ABSTRACT

We use the grid of models described in Paper I to analyse those millisecond pulsar binaries whose secondaries have been studied optically. In particular, we find cooling ages for these binary systems that range from \(< 1\) to \(\sim 15\) Gyr. Comparison of cooling ages and characteristic spin-down ages allows us to constrain the initial spin periods and spin-up histories for individual systems, showing that at least some millisecond pulsars had sub-Eddington accretion rates and long magnetic field decay times.

Key words: binaries: general – stars: evolution – pulsars: general – pulsars: individual: J0437–4715 – pulsars: individual: J1012+5307 – white dwarfs.

1 INTRODUCTION

The ages of millisecond pulsars are important for understanding both their nature and their origin. Ages are usually estimated from the characteristic age \(t_P = P/2\dot{P}\), but such estimates could be seriously in error if the current spin period is still close to the initial spin period at the beginning of the millisecond pulsar phase. If the average millisecond pulsar were significantly younger than its characteristic age, as suggested by Lorimer et al. (1995a), then it would affect current ideas about magnetic field decay in such stars (Kulkarni 1986; Camilo, Thorsett & Kulkarni 1994b) as well as the possible birth-rate discrepancy between low-mass binary pulsars and low-mass X-ray binaries (Kulkarni & Narayan 1988; van den Heuvel 1995).

Many millisecond pulsars are found in binaries, often with low-mass degenerate companions. Accurate modelling of the cooling of the companions can allow one to estimate the age of the system (or rather the age of this particular incarnation). Since millisecond pulsars are thought to be spun up as the result of accretion from the companion star, the pulsar will begin to spin down at approximately the same time as the companion shrinks within its Roche lobe, ending mass loss and beginning the process of cooling to its final degenerate white dwarf configuration. Hence the cooling age of the white dwarf should represent the millisecond pulsar age as well.

In Paper I, we calculated accurate cooling models for the low-mass helium core white dwarfs thought to be the companions in these low-mass binary pulsar systems. In this paper we shall now apply the models to the optical observations of these systems to infer the cooling ages for such objects. Section 2 reviews the basic concepts used to infer the age of a pulsar from its spin parameters, as well as simple models of magnetic field decay in such a pulsar. In Section 3 we apply our cooling models to the observational data, and in Section 4 we discuss the implications.

2 PULSAR SPIN-DOWN

For a pulsar with period \(P\) and spin-down rate \(\dot{P}\) related by \(P \propto P^{2-n}\), the age is given by

\[
t = \frac{P}{(n-1)\dot{P}} \left[ 1 - \left(\frac{P_0}{P}\right)^{n-1} \right],
\]

where \(n\) is the braking index and \(P_0\) is the initial period. For magnetic dipole radiation \(n = 3\), leading to the familiar expression for the pulsar characteristic age \(t_P = P/2\dot{P}\). For some young pulsars, measurements yield a range for \(n\) of 2.0 to 2.8 (Lyne 1996 and references therein). However, \(n\) is not known for any millisecond pulsars. Because characteristic ages for millisecond pulsars are of the order of gigayears or higher, there is a very real danger that estimates of the pulsar age based on this quantity will be gross overestimates because of the second factor in equation (1).

The characteristic time is calculated from the spin-down rate \(\dot{P}\), which can also be seriously affected by the proper motion of the pulsar (e.g. Camilo et al. 1994b). This is because of the changing Doppler shift (Shklovskii 1970), which produces an additional contribution to the period derivative such that

\[
\dot{P} = \frac{P}{P_i} \left[ \frac{V_\perp^2 + \left(\frac{P}{P_i}\right)^2}{cD} \right] = \left(\frac{P}{P_i}\right) + 2.432 \times 10^{-21} \left(\frac{\mu}{\text{mas yr}^{-1}}\right)^2 \left(\frac{D}{\text{kpc}}\right),
\]

where \((P/P_i)\) is the intrinsic contribution due to pulsar rotation, \(D\) is the distance to the pulsar, \(V_\perp \propto D\mu\) is the transverse velocity and \(\mu\) is the proper motion of the pulsar. Once \(\mu\) is measured, we may remove this contribution to obtain the intrinsic characteristic time.

