The Saxl Conjecture and the Dominance Order

Christian Ikenmeyer*

2014-Oct-23

Abstract

In 2012 Jan Saxl conjectured that all isomorphy types of irreducible representations of the symmetric group occur in the decomposition of the tensor square of the irreducible representation corresponding to the staircase partition. We make progress on this conjecture by proving the occurrence of all those types which correspond to partitions that are comparable to the staircase partition in the dominance order. Moreover, we use our result to show the occurrence of all types corresponding to hook partitions. This generalizes results by Pak, Panova, and Vallejo from 2014.

Keywords: Kronecker coefficients, symmetric group, irreducible representations, tensor square conjecture, Saxl conjecture

2010 Mathematics Subject Classification: 20C30; 20G05.

1 Introduction

In their recent work [PPV14] Pak, Panova, and Vallejo study the tensor square conjecture for symmetric groups and the related Saxl conjecture. The tensor square conjecture states that for all natural numbers \( d \) besides 2, 4 and 9 there exists an irreducible representation \( [\lambda] \) of the symmetric group \( S_d \) on \( d \) letters such that every irreducible representation of \( S_d \) is a constituent of the tensor square of \( [\lambda] \). Jan Saxl conjectured in 2012 that in the case of \( d \) being a triangle number the isomorphy type \( \lambda \) can be chosen to be the staircase partition \( \varphi \). We make progress on the Saxl conjecture by showing that all those partitions which are comparable to the staircase partition in the dominance order actually appear in the decomposition of the tensor square of \( [\varphi] \), see Theorem 2.1 below. As a corollary, we also proof that all hook partitions appear in the decomposition of the tensor square of \( [\varphi] \), see Corollary 6.1 which is also proved in [PP].

Besides hooks, the recent paper [PPV14] contains partial results about two-row partitions, certain three-row-partitions, and the case of a two-row partition with an additional column. Our work generalizes the first two of these three cases.

*Texas A&M University, ciken@math.tamu.edu
The aforementioned conjectures are questions about the positivity of certain Kronecker coefficients. Recently the study of these coefficients has intensified, as they arise prominently in geometric complexity theory (see e.g. [MS01, MS08, BI11, BI13, BLMW11, Ike12, PP14] to name a few) and in quantum information theory (see e.g. [Chr06, CM06, Kly06, CHM07, CDW12] and references therein). Other work on the Saxl conjecture can be found in [Val14].

Our proof of Theorem 2.1 uses the interpretation of the Kronecker coefficient as the dimension of the space of homogeneous highest weight polynomials on the triple tensor product space, and we show nonzeroness of these polynomials using polarization, a standard method from multilinear algebra.

Acknowledgments

I am grateful to the Simons Institute for the Theory of Computing in Berkeley for hosting me during this research. I want to thank Cameron Farnsworth, Igor Pak, Greta Panova, and Ernesto Vallejo for helpful discussions.

2 Preliminaries

A partition \( \lambda \) is defined to be a finite sequence of nonincreasing nonnegative integers \( \lambda = (\lambda_1, \lambda_2, \ldots, \lambda_n) \). A pictorial description of partitions are Young diagrams, which are upper-left-justified arrays having \( \lambda_i \) boxes in the \( i \)th row, for example the partition \((5, 3, 1, 1)\) can be depicted as follows:

\[
\begin{array}{cccccc}
& & & & & \\
& & & & & \\
& & & & & \\
& & & & & \\
& & & & & \\
& & & & & \\
& & & & & \\
& & & & & \\
& & & & & \\
& & & & & \\
\end{array}
\]

The transposed Young diagram of \( \lambda \) is obtained by flipping the Young diagram of \( \lambda \) at the main diagonal. The corresponding partition is called \( ^t\lambda \). For example \((5, 3, 1, 1) = (4, 2, 2, 1, 1)\). The length of the \( i \)th row of \( \lambda \) is given by \( \lambda_i \) and the length of the \( i \)th column of \( \lambda \) is given by \( ^t\lambda_i \). We call \( |\lambda| := \sum_{i=1}^{n} \lambda_i \) the number of boxes of \( \lambda \). If the number of boxes of \( \lambda \) is \( d \), then we say that \( \lambda \) is a partition of \( d \). A partition \( \lambda \) dominates another partition \( \varphi \) if \( \forall k : \sum_{i=k}^{n} \lambda_i \geq \sum_{i=k}^{n} \varphi_i \).

