate the impact of the sky residual in the spectrum from multiple nearby emission lines. First, we select only the strongest sky emitters (with parameter $\text{Flux} \geq 0.9$ in Hanuschik 2003) and shift their reference wavelength into a stellar rest frame. After that, we use a simple thresholding (see Figure 10) to estimate their number. By the thresholding procedure, we want to simultaneously catch over- and under-corrected stellar spectra.

When a sufficient number ($\geq 4$) of strong residual sky lines with a normalised flux above 10% is detected, a quality flag (see Section 3.8) is raised, warning a user that the equivalent width of the Hα emission could be affected by uncorrected sky emission. As this potential contamination is present only in the red HERMES arm, we do not check for spurious strong emitters in the region around the Hβ line.

### 3.6 Determination of spectral binarity

During the inspection of our initial results, we noticed that the spectra of spectroscopically resolved binary stars (SB2) produce a mismatch between observed and reference spectra whose $f_{\text{mag}}$ have a profile similar to the P Cygni or inverted P Cygni profile (Castor & Lamers 1979) that is often observed in emission-line objects. To detect SB2 candidates, we performed cross-correlation between the reference and the observed spectra, disregarding the wavelength range of ±10Å around the centre of the Balmer lines to avoid broadening of the cross-correlation function (CCF) peak. Cross-correlation was performed independently for both (the blue and red) HERMES spectral arms. The resulting CCF, shown as the black curve in Figure 11, was fitted by three Gaussian functions, centred at three strongest peaks, to describe its shape. The location, amplitude and width of those peaks were assessed to determine the number of stellar components in the spectrum. When fitting three peaks, there is a possibility of finding triple stars and distinguishing them from binaries. Every spectral arm with more than one prominent peak was assessed as potential SB2 detection in the final results (see Table A1), where binarity indication is given independently.
for both arms. Nevertheless, the results of the blue arm (column SB2_c1) are more trustworthy because of the higher number of absorption lines in the red arm (column SB2_c3). For even greater completeness of detected SB2 candidates, a list of analyzed binaries, compiled by Traven et al. (2020) can be used. They combined unsupervised spectral dimensionality reduction algorithm t-SNE and semi-supervised CCF analysis (Merle et al. 2017) to compile their list of SB2 binaries. After their analysis, they discarded spectra that were falsely identified as SB2 by their detection procedures.

An unexpected result of this binarity search was the realization that some reduced spectra show duplicated lines only in the red arm or even stranger, only in a smaller subsection of it. After a thorough investigation, we uncovered that this effect is caused by improper treatment of fibre cross-talk while extracting spectra from the original 2D image (Kos et al. 2017). A partial culprit of this is also a poorer cross-talk while extracting spectra from the original 2D image. Median squared error (MSE) between them was $\geq 0.002$. Large difference between reference and observed spectrum in the red arm of a spectrum. Median squared error (MSE) between them was $\geq 0.008$. The spectrum most likely contains duplicated spectral absorption lines of a resolved SB2 binary. Binarity was detected in both arms. Possible strong contamination by sky emission features. 4 or more residual sky lines were detected. Could be a result of under- or over-correction. Wavelength solution (or determined radial velocity) might be wrong in the red arm of the spectrum. Determined from cross-correlation peak between observed and reference spectra. Wavelength solution (or determined radial velocity) might be wrong in the blue arm of the spectrum.

A suggested set of limiting parameter thresholds and quality flags is provided in Section 3.8. Their use depends on user specific requirements and the analysed science case.

### 3.8 Flagging, quality control and results selection

The above described pipeline runs blindly on every successfully reduced spectrum ($\text{guess\_flag} = 0$, for details see Kos et al. 2017), and could therefore produce wrong or misleading results for some spectra. To have the ability to filter out such possible occurrences, we created a set of warning flags for different pipeline steps that are listed and described in detail in Table 1. An interested user can base their selection of results according to the desired confidence level and a physical question of interest. The cleanest set of 10,364 Hα emission stars can be produced by selecting unflagged stars that do not show any signs of possible binarity, defined such that parameter $\text{emiss}$ in the published Table A1 is set to one (the equivalent of true). To be included among the cleanest set of detections, we considered only spectra whose $\text{Ha\_EW} > 0.25$ Å. Below this limit, we are less confident in marking an object as having an emission feature because visual inspection showed that this strength could be mimicked by spectral noise, the uncertainty of the reference spectrum, or induced by the reduction pipeline. This selection criteria at the same time discards the weakest chromospheric components, which might be of great interest for specific studies. If the user is interested only in stronger emitters, the threshold should be raised to $\text{Ha\_EW} > 0.5$ Å or above.