Let us define \(t_P^*\) as the characteristic age before the correction and \(t_P\) as the intrinsic pulsar characteristic age. Thus, with \(n = 3\), the intrinsic characteristic age is found by

\[
t_P = \frac{t_P^*}{1 - 2V_\perp^2 \dot{P}cD}.
\]
We may then obtain an expression for the ratio of the true age of the pulsar to $t_P^*$ by

$$\frac{t}{t_P^*} = \left[ 1 - \left( \frac{P_0}{P} \right)^2 \right] \left( 1 - 2V_c^2 \frac{\rho}{c} \right).$$

(4)

Apart from the initial period $P_0$, all the quantities on the right-hand side are measurable in principle. An independent age estimate, such as the ones we address here.

There is an additional complication, namely the possibility of magnetic field decay. For magnetic dipole radiation, the spin-down rate is given by

$$P = \frac{(8\pi^2 R^6)}{(3C^3)} \times \frac{B^2}{P},$$

(5)

where $B$ is the magnetic field strength on the surface of the neutron star ($B$ is in fact $B \sin \alpha$, where $\alpha$ is the angle between the magnetic dipole axis and the spin-axis, and so ‘decay’ could be the result of field alignment). Thus decay of $B$ will alter the spin-down rate. The possibility of field decay was first advanced by Gunn & Ostriker (1970) but its occurrence is still not conclusively proven. Narayan & Ostriker (1990) have argued for an exponential field decay with an exponential time scale. Nevertheless, we can obtain a lower limit to $t_D$ by setting $P_0 = 0$, so that, using equation (6), we obtain

$$t_D > \frac{2t}{\exp(2/t_D) - 1} \leq \frac{P_0^*}{t_D} \frac{1}{(1 - 2V_c^2 \frac{\rho}{c} D)},$$

(7)

Once we have an estimate for $t$, the left-hand side is a monotonically decreasing function of $t_D$ and the right-hand side consists of measurable quantities. Hence we may constrain the exponential field decay time.

3 RESULTS

Most low-mass binary pulsars have helium core companions (inferred from their mass, since one requires $\sim 0.5 \, M_\odot$ to burn helium to carbon in a stellar interior), although three have companions whose masses indicate that they are carbon/oxygen white dwarfs. These measurements come from pulsar timing and are shown in Table 1 for those pulsars discussed here. In order to determine a cooling age, we need optical identifications of the companions. Those systems with detections or upper limits are shown in Table 2. It is these systems that we shall now discuss in turn. We note that, while the following analysis is quantitative, such an exercise is likely to contain small residual systematic uncertainties resulting both from the use of a heterogeneous sample set from a number of independent groups using different instruments and analysis procedures, and from uncertainties in the atmospheric composition and modelling. The cooling curves used in this procedure will be made public to enable improved estimates to be made in the future with better understanding of individual measurement errors and better atmospheric models.

To determine a conservative and robust effective temperature range from the observed colours, we have assumed a blackbody

spectrum. We use the bandpasses as described in Bessell (1979). In the case of the more massive white dwarfs, we use the pure hydrogen broad-band colours of Bergeron, Saumon & Wesemael (1995) (their calculations do not extend to low enough log $g$). Fig. 1 shows the blackbody relation between temperature and $V-I$ colour (the most common colour amongst this sample). For $V-I > 1.2/\text{T}_{\text{eff}} > 4500$ K, the blackbody colour is in good agreement with the Bergeron et al. colours. At the lower temperature end, the blackbody approximation is expected to fail because of the contribution of collisionally induced absorption in the hydrogen atmospheres. In Fig. 1 we use the log $g = 7.5$ curves to give us a limit on the deviation of our blackbody colours from the true colours. We do this because the collisionally induced absorption is an inherently high-density phenomenon (since it requires collisional interactions) and thus the deviations from a blackbody should be less for lower gravities (which have lower photospheric pressures). Thus by using this procedure we believe that our temperature estimates are robust.

In the following sections, we shall derive cooling ages for the various binary systems, using the cooling models described in Paper I. When the companion is thought to be a carbon/oxygen core white dwarf as opposed to a helium core white dwarf, we use the latest models derived using the model of Wood (1992). We shall also convert these results into constraints on the initial periods of the millisecond pulsars. In order to obtain conservative estimates, we consider dispersion measure distances to be accurate to within 30 per cent, transverse velocities up to 100 km s$^{-1}$ for systems without a measured proper motion, and a braking index between $n = 2$ and 3.