If \( \lambda \) dominates \( \varphi \) or \( \varphi \) dominates \( \lambda \), we say that \( \lambda \) and \( \varphi \) are comparable in the dominance order. Let \( \varphi(n) := (n, n-1, n-2, \ldots, 1) \) denote the so-called staircase partition with \( d := n(n+1)/2 \) boxes.

Our base field are the complex numbers. Every partition \( \lambda \) with \( d \) boxes corresponds to an isomorphism type \([\lambda]\) of irreducible representations of the symmetric group \( \mathfrak{S}_d \). For two partitions \( \lambda \) and \( \mu \) of \( d \) we have that the group \( \mathfrak{S}_d \) also acts naturally on the tensor product \([\lambda] \otimes [\mu]\) by diagonally embedding \( \mathfrak{S}_d \hookrightarrow \mathfrak{S}_d \times \mathfrak{S}_d, \pi \mapsto (\pi, \pi) \) and this tensor product decomposes into irreducibles. Our main result is the following theorem.

2.1 Theorem. For every partition \( \nu \) with \( n(n+1)/2 \) boxes that is comparable in the dominance order to the staircase partition \( \varphi(n) \) we have that the tensor
square representation $[\varrho(n)] \otimes [\varrho(n)]$ contains the irreducible representation $[\nu]$ as an irreducible constituent.

Let $\varrho := \varrho(n)$. The number of occurrences of $[\nu]$ in $[\varrho] \otimes [\varrho]$ is called the Kronecker coefficient $k_{\varrho \nu \nu}$. Hence Theorem 2.1 states that $k_{\varrho \nu \nu}$ is nonzero for all $\nu$ that are comparable to $\varrho$ in the dominance order. Our proof uses a different but also well known interpretation of Kronecker coefficients which is also used in \cite{Ike12, BI13, HIL13}. We explain this description in section 3.

For proving Theorem 2.1 without loss of generality we can assume that $\nu$ dominates $\varrho$: Indeed, if $\varrho$ dominates $\nu$, then $\nu$ dominates $\varrho = \varrho$ and we have $k_{\varrho \nu \nu} = k_{\varrho(\nu)(\nu)} > 0$, because it is well known that the Kronecker coefficient is invariant under transposition of any two of its parameters, see e.g. \cite{Ike12} Lemma 4.4.7.

3 Highest Weight Vectors

Let $\lambda, \mu, \nu$ be partitions of $d$ with at most $n$ rows. The group $\text{GL}_n^3 := \text{GL}_n \times \text{GL}_n \times \text{GL}_n$ acts on the third tensor power $\bigotimes^3 \mathbb{C}^n$ via

$$(g' \otimes g'' \otimes g''')(v' \otimes v'' \otimes v''') := (g'v') \otimes (g''v'') \otimes (g'''v''').$$

Since $\text{GL}_n^3$ acts on $\bigotimes^3 \mathbb{C}^n$, the symmetric power $\text{Sym}^d(\bigotimes^3 \mathbb{C}^n)$ is a finite dimensional $\text{GL}_n^3$-representation. Indeed, $\text{Sym}^d(\bigotimes^3 \mathbb{C}^n) \subseteq \bigotimes^d(\bigotimes^3 \mathbb{C}^n)$ is the subrepresentation of tensors that are invariant under permuting the $d$ tensor factors. For $\alpha \in \mathbb{C}^n$ let $\text{diag}(\alpha_1, \ldots, \alpha_n)$ denote the diagonal matrix with $\alpha_i$ on the main diagonal, i.e., an element of the maximal torus of $\text{GL}_n$ (for the standard basis).