The published Table A1 also contains a flag that describes whether the spectrum is considered to contain an additional nebular contribution. Such spectra can be filtered out by choosing the parameter $\text{nebular}$ to be equal to 1. To compile this less restrictive list of 4004 spectra, we selected entries with at least three prominent forbidden emission lines ($\text{NII} + \text{SII} \geq 3$) and a small difference in their measured radial velocities ($|\text{rv\_NII} - \text{rv\_SII}| \leq 15$ km s$^{-1}$).

### 4 TEMPORAL VARIABILITY

The strategy of the GALAH survey is to observe as many objects as possible, and as a result, not many repeated observations were made. The repeated fields were mostly observed to assess the stability of the instrument. Time spans between observations are therefor on the orders of days or years. This limits the possibility of finding a variable object greatly, but still enables us to discover potential interesting objects and diagnose analysis issues.

To find possible emission stars with repeated observations, we selected stars with repeats, among which at least one spectrum was identified to harbour a stronger ($\text{Ha\_EW} > 0.5$ Å) unflagged emission feature. This selection produced 621 stars, having between 2 and 9 observations. To be confident about the observed variability, we visually inspected the observed and the reference spectra of 208 stars with at least three observations. A subset of these spectra was collected in Table A1. The complete table is available in electronic form at the CDS. An excerpt of the published results, containing a subset of 30 rows and 11 most interesting columns for the strongest unflagged emitters is given in Table B1.

As we do not perform any quality cuts on our results, a suggested set of limiting parameter thresholds and quality flags is provided in Section 3.8. Their use depends on user specific requirements and the analysed science case.

### Table 1. Quality binary flags produced during different steps of our detection and analysis pipeline. Lower value of the flag represents lower significance to the quality of detection and classification. The final reported flag value in Table A1 is a sum of all raised binary quality flags.

| Flag   | Description                                                                 |
|--------|-----------------------------------------------------------------------------|
| 128    | Reference spectrum for the Hα range does not exist.                         |
| 64     | Reference spectrum for the Hβ range does not exist.                         |
| 32     | Large difference between reference and observed spectrum in the red arm     |
|        | of a spectrum. Median squared error (MSE) between them was $\geq 0.002$     |
| 16     | Large difference between reference and observed spectrum in the blue arm    |
|        | of a spectrum. MSE was $\geq 0.008$.                                        |
| 8      | The spectrum most likely contains duplicated spectral absorption lines of a |
|        | resolved SB2 binary. Binarity was detected in both arms.                    |
| 4      | Possible strong contamination by sky emission features. 4 or more residual  |
|        | sky lines were detected. Could be a result of under- or over-correction.    |
| 2      | Wavelength solution (or determined radial velocity) might be wrong in the   |
|        | red arm of the spectrum. Determined from cross-correlation peak between     |
|        | observed and reference spectra.                                             |
| 1      | Wavelength solution (or determined radial velocity) might be wrong in the   |
|        | blue arm of the spectrum.                                                   |

To be confident about the observed variability, we visually inspected the observed and the reference spectra of 208 stars with at least three observations. A subset of these spectra was collected in Table A1. The complete table is available in electronic form at the CDS. An excerpt of the published results, containing a subset of 30 rows and 11 most interesting columns for the strongest unflagged emitters is given in Table B1.

As we do not perform any quality cuts on our results, a suggested set of limiting parameter thresholds and quality flags is provided in Section 3.8. Their use depends on user specific requirements and the analysed science case.

### 3.8 Flagging, quality control and results selection

The above described pipeline runs blindly on every successfully reduced spectrum ($\text{guess\_flag} = 0$, for details see Kos et al. 2017), and could therefore produce wrong or misleading results for some spectra. To have the ability to filter out such possible occurrences, we created a set of warning flags for different pipeline steps that are listed and described in detail in Table 1. An interested user can base their selection of results according to the desired confidence level and a physical question of interest. The cleanest set of 10,364 Hα emission stars can be produced by selecting unflagged stars that do not show any signs of possible binarity, defined such that parameter $\text{emiss}$ in the published Table A1 is set to one (the equivalent of true). To be included among the cleanest set of detections, we considered only spectra whose $\text{Ha\_EW} > 0.25$ Å. Below this limit, we are less confident in marking an object as having an emission feature because visual inspection showed that this strength could be mimicked by spectral noise, the uncertainty of the reference spectrum, or induced by the reduction pipeline. This selection criteria at the same time discards the weakest chromospheric components, which might be of great interest for specific studies. If the user is interested only in stronger emitters, the threshold should be raised to $\text{Ha\_EW} > 0.5$ Å or above.