### 3.1 PSR J0437$-$4715

We shall start with the best-determined case. The PSR J0437$-$4715 system contains the closest known millisecond pulsar, at a nominal dispersion measure distance of 0.14 kpc, with a 30 per cent error (Taylor & Cordes 1993). Bell et al. (1995) report a lower limit of the parallax distance (from pulsar timing) of 90 pc. Sandhu et al. (1997), using improved dispersion measurements, report a timing parallax distance of 0.178 $\pm$ 0.026 kpc. VLBI parallax

The error is much smaller than the others because this temperature was determined spectroscopically, rather than photometrically.
measurements are also expected, which will eventually determine the most accurate distance to this pulsar. PSR J0437–4715 has a large proper motion ($\mu = 135 \pm 4$ mas yr$^{-1}$) (Bell et al. 1995), which gives it a transverse velocity of 115 km s$^{-1}$ at 180 pc. This affects the spin-down rate, leading to a kinematically corrected characteristic age of 4.5–50.3 Gyr, depending on the distance to the pulsar based on the parallax.

Optical observations of the companion have been carried out by Bell, Bailes & Bessell (1993), Bailyn (1993) and Danziger, Baade & Della Valle (1993). Between them these three groups measured $B, V, R$ and $I$ magnitudes. The best data are from Danziger et al. and we will use their measurements. Using the $V - I$ colour and our blackbody approximation, we obtain a temperature estimate of $T_{\text{eff}} = 4600 \pm 200$ K.

Given the above parallax distance, we can find the absolute magnitude range allowed, namely $M_I = 13.2 \pm 0.3$. Our models must satisfy both the temperature and magnitude requirements. We can find consistent solutions for all mass $0.15$–$0.375$ $M_\odot$ models as shown in Fig. 2. (If we use only the lower distance limit of Bell et al. then solutions for all masses are possible.) These models are for a hydrogen envelope of $3 \times 10^{-4}$ $M_\odot$ (thick hydrogen envelope in the terminology of Paper I). Similar analysis with thin hydrogen envelope models ($10^{-6}$ $M_\odot$) yields similar answers, with cooling ages $\sim 0.3$ Gyr smaller on average.

Further timing measurements by Sandhu et al. have detected, in addition to the parallax, a rate of change in the projected orbital separation $x = a \sin i$, which they interpret as a change in the inclination angle. Assuming that this is the result of the known proper motion, this implies an upper limit to the inclination angle ($i < 43^\circ$) and a new lower limit to the mass of the companion, $M < 0.22$ $M_\odot$. This constrains the mass range to lie between 0.22 and 0.375 $M_\odot$ (for a 1.4 $M_\odot$ neutron star) and the cooling age is thus 2.5–5.3 Gyr. If we reverse the argument, we can use the upper limit on the companion mass to constrain the neutron star mass to be $< 3.36 M_\odot$.

Furthermore, as we can see from Fig. 3, this further restricts the distance to the system. Using the companion mass limit, the allowed cooling models and the apparent magnitude, one can restrict the distance to $< 188$ pc (which implies that the intrinsic period derivative is $P > 6.16 \times 10^{-24}$). This allows us to set a better upper limit on the timing age of 14.9 Gyr. If we assume a pulsar mass of 1.4 $M_\odot$, then the upper companion mass limit also gives us a lower limit on the inclination $i > 2^\circ$. These various constraints are demonstrated in Fig. 3, which illustrates the relationships between the various constraints on distance and mass.

system is obviously much brighter than it should be if the system were truly as old as the pulsar characteristic age of >5.4 Gyr (Lorimer et al. 1995a). The characteristic age could be even larger if the pulsar has a significant transverse velocity.

The system is also closer than average at a distance of 0.52 kpc, thus making it an ideal candidate for more detailed study. van Kerkwijk, Bergeron & Kulkarni (1996) have determined the effective temperature and gravity using the spectroscopic analysis procedure of Bergeron, Wesemael & Fontaine (1991). The star has \( \log g = 6.75 \pm 0.07 \) and \( T_{\text{eff}} = 8550 \pm 25 \) K. Furthermore, we can use the photometry of Lorimer et al. (1995a) to infer an absolute magnitude. Combining these three data in Fig. 4 we find that we can obtain consistent solutions for both thick and thin hydrogen atmospheres.