Given a partition triple $(\lambda, \mu, \nu)$ with $d$ boxes each, a vector $f \in \text{Sym}^d(\bigotimes^3 \mathbb{C}^n)$ is called a weight vector of type $(\lambda, \mu, \nu)$ if for all triples $(g', g'', g''')$ of diagonal matrices $g' = \text{diag}(g'_1, g'_2, \ldots, g'_n)$, $g'' = \text{diag}(g''_1, g''_2, \ldots, g''_n)$, $g''' = \text{diag}(g'''_1, g'''_2, \ldots, g'''_n)$ we have

$$(g' \otimes g'' \otimes g''')f = \prod_{i=1}^{n}(g'_i)^{\lambda_i} \prod_{i=1}^{n}(g''_i)^{\mu_i} \prod_{i=1}^{n}(g'''_i)^{\nu_i} f.$$

Let $U_n \subseteq \text{GL}_n^3$ denote the group of triples of upper triangular matrices with $1$s on the main diagonals, i.e., the maximal unipotent group of $\text{GL}_n^3$. A weight vector is called a highest weight vector if $\forall g \in U_n : gf = f$. The set of highest weight vectors of a given type $(\lambda, \mu, \nu)$ in $\text{Sym}^d(\bigotimes^3 \mathbb{C}^n)$ forms a vector space which we denote by $\text{HWV}_{\lambda, \mu, \nu}(\text{Sym}^d(\bigotimes^3 \mathbb{C}^n))$. One of the definitions of the Kronecker coefficient is that $k_{\nu \mu \nu}$ is the dimension of $\text{HWV}_{\lambda, \mu, \nu}(\text{Sym}^d(\bigotimes^3 \mathbb{C}^n))$, see \cite{Ike12} Sec. 4.4 for more information.

The main idea is to study the $d$th tensor power instead of the $d$th symmetric power and project down to the symmetric power afterwards. The tensor power $\bigotimes^d(\bigotimes^3 \mathbb{C}^n)$ is a $\text{GL}_n^3$-representation and for every partition triple $(\lambda, \mu, \nu)$ we know a generating set (even a basis) of the highest weight vector space $\text{HWV}_{\lambda, \mu, \nu}(\bigotimes^d(\bigotimes^3 \mathbb{C}^n))$. 3
We now construct an element in $\text{HWV}_{\lambda,\mu,\nu}(\bigotimes^d(\bigotimes^3\mathbb{C}^n))$. Let $\lambda$, $\mu$, and $\nu$ have $d$ boxes each. Let $e_1, e_2, \ldots, e_n$ denote the standard basis of $\mathbb{C}^n$. For $i \in \mathbb{N}$ let
\[ \hat{i} := e_1 \wedge e_2 \wedge \cdots \wedge e_i \in \bigotimes^i \mathbb{C}^n. \]
Define
\[ \hat{\nu} := \hat{\nu}_1 \otimes \hat{\nu}_2 \otimes \cdots \in \bigotimes^d \mathbb{C}^n. \]
It is readily checked that $\hat{\lambda} \otimes \hat{\mu} \otimes \hat{\nu} \in \text{HWV}_{\lambda,\mu,\nu}(\bigotimes^d(\bigotimes^3\mathbb{C}^n))$. We define $\hat{\lambda}, \hat{\mu}, \hat{\nu} \in \text{HWV}_{\lambda,\mu,\nu}(\bigotimes^d(\bigotimes^3\mathbb{C}^n))$ to be the image of $\hat{\lambda} \otimes \hat{\mu} \otimes \hat{\nu}$ under the isomorphism $\text{HWV}_{\lambda,\mu,\nu}(\bigotimes^d(\bigotimes^3\mathbb{C}^n)) \cong \text{HWV}_{\lambda,\mu,\nu}(\bigotimes^3(\bigotimes^d\mathbb{C}^n))$, which is just reordering the tensor factors.