The published Table A1 also contains a flag that describes whether the spectrum is considered to contain an additional nebular contribution. Such spectra can be filtered out by choosing the parameter $\text{nebular}$ to be equal to 1. To compile this less restrictive list of 4004 spectra, we selected entries with at least three prominent forbidden emission lines ($\text{NII} + \text{SII} \geq 3$) and a small difference in their measured radial velocities ($|\text{rv\_NII} - \text{rv\_SII}| \leq 15$ km s$^{-1}$).

### 4 TEMPORAL VARIABILITY

The strategy of the GALAH survey is to observe as many objects as possible, and as a result, not many repeated observations were made. The repeated fields were mostly observed to assess the stability of the instrument. Time spans between observations are therefor on the orders of days or years. This limits the possibility of finding a variable object greatly, but still enables us to discover potential interesting objects and diagnose analysis issues.

To find possible emission stars with repeated observations, we selected stars with repeats, among which at least one spectrum was identified to harbour a stronger ($\text{Ha\_EW} > 0.5$ Å) unflagged emission feature. This selection produced 621 stars, having between 2 and 9 observations. To be confident about the observed variability, we visually inspected the observed and the reference spectra of 208 stars with at least three observations. A subset of these spectra was collected in Table A1. The complete table is available in electronic form at the CDS. An excerpt of the published results, containing a subset of 30 rows and 11 most interesting columns for the strongest unflagged emitters is given in Table B1.

As we do not perform any quality cuts on our results, a suggested set of limiting parameter thresholds and quality flags is provided in Section 3.8. Their use depends on user specific requirements and the analysed science case.
are shown in Figure 12, where we present typical types of variability discovered by visual inspection. The types can roughly be described as shape transformation (e.g. change from single- to double-peak or P Cygni emission profile), peak location shift, intensity change, and possible reduction issue.

In the sample of 208 stars, whose spectra were visually inspected, we found that ~ 20% of the inspected spectra display a stable Hα profile. Noticeable profile shape transformation was observed in ~ 10% of the cases, and peak location change in ~ 5% of the cases. Some degree of emission intensity change was noticed for ~ 40% of the cases. Visually similar is reduction induced variability (see the rightmost panel in Figure 12), observed for ~ 25% of all inspected repeated observations. In the case of multiple observations of the same star, we can distinguish between the last two profile changes (intrinsic and reduction induced intensity change) by looking at the whole spectrum to inspect whether variability is also exhibited in other absorption lines as shown by the last example in Figure 12. That kind of reduction induced variability is limited to a few observed fields.

5 DISCUSSION AND CONCLUSIONS

In this paper, we describe the development and application of a neural network autoencoder structure that is able to extract the most relevant latent features from the spectrum. Low feature dimensionality contains only the most basic spectral informations that are used to reconstruct a non-peculiar spectrum with the same physical parameters as the input spectrum.

Our method of differential spectroscopy is one of the most widely used approaches to find peculiar spectral features that are not found in normal stars. As a part of this paper, we showed that a dense autoencoder neural network structure can be reliably used for generation of non-peculiar reference spectra if trained on a large set of normal spectra. With the additional exclusion of our detected emission-line stars, the training set could iteratively be further cleaned of peculiar stars before training the network. As all the information about the spectral look is contained in the real flux values, there is no need to add additional convolutional layers for the extraction of more complex spectral shapes.

By identifying significant residuals after subtracting the generated reference spectra from the observed spectra, we detected emission star candidates in the GALAH fields all over the sky. Figure 13 shows that we can identify few locations with a higher density of detected emission-line objects. The position of emission-line objects coincides with regions of young stars such as the Orion complex, Blanco 1, Pleiades, and other possibly random over-densities of interstellar gas and dust. Detected nebular emission in stellar spectra, shown in Figure B4, coincide with large visually-identified nebular clouds (by comparing detected locations with the red all-sky photographic composite of The Second Digitized Sky Survey, described by McLean et al. 2000) such as the Antares Emission nebulae, clouds around π Sco and δ Sco, Barnard’s loop, Carina Nebula, nebulae around λ Ori, nebular veils in the constellations of Puppis, Pyxis and Antlia, and other less prominent features.
By combining our detections with additional auxiliary data sets, we can start exploring more detailed physical explanations of the observed emissions and their structure. Among them are two specific photometric surveys, VPHAS (Drew et al. 2014) and IPHAS (Witham et al. 2008) which were designed to detect and study emission-line sources close to the Galactic plane. Because of their positional selection function, their combined photometric data are available only for 4431 GALAH spectra. Of these, the spectroscopically confirmed emission stars are shown in Figure 14, whose color-color diagram can be used to infer accreting objects.