Using our mass–radius relations from Paper I, we can determine that the mass limits on the companion are 0.157–0.215 M\(_\odot\) for a thick hydrogen envelope and 0.13–0.183 M\(_\odot\) for a thin hydrogen envelope. The corresponding cooling ages are thus 0.18–0.4 and \( \leq 0.23 \) Gyr respectively. Thus our combined result for the PSR J1012+5307 companion is that \( M \sim 0.165 – 0.215 M_\odot \) and the age is \( < 0.4 \) Gyr.

van Kerkwijk et al. (1996) have also measured the radial velocity of the companion, making this a double-lined spectroscopic binary. This allows us to calculate the mass ratio of the two components. The original published value was \( M_{\text{NS}}/M_{\text{WD}} = 13.3 \pm 0.7 \) but it has recently been revised to \( M_{\text{NS}}/M_{\text{WD}} = 10 \) (van Kerkwijk, private communication). Thus, given the companion mass range inferred from the spectroscopic gravity, one can deduce the neutron star mass directly. Using the two different gravities inferred for this object, we deduce neutron star masses of 1.3 – 1.8 M\(_\odot\) (Callanan & Koester 1998) or 1.7 – 2.1 M\(_\odot\) (van Kerkwijk et al. 1996). The former number is in excellent agreement with the original author’s estimates. These estimates are shown in Fig. 5.

Alberts et al. (1996) claim that a 0.185-M\(_\odot\) white dwarf burning \( \sim 2 \times 10^{-3} \) M\(_\odot\) of hydrogen can have the correct gravity and effective temperature at a cooling age commensurate with the pulsar’s characteristic age (although, as noted above, the characteristic age could increase further). Their solar metallicity model does not undergo shell flashes, and constitutes this decade’s installment in the conflict between the calculations of Webbink (1975) and Iben & Tutukov (1986)! An examination of fig. 1 and table 1 of Iben & Tutukov (1986) suggests that the > 50-yr timesteps used by Alberts et al. may still not be enough to resolve the shell flash behaviour reported by Iben & Tutukov. The shell flash results in the burning of much of the surface hydrogen, which leads to a decrease in the surface hydrogen mass at the source of the different cooling ages. Although Alberts et al. obtain \( \log g \sim 6.7 \) and \( T_{\text{eff}} = 8481 \) K, we find that our code (which we believe to contain more accurate input physics at the low temperatures appropriate to these studies) yields a lower \( \log g \sim 6.6 \) for the same parameters at this temperature, too low to be a consistent solution.

One other uncertainty with this measurement is the possible presence of helium in the white dwarf atmosphere. Bergeron et al. (1991) have shown that a small amount of helium in a hydrogen-dominated atmosphere can mimic the effect of a larger gravity, a result confirmed by Reid’s (1996) comparison of spectroscopic gravities and gravitational redshifts for cool white dwarfs. However, when combined with the temperature and luminosity

3 As yet unpublished results of Callanan & Koester (1998) imply a different gravity of \( \log g = 6.4 \pm 0.2 \). We will consider both values in our analysis.
constraints above, our models provide good agreement with pure hydrogen atmospheres. The admixture of trace amounts of helium would not affect the cooling significantly on these time-scales but would measurably raise the gravity. Hence we believe these to be hydrogen-dominated white dwarfs.

With the present uncertain status of the observations, our models yield the following results for the J1012+5307 system. The companion mass lies in the range 0.13–0.21 M☉, the neutron star mass is in the range 1.3–2.1 M☉, and the age is < 0.6 Gyr. Allowing for a braking index of n = 2–3, this results in the constraint P₀ > 5.06 ms. Given the above uncertainties about the gravity measurement, it is useful to calculate the constraints without using the gravity. If we use only the magnitude and temperature, then the white dwarf mass is constrained to lie in the range 0.12–0.32 M☉, and the age is < 0.8 Gyr. Thus, even ignoring the gravity information, we find that this pulsar is still much younger than the pulsar characteristic age.

### 3.3 PSR B0820+02

The pulsar in this system has the longest spin period (864.8 ms), largest magnetic field (10¹¹⁵ G) and shortest characteristic time (0.13 Gyr) (of course, these are not independent quantities!) of all the low-mass binary pulsars. The companion has been studied optically by Kulkarni (1986) and Koester, Channugam & Reimers (1992). We shall use the Koester et al. apparent magnitude V = 22.76 ± 0.05. van Kerkwijk & Kulkarni (1995) have also identified hydrogen Balmer lines in the companion spectrum, yielding an effective temperature consistent with the photometric temperature estimate of 15 250 ± 1250 K by Koester et al. The signal-to-noise ratio is not yet good enough to determine a spectroscopic gravity.

The dispersion measure distance to this pulsar is 1.4 ± 0.4 kpc. This yields an absolute V magnitude M_V ≈ 12.1 ± 0.7. This leads to a problem when we try to find consistent temperature–luminosity solutions for this pulsar. As shown in Fig. 6, the effective temperature and absolute magnitude give a consistent solution for C/O models with M > 0.8 M☉. However, these solutions require ages longer than the timing age (even for n = 2). If one requires that t < t_p, then one is forced to the conclusion that the true distance is larger than the dispersion measure distance. If we use the characteristic age as a constraint (an upper limit to the true age), then we can place some constraints on the acceptable models using only the temperature constraints and infer what the true distance would have to be for a consistent solution.