We will now study a graphical interpretation of the contraction of $\hat{\lambda}, \hat{\mu}, \hat{\nu}$ with other tensors. For a list of vectors $v_1, \ldots, v_m \in \mathbb{C}^n$, $m \leq n$, let the evaluation $\text{eval}(v_1, \ldots, v_m)$ denote the determinant of the $m \times m$ matrix obtained from the column vectors $v_1, \ldots, v_m$ by taking only the first $m$ entries of each $v_i$. For example
\[ \text{eval} \begin{pmatrix} 1 & 2 \\ 0 & -1 \\ 3 & 1 \end{pmatrix} = \det \begin{pmatrix} 1 & 2 \\ 0 & -1 \end{pmatrix} = -1. \]

We now construct a hypergraph $H$ with vertex set $\{1, 2, \ldots, d\}$ as follows. There are three layers of hyperedges corresponding to $\lambda$, $\mu$, and $\nu$, respectively. Every vertex lies in exactly three hyperedges, one from each layer. Every hyperedge in layer 1 corresponds to a column in $\lambda$, analogously for layer 2 and $\mu$ and for layer 3 and $\nu$. Filling a Young tableau of shape $\lambda$ columnwise from top to bottom gives the hyperedges of the first layer, for example for $\lambda = (4, 3, 2, 1)$ we would fill columnwise and obtain
\[
\begin{array}{c}
1 & 5 & 8 & 10 \\
2 & 6 & 9 \\
3 & 7 \\
4
\end{array}
\]
so the hyperedges of layer 1 are arranged as follows:

\[
\begin{array}{cccc}
1 & 2 & 3 & 4 \\
5 & 6 & 7 \\
8 & 9 \\
10
\end{array}
\]

We do the same for $\mu$ and $\nu$. For example, if $\lambda = \mu = \varnothing(4)$ and $\nu = (5, 3, 1, 1)$ we obtain the following hypergraph:

\[
\begin{array}{cccc}
1 & 2 & 3 & 4 \\
5 & 6 & 7 \\
8 & 9 \\
10
\end{array}
\]

where layer 2 is drawn with dashed lines and layer 3 with dotted lines. Let us call this hypergraph $H$. Let $E_i(H)$ denote the set of hyperedges in layer $i$,
1 \leq i \leq 3. For a hyperedge \( S \) let \( S_1 \) denote its smallest entry, \( S_2 \) denote its second smallest entry, and so on. Let \( \circ \) denote the contraction of tensors.

The main property of \( \hat{\lambda}, \mu, \nu \) is the following, which can be readily checked by calculation. For all \( a_i, b_i, c_i \in \mathbb{C}^n, 1 \leq i \leq n \), we have

\[
\hat{\lambda}, \mu, \nu \circ \left( (a_1 \otimes b_1 \otimes c_1) \otimes (a_2 \otimes b_2 \otimes c_2) \otimes \cdots \otimes (a_d \otimes b_d \otimes c_d) \right)
= \prod_{S \in E_1(H)} \text{eval}(a_{S_1}, a_{S_2}, \ldots, a_{S_{|S|}})
\cdot \prod_{S \in E_2(H)} \text{eval}(b_{S_1}, b_{S_2}, \ldots, b_{S_{|S|}})
\cdot \prod_{S \in E_3(H)} \text{eval}(c_{S_1}, c_{S_2}, \ldots, c_{S_{|S|}}).
\]

Let us summarize the key properties of \( H \) in the following definition.

3.2 Definition. Let \( d := |\lambda| = |\mu| = |\nu| \). A Young hypergraph \( H \) of type \((\lambda, \mu, \nu)\) is a hypergraph with \( d \) vertices such that

- There are three layers of hyperedges corresponding to \( \nu \), \( \mu \), and \( \nu \), respectively.
- Every vertex lies in exactly three hyperedges, one from each layer.
- There is a bijection between the vertices of \( H \) and the boxes in \( \lambda \) such that two vertices lie in a common hyperedge in layer 1 iff the corresponding boxes in \( \lambda \) lie in the same column. Analogously for layer 2 and \( \mu \) and for layer 3 and \( \nu \)\].