Our detected emission spectra have a broad range of emission components - these range from very strong to barely detectable chromospheric emission component whose identification can be mimicked or masked at multiple steps of the analysis and data preparation. To limit the number of false-positive classifications due to reduction and analysis limitations, we focused on stronger components (Ha_w > 0.25 Å) whose existence can be confirmed visually. Because that kind of process would be slow for the whole sample, we introduced quality flags that can be used to filter out unwanted or specific cases. Additionally, the stability of the spectra and emission features was investigated by repeated observations of the same objects. Among them, we observed different variability types, of which one could be attributed to the data reduction pipeline, limiting the confidence of finding weak emission profiles in the spectra.

To reliably detect even the weakest chromospheric emissions, uncertainty of the used reference spectra must be well known as well. By showing that the proposed neural network structure can be used as intended, we are looking into possibilities to improve our methodology using variational autoencoder. Its advantage lies in the possibility of simultaneous determination of a reference spectrum and its uncertainty which would enable uncertainty estimation of the measured emission-line indices.

ACKNOWLEDGEMENTS

| ra              | deg             | Right ascension coordinate from 2MASS                                                                                                       |
| dec             | deg             | Declination coordinate from 2MASS                                                                                                           |
| Ha_EW           | Å               | Equivalent width of a difference between observed and template spectrum in the range of ±3.5 Å around the Hα line                              |
| Hb_EW           | Å               | Same as the Ha_EW, but for the Hβ line                                                                                                      |
| Ha_EW_abs       | Å               | Equivalent width of an absolute difference between observed and template spectrum in the range of ±3.5 Å around the Hα line                    |
| Hb_EW_abs       | Å               | Same as the Ha_EW_abs, but for the Hβ line                                                                                                  |
| Ha_W10          | km s⁻¹          | Width (in km s⁻¹) of the Hα emission feature at 10% of its peak flux amplitude                                                               |
| Ha_EW_asym      |                | Value of asymmetry index for the Hα line                                                                                                |
| Hb_EW_asym      |                | Value of asymmetry index for the Hβ line                                                                                                |
| SB2_c3          |                | Was binarity detected in the red arm                                                                                                        |
| SB2_c1          |                | Was binarity detected in the blue arm                                                                                                       |
| NII             |                | Number of detected [NII] peaks in the doublet                                                                                              |
| SII             |                | Number of detected [SII] peaks in the doublet                                                                                        |
| NII_EW          | Å               | Equivalent width of a fitted Gaussian profile to the [NII] emission features                                                                |
| SII_EW          | Å               | Same as the NII_EW, but for the [SII] doublet                                                                                              |
| rv_NII          | km s⁻¹          | Intrinsic radial velocity of the [NII] doublet, corrected for the barycentric and stellar velocity                                           |
| rv_SII          | km s⁻¹          | Same as rv_NII, but for the [SII] doublet                                                                                                  |
| nebular         |                | Is spectrum considered to have an additional nebular component                                                                            |
| emiss           |                | Is spectrum considered to have an additional Hα emission component                                                                         |
| flag            |                | Sum of all bitwise flags raised for a spectrum                                                                                              |

Figure B1. Same plots and objects as in Figure 3 but for the blue spectral arm.
Table B1. Excerpt of 30 strongest unflagged emitters from the published table presented in detail by Table A1. The rest of the table can be downloaded in electronic form CDS service and publishers’ website.

MNRAS 000, 1–14 (2020)
Figure B2. Same plots as shown in Figure 4, but for the latent features of the blue HERMES band, coloured by parameter $T_{\text{eff}}$ on lower triangle and by log g on the upper triangle.
Figure B3. Same plots as shown in Figure 4, but for the latent features of the blue HERMES band, coloured by parameter $T_{\text{eff}}$ on lower triangle and by $[\text{Fe/H}]$ on the upper triangle.
Figure B4. Same as Figure B4 but showing stars with at least three detected nebula emission lines, shown with black dots.