If we assume a helium core white dwarf (allowing for n = 3 and n = 2), then the mass is limited to the range 0.27–0.42 M☉, and the true distance has to be ~ 3.5–4.5 kpc! If we assume a carbon core white dwarf, the mass range is 0.5–1.0 M☉, with a true distance of ~ 2–2.8 kpc. This is probably the more palatable of the options, which would make this the fourth binary pulsar to contain a ‘normal’ white dwarf, and the first of those to have not undergone significant spiralling in during its evolution. We note that Koester et al. (1992) also infer a distance range of 1.7–3 kpc based on a similar analysis (although their final published solution is 1.7–1.9 kpc, based on the supposed allowed error in the dispersion measure).

If we choose to believe the distance limits, then we are faced with the problem that the white dwarf is older than the pulsar. One possible way of arranging such a situation is if the white dwarf is formed from the initially more massive star (e.g. ~8 M☉) which conservatively transfers most of its mass to its initially less massive companion (~4 M☉) thereby creating a system of white dwarf (~0.8 M☉) and massive companion (~11 M☉). The subsequent
lifetime of this companion is $\sim 2 \times 10^8$ yr (approximately the age difference we infer between white dwarf and pulsar), after which it forms a neutron star. The problem with this scenario is that it will be difficult for the system to remain bound and with small eccentricity (the post-supernova eccentricity is likely to be preserved in a system containing compact stars). Although a suitably directed kick velocity can account for this, the probability of obtaining the correct direction and magnitude ($\sim 30$ km s$^{-1}$) is rather small. Nevertheless, if true, this scenario implies a population of isolated pulsars with similar fields and spin-down times with a binary origin.

The determination of a spectroscopic gravity for this star should help to constrain the models, as the helium dwarfs should have $\log g \sim 7$ and the carbon dwarfs should have $\log g \sim 7.8$.

### 3.4 PSR J1713+0747

Lundgren, Foster & Camilo (1996b) have measured $V = 26.0 \pm 0.2$ and $I = 24.1 \pm 0.1$ for this companion. This yields a conservative temperature limit of $<3800$ K. Camilo, Foster & Wolszczan (1994a) obtained a timing parallax, yielding a distance of $1.2 \pm 0.4$ kpc. Given this pulsar distance, we use the temperature and the absolute magnitude $M_I = 13.8 \pm 0.7$. The characteristic age for this pulsar is $9.2 \pm 0.4$ Gyr, including the correction for proper motion from Camilo et al.

We can find acceptable solutions for all masses from 0.15 to 0.31 $M_\odot$ with a thick H envelope and for all masses below 0.27 $M_\odot$ for a thin H envelope. However, the mass function for this system restricts the companion mass to be $\geq 0.28 M_\odot$, so that many of these solutions are excluded. If we keep only those models with masses greater than 0.28 $M_\odot$, then the cooling age must lie in the range 6.3–6.8 Gyr. We use this result below, but note that, using the dispersion measure distance estimates (which allow smaller distances), we can obtain cooling ages up to 13.2 Gyr and encompassing the full range up to 0.45 $M_\odot$. If we assume an $n = 3$ braking index, we may constrain the initial period to lie in the range $2.18 < P_0 < 2.68$ ms (the lower limit goes to zero for the dispersion measure distances). To be conservative we also consider the effects of $n = 2$. This leads to a more conservative upper limit of 3.0 ms.

Inverting the normal procedure for the mass function, we can thus constrain the a neutron star mass to be less than 1.64 $M_\odot$ (assuming the parallax distance).

We can find no consistent C/O solutions for this object.

### 3.5 PSR J1640+2224

Lundgren et al. (1996b) have also detected the companion in this system, with $V = 26.0 \pm 0.3$ and $I = 24.6 \pm 0.2$, yielding $T_{\text{eff}} = 4460 \pm 1125$ K. The characteristic age for this system is at least 16.2 Gyr and the distance 1.2 kpc, so that (including distance errors) we have an absolute magnitude $M_I = 14.2 \pm 0.7$. Once again, the mass function of this system requires the companion to be more massive than 0.252 $M_\odot$.

We obtain consistent solutions for all masses 0.25–0.45 $M_\odot$. The range of cooling ages obtained is 3.2–12.2 Gyr, including both thick and thin hydrogen envelopes. The extremely low $P$ of this pulsar means that $t_P$ is both large and sensitive to $V_L$. Thus we can only obtain a lower limit on the initial period by taking the smallest characteristic age and largest cooling age, yielding $P_0 > 1.6$ ms.