The crucial point is the following. The fact that the actions of the groups \( \text{GL}_n \times \mathfrak{S}_d \times \mathfrak{S}_d \) on \( \bigotimes^d((\boxtimes^3 \mathbb{C}^n)) \) commute implies that we can use any Young hypergraph \( H \) instead of the one we just constructed and in this manner define a highest weight vector \( \hat{\lambda}, \mu, \nu_H \) whose tensor contraction works exactly as in equation (3.1).

The group \( \mathfrak{S}_d \) acts on \( \bigotimes^d((\boxtimes^3 \mathbb{C}^n)) \) by rearranging the tensor factors.

To prove that \( \text{HWV}_{\lambda, \mu, \nu}(\text{Sym}^d((\boxtimes^3 \mathbb{C}^n)) \neq 0 \) it is sufficient to create a Young hypergraph \( H \) of type \((\lambda, \mu, \nu)\) such that the projection of \( \hat{\lambda}, \mu, \nu_H \) to \( \text{HWV}_{\lambda, \mu, \nu}(\text{Sym}^d((\boxtimes^3 \mathbb{C}^n)) \) is nonzero. For this, it is sufficient to find a symmetric tensor \( v \in \text{Sym}^d((\boxtimes^3 \mathbb{C}^n)) \) such that \( \hat{\lambda}, \mu, \nu_H \circ v \neq 0 \). To prove Theorem 2.1 it remains to construct a Young hypergraph of type \((g(n), g(n), \nu)\) and a tensor \( v \in \text{Sym}^d((\boxtimes^3 \mathbb{C}^n)) \) with the property \( \hat{\lambda}, \mu, \nu_H \circ v \neq 0 \). We will do so in the next sections.

4 Construction of the Young Hypergraph

For the rest of this paper we fix \( n \), we let \( g := g(n), d := \frac{n(n+1)}{2}, \) and we fix \( \nu \) a partition of \( d \) such that \( \nu \) dominates \( g \). We construct a Young hypergraph
$H$ of type $(\varphi, \chi, \nu)$ with $d$ vertices as follows. We start by defining a finite set
$\Delta_n := \{(r, c) \in \mathbb{N} \times \mathbb{N} \mid 1 \leq r, c \leq n,\ r + c \leq n + 1\}$ of $d$ points in the planar
grid. For example for $n = 4$ the arrangement $\Delta_n$ can be depicted as follows:

$$\Delta_4 = \bullet \bullet \bullet \bullet$$

The set $\Delta_n$ forms the vertex set of the Young hypergraph $H$. We will see that
the numbering of the vertex set can be done in any way, so we omit it. The
hyperedges for the first layer of $H$ are formed by the rows and the hyperedges
of the second layer are given by the columns, so for example for $n = 4$ we have
the following picture.

Besides a row number $r(x) \in \{1, 2, \ldots, n\}$ and a column number $c(x) \in \{1, 2, \ldots, n\}$, each vertex $x$ has a value $\beta(x) \in \{1, 2, \ldots, n\}$, which we define
as $\beta(x) = n + 2 - r(x) - c(x)$. The $\beta$ value can be interpreted as the distance
from the diagonal edge of the triangular array $\Delta_n$. For example in the case
$n = 4$ the $\beta$ values are as follows:

$$\begin{align*}
4 & \ 3 & \ 2 & \ 1 \\
3 & \ 2 & \ 1 \\
2 & \ 1 \\
1 & 
\end{align*}$$

Recall that the sizes of the hyperedges of the third layer correspond to the
column lengths of $\nu$. We now choose the hyperedges of the third layer in a way
that for each hyperedge the $\beta$ values of all its vertices are distinct. The key
insight is that this is possible! Indeed, the following lemma says that this can
be done iff $\nu$ dominates $\varphi$.

### 4.1 Lemma.
The following two statements are equivalent:

- In $\Delta_n$ there exists a partition of the vertex set into hyperedges of sizes
given by the column lengths of $\nu$ such that for each hyperedge the $\beta$ values
of all vertices in the hyperedge are distinct.

- $\nu$ dominates $\varphi$. 