In order to maintain small eccentricity, the pre-supernova orbital period has to be similar to the post-supernova period and thus the kick velocity is required to match the change in orbital velocity due to mass loss.

### 3.6 PSR J0034–0534

The uncorrected characteristic age is $4.4 \pm 0.4$ Gyr and the distance is $1.0 \pm 0.3$ kpc. The proper motion of this pulsar is not known. However, if the pulsar had a transverse velocity of 100 km s$^{-1}$, the characteristic age could be as much as 9.3 Gyr, so we adopt this as an upper limit to the characteristic age. Lundgren et al. (1996b) have detected this companion at $I = 24.8 \pm 0.3$ and set a limit of $V > 26.8$, which implies that the temperature is $< 3500$ K. This is sufficient to constrain the ages of cooling models of various masses (see Fig. 7) to lie within the range 4.4–14.9 Gyr. However, if we require that the cooling age be less than the characteristic age (using our upper limit of 9.3 Gyr), then the mass range is 0.15–0.32 $M_\odot$ (assuming $n = 3$). If we use $n = 2$, then all masses are allowed. Thus our conservative upper limit on the initial period is $P_0 < 1.4$ ms (using $n = 2$ and assuming a 100 km s$^{-1}$ transverse velocity). A measurement of the proper motion for this pulsar could improve the constraint on the initial period, although it will not prove to be a useful constraint on the nuclear equation of state unless the braking index can be constrained.

### 3.7 PSR J2145–0750

For the carbon/oxygen core white dwarfs, we use Wood’s models (Wood 1992), which have a more complete description of crystallization, to perform the same sort of analysis as above. For PSR J2145–0750, the characteristic age is $> 8.2$ Gyr and the dispersion measure distance is 0.5 kpc. The minimum mass is 0.43 $M_\odot$.

Optical observations by Lundgren et al. (1996b) give $V = 23.7 \pm 0.1$ and $I = 23.0 \pm 0.1$. The $V - I$ broad-band colours of Bergeron et al. (1995) yield a temperature estimate of $6235 \pm 970$ K.

The determination of ages and masses for the carbon sequences requires a little care, because the cores of $M > 1 M_\odot$ white dwarfs...
can begin to crystallize after $\sim 1$ Gyr. This means that the absolute magnitude curves for different masses can cross, making the determination of consistent solutions slightly more complicated. We show the $V$-band magnitudes for this case because the theoretical $M_V$ curves are more dispersed than the $M_I$ curves. Fig. 8 shows the analysis using the Wood curves for carbon cores, a helium mass fraction of $10^{-2}$ and a hydrogen mass fraction of $10^{-4}$. For models with pure helium envelopes, the age limits are similar. We find consistent models for all masses (in both C and O cases, the cores have begun to crystallize for the more massive cases), and a range of cooling ages 1.6–6.9 Gyr.

A transverse velocity of 100 km s$^{-1}$ would change the sign of $P$ for this pulsar, so the characteristic age of 8.2 Gyr is only a lower limit. Using the largest cooling age, we can thus get a lower limit on the initial period $P_0 > 6.4$ ms (assuming an $n = 3$ braking index).

### 3.8 PSR J1022+10

This pulsar has a spin period of 16.45 ms and spin-down age $>5.8$ Gyr. It lies at a distance of 0.6 kpc and has been observed by Lundgren et al. (1996b), yielding $V = 23.09 \pm 0.04$ and $I = 22.665 \pm 0.007$. The mass function for this pulsar requires a companion of mass $M > 0.72 M_\odot$, putting this firmly in the carbon/oxygen mass range. Our temperature estimate for this star is $8050 \pm 950$ K. Comparison of the observations with the Wood models yields an age range of 1.5–3.9 Gyr and a mass range $M > 0.7 M_\odot$. Thus we obtain $P_0 > 9.4$ ms.

### 3.9 PSR B0655+64

This was one of the first pulsars with an optically identified companion. Upper limits on the proper motion mean that we can constrain the characteristic age to the range 4.4–146(!) Gyr. The distance is 0.48 kpc. The mass function constrains the companion to have $M \geq 0.67 M_\odot$. van Kerkwijk & Kulkarni (1995) have identified the white dwarf companion as a DQ star, i.e. it shows traces of molecular carbon in the optical spectrum. This makes accurate temperature determination difficult but does constrain the temperature to be in the range 5500–8000 K, when the convection zone is deep enough to dredge up trace amounts of carbon from the core and deposit them in the atmosphere (Pelletier et al. 1986). Kulkarni (1986) has measured $V = 22.2$ for this star. Since molecular carbon is seen, the helium and hydrogen envelopes must be quite thin. We use the pure helium envelope/carbon core models ($q_{\text{hel}} = 10^{-4}$) of Wood (1992) to calculate the cooling ages in Fig. 9. We find solutions for all models $M \geq 0.7 M_\odot$. The range of cooling ages is 2.5–4.7 Gyr. The large range in characteristic age means that no useful limits can be obtained for $n = 3$. For $n = 2$, the smallest characteristic age and largest cooling age yield $P_0 > 94$ ms (since, in this case, the maximum cooling age is less than the minimum timing age).

### 3.10 PSR 2019+2425

This pulsar has one of the largest characteristic ages (corrected for proper motion) of any pulsar, ranging from 14.7 to 112 Gyr, depending on the rather uncertain distance. It lies close to the Galactic plane, which means that extinction is an important problem. Lundgren et al. (1996b) have detected the pulsar companion at $V = 26.4 \pm 0.4$ and $I = 25.0 \pm 0.3$. To estimate the extinction to the companion, we find the extinction in the general direction of J2019+2425 from Neckel & Klare (1980). For distances less than 1 kpc, $A_V$ rises linearly to 0.4 mag, but then rises steeply to $\sim 3$ mag at a distance of 1.5 kpc (i.e. 1.5 mag for $A_I$). Using this extinction law and the 30 per cent distance uncertainty, we find that $V - I = 1.0 \pm 0.4$, which implies $T_{\text{eff}} \sim 4000$–6500 K. Similarly, we estimate the absolute $I$-band magnitude as $M_I = 14.9 \pm 1.0$. A
Figure 10. J2019+2425: the solid lines are the models for a 0.35-M⊙ thick layer model. The heavy dashed line is for a 0.60-M⊙ carbon core model. The dotted line in the upper panel indicates the allowed range of V − I for each Mf (and hence each distance). The shaded region demonstrates the consistent solution for the 0.35-M⊙ model. The filled circle (with error bars) is the allowed range at the nominal dispersion measure distance. In the bottom panel the vertical and horizontal bars indicate the allowed range of cooling ages (for all models) and the expected range in Mf consistent with the dispersion measure uncertainty.

Figure 11. Limits for other pulsar companions. We compare the absolute V magnitudes of our models with the limits determined for two other binary pulsar systems. The vertical dotted lines indicate the characteristic ages for each binary system and the horizontal dotted lines are the magnitude limits determined from the observations. The models are for 0.15, 0.25, 0.35 and 0.45 M⊙ respectively. The heavy solid line indicates the 0.25-M⊙ model (for comparison with the B1855+09 limits).

3.11 PSRs B1855+09 and J0751+1807

For those systems where we have only upper limits on the companion magnitudes, it is sometimes still possible to place some constraints on the ages and masses of the stars involved.

For PSR 1855+09, the almost 90° inclination of this orbit has allowed Kaspi, Taylor & Ryba (1994) to determine the masses of both components as well as the parallax and distance. The companion mass is 0.258 ± 0.028 M⊙ and the distance is 0.9 ± 0.02 kpc. The characteristic age, corrected for kinematic effects, is 4.95 ± 0.05 × 10^7 yr. We can thus restrict our model comparisons to the 0.25-M⊙ model in this case. Kulkarni, Djorgovski & Klemola (1991) obtained limits of R > 24.6 and I > 23.4, while Callanan et al. (1989) obtained V > 25.4. Callanan et al. estimated the extinction to the system to be A_V = 1.5–2.0 mag kpc^{-1}. Using the extinction law of Savage & Mathis (1979), this becomes A_k = 1.1–1.5 and A_j = 0.7–1.0 mag kpc^{-1}. Fig. 11 shows the comparison of the model curves with each constraint. We use two constraints, using the largest extinctions and furthest distance estimate, and the smallest extinctions and closest distance estimates, to examine the range of possible solutions. We see that the 0.25-M⊙ sequence is perfectly consistent with the bounds on the absolute magnitude for all ages from the characteristic age of 4.95 Gyr to a minimum age of 1.4 Gyr. This yields a constraint P_0 > 4.5 ms.