6
Proof. A filling of shape $\nu$ and content $\gamma \in \mathbb{N}^n$ is an assignment of numbers to the boxes of $\nu$ such that each entry $i$ appears exactly $\gamma_i$ times. A filling is semistandard if the entries are increasing along each column and nondecreasing along each row. We prove that the following four statements are all equivalent:

1. In $\Delta_n$ there exists a partition of the vertex set into hyperedges of sizes given by the column lengths of $\nu$ such that for each hyperedge the $\beta$ values of all vertices in the hyperedge are distinct.

2. There exists a filling of $\nu$ with content $\varrho$ such that there is no column with two coinciding entries.

3. There exists a semistandard filling of $\nu$ with content $\varrho$.

4. $\nu$ dominates $\varrho$.

The statement that (3) is equivalent to (4) is known as the Gale-Ryser theorem, see e.g. [FH91, p. 457, Ex. A.11], [Ful97, p. 26, Ex. 2], or [Mac95, I.7 Exa. 9]. Clearly (3) implies (2). But (2) also implies (3) by straightening the filling, see e.g. [Ful97, p. 110]. It remains to show that (1) iff (2). From a partition of the vertex set into hyperedges we obtain a filling of shape $\nu$ by constructing for each hyperedge a column whose entries are exactly the $\beta$ values of the vertices in the hyperedge. On the other hand, from a filling we get a partition of the vertex set into hyperedges by constructing for each column a hyperedge that has vertices whose $\beta$ values are exactly the values in the column. For example, for $\nu = (5, 3, 1, 1)$ we can find a filling

\[
\begin{array}{cccc}
1 & 1 & 1 & 2 \\
2 & 2 & 3 \\
6 & \\
4 \\
\end{array}
\]

from which we can construct the third layer such that the $\beta$ values of the vertices in a hyperedge are exactly the numbers appearing in a column:

\[
\begin{array}{ccc}
\ast & \ast & \ast \\
3 & \ast & \ast \\
2 & \ast & \ast \\
1 & & \\
\end{array}
\]

\[\Box\]

5 Contraction with the Symmetric Tensor

Let $e_1, e_2, \ldots, e_n$ denote the standard basis of $\mathbb{C}^n$. Choose generic vectors $c_1, \ldots, c_n \in \mathbb{C}^n$. Let

\[
\tilde{v} := (e_1 \otimes e_1 \otimes c_1) \otimes (e_2 \otimes e_2 \otimes c_2) \otimes (e_3 \otimes e_3 \otimes c_3) \otimes \cdots \otimes (e_n \otimes e_n \otimes c_n) \otimes 1 \in \mathcal{S}_{d}(\mathcal{S}^3 \mathbb{C}^n).
\]
Define \( v := \sum_{\sigma \in \mathfrak{S}_d} \sigma(v) \in \text{Sym}^d(\mathbb{C}^n) \). As described at the end of section 3 it remains to show that \( \lambda, \mu, \nu_H \circ v \neq 0 \). By linearity we have

\[
\lambda, \mu, \nu_H \circ v = \sum_{\sigma \in \mathfrak{S}_d} \lambda, \mu, \nu_H \circ \sigma(v). \quad (5.1)
\]

Note that the stabilizer of \( \bar{v} \) in \( \mathfrak{S}_d \) is the Young subgroup \( \mathfrak{S}_n \times \mathfrak{S}_{n-1} \times \cdots \times \mathfrak{S}_1 \subseteq \mathfrak{S}_d \), so actually (5.1) is a sum of \( \frac{d!}{n!(n-1)\cdots2!} \) summands, each with coefficient \( \theta := \frac{n!(n-1)\cdots2!}{n!} \).

Let \( M \) denote the set of all mappings \( \tau : \{1, \ldots, d\} \to \{1, \ldots, n\} \) such that the cardinality \( |\tau^{-1}(i)| \) of the preimage of \( i \) is \( n + 1 - i \) for all \( 1 \leq i \leq n \). Then we can rewrite (5.1) as

\[
\lambda, \mu, \nu_H \circ v = \theta \sum_{\tau \in M} \lambda, \mu, \nu_H \circ (e_{\tau(1)} \otimes e_{\tau(1)} \otimes c_{\tau(1)}) \otimes \cdots \otimes (e_{\tau(d)} \otimes e_{\tau(d)} \otimes c_{\tau(d)}). \quad (5.2)
\]

The map \( \tau \) can be thought of as placing numbers 1 up to \( n \) on the vertices of \( \Delta_n \), each number \( i \) exactly \( n + 1 - i \) times. The key observation we want to prove is that there is exactly one nonzero summand in (5.2), namely the one where \( \tau = \beta \). We now give strong restrictions on how \( \tau \) can look like in the case where the summand corresponding to \( \tau \) in (5.2) is nonzero. The main argument we use is that for every hyperedge \( \{x_1, x_2, \ldots, x_k\} \) the evaluation \( \text{eval}(e_{\tau(x_1)}, e_{\tau(x_2)}, \ldots, e_{\tau(x_k)}) \) is nonzero iff the list \( (\tau(x_1), \ldots, \tau(x_k)) \) is a permutation of \( (1, 2, \ldots, k) \). We refer to this fact as (\( * \)). The fact that there is only a single vertex \( x \) in the bottom row implies that \( \tau(x) = 1 \) by (\( * \)), because otherwise this singleton hyperedge in the row contributes a zero factor in the evaluation of the first layer. For the vertex \( y \) directly above \( x \) by applying (\( * \)) we see that we cannot set \( \tau(y) = 1 \), because the first column is a hyperedge in the second layer. But from (\( * \)) we know that in the row of \( y \) the map \( \tau \) has to place exactly the numbers 1 and 2, so we must set \( \tau(y) = 2 \) and \( \tau(y') = 1 \) for the right neighbor \( y' \) of \( y \). This argument continues up through all rows until we see that at any vertex \( x \) we can only place \( \tau(x) = \beta(x) \). The determinants of all hyperedges of the first and second layer are determinants of permutation matrices, so they are either 1 or \(-1\), but certainly nonzero. Since the hyperedges in the third layer have the property that no hyperedge has two vertices with the same \( \beta \) value, and since the \( c_i \) were chosen generically, the determinants of the hyperedges of the third layer are all nonzero. This finishes the proof of Theorem 2.1.

\section{Hooks}

In this section we use Theorem 2.1 to prove the Saxl conjecture for hooks, see Corollary 6.1. Interestingly, the proof of Corollary 6.1 in \cite{PP} uses a very different technique.

Let \( n \times 1 \) denote the partition with \( n \) boxes in a single column and let \( 1 \times n \) denote the partition with \( n \) boxes in a single row. The addition of partitions is
defined as the addition of their row lengths. A partition $\nu$ is called a hook if $\nu$ can be written as $\nu = 1 \times n + m \times 1$ for some $n, m \in \mathbb{N}_0$.

6.1 Corollary. Let $d := n(n + 1)/2$. For every hook $\nu$ with $d$ boxes we have $k_{\varrho(n), \varrho(n), \nu} > 0$.

Proof. We use induction on $d$, where the base case $d = 1$ is trivial. If $\nu$ has at most $n$ rows, then the statement holds by Theorem 2.1 because $\nu$ dominates $\varrho(n)$. If $\nu$ has more than $n$ rows, then we can obtain the partition $\bar{\nu}$ by removing $n$ boxes from the first column of $\nu$. By induction hypothesis $k_{\varrho(n-1), \varrho(n-1), \bar{\nu}} > 0$ and thus $k_{\varrho(n), \varrho(n), \bar{\nu}} > 0$. Since $k_{n \times 1, n \times 1, 1 \times n} = 1 > 0$ and $n \times 1 + \varrho(n - 1) = \varrho(n)$, the semigroup property (see e.g. [Ike12, Prop. 4.4.10]) implies $k_{\varrho(n), \varrho(n), \bar{\nu} + 1 \times n} > 0$ and hence $k_{\varrho(n), \varrho(n), \nu} > 0$.