Also shown in Fig. 11 are the detection limits for the companion to J0751+1807, with a characteristic age of 6.3–12.2 Gyr. The only meaningful limit that can be placed on this system is that the cooling time is longer than 0.8 Gyr. So this could still be a slightly older version of the J1012+5307 system. Given the small orbital period, we might expect a low companion mass (~0.15 M⊙), so that extending the detection limit to V ~ 26 would detect the companion if it were younger than 2 Gyr. Such a detection would be extremely interesting.

The various constraints on the cooling ages are collected together in Fig. 12.

4 DISCUSSION

4.1 Binary evolution

The formation of low-mass binary pulsars (LMBPs) has been
discussed by many authors (for reviews see Phinney & Kulkarni 1994, Verbunt 1993 and references therein). If we consider a binary containing a pulsar and a stellar companion, the binary will undergo mass transfer if the non-degenerate companion begins to expand as a result of nuclear evolution or if the orbit decreases due to magnetic braking or gravitational wave radiation. This mass transfer results in the spin-up of the neutron star to form a millisecond pulsar. The mass loss also means that the companion never evolves far enough to grow a core of mass large enough to ignite helium. Rather, the envelope is lost during the course of the evolution and the remnant of the secondary settles down to a degenerate configuration, a low-mass helium core white dwarf. The fact that giants have a well-defined relationship between core mass and giant radius, allied with the fact that the star must fill its Roche lobe to lose matter to the companion (assuming corotation), means that there exists a relationship between orbital period and secondary mass in the LMBPs (Refsdal & Weigart 1971; Rappaport et al. 1995; Joss, Rappaport & Lewis 1987). However, this holds only as long as the secondary star is sufficiently evolved to have a convective envelope when it overflows its Roche lobe. This is because mass loss from the secondary results in expansion of the orbit, shutting off mass loss unless the donor star increases as well (which requires a convective envelope, rather than a radiative one). Thus this scenario describes systems with orbital periods \( \sim 50-10^5 \) d.

For shorter period systems, the donor star overflows its Roche lobe either on the main sequence or during the transition from the main sequence to the giant branch. The envelope is still primarily radiative in this case, and the star will shrink in response to mass loss. The result is that one needs angular momentum loss mechanisms such as gravitational radiation and magnetic braking to maintain mass transfer in these systems. The competition between these loss mechanisms and the mass transfer induced evolution of the system leads to a very steep relationship between final orbital period and initial orbital period/final core mass (Plyser & Savonije 1988; Coté & Plyser 1989).

In Fig. 13 we compare our mass determinations for these companions with the results of Rappaport et al. (1993) and Plyser & Savonije (1988) (omitting models in the latter sample where the accretor was far from 1 M\(_\odot\)). We find excellent agreement with the models, especially that of Pylyser & Savonije, where the mass estimates of B1855+09, J0034–0534, J0437–4715 and J1012+5307 trace out the mass–period relation very nicely. Thus the two different scenarios provide a natural explanation for the orbital period gap between 20 and 50 d.

### 4.2 Neutron star spin-up

Under the assumption that the magnetic field does not decay, the cooling age of the white dwarf allows us to estimate the initial spin period of the millisecond pulsar, by inverting formula (1). These estimates are shown in Table 3. The simplest theories regarding spin-up of recycled pulsars to millisecond periods (Smarr & Blandford 1976; Ghosh 1995 and references therein) predict that the initial period should be equal to the equilibrium spin period of the neutron star of magnetic field \( B \).
accoring at a rate $\dot{M}$. This predicts an initial spin period

$$P_0 = 1.88 \text{ ms} \frac{\dot{M}}{\dot{M}_{\text{Edd}}} \frac{\mu}{10^{26} \text{ G cm}^3} \frac{I}{10^{37}} ,$$

(8)

where $\dot{M}_{\text{Edd}}$ is the Eddington accretion rate. Thus a comparison between the inferred initial spin period and magnetic field can determine the accretion rate on to the neutron star during spin-up. However, this inversion is complicated somewhat by the uncertainty in the macroscopic dimensions of the neutron star. Fig. 14 shows the spin-period–magnetic field diagram for the millisecond pulsars, scaled in such a way that it reflects observational parameters ($P$ and $I$) only. This is done by plotting

$$\frac{\mu^2}{I_{30}} = 1.026 \left( \frac{I}{10^{37}} \right) \left( \frac{P}{10^{-10}} \right) ,$$

(9)

where $\mu = R^2 \dot{B}$ is the magnetic moment (in this case expressed in terms of units of $10^{26} \text{ G cm}^3$) and $I$ is the moment of inertia of the pulsar. Thus we infer accretion rates $\sim 10^{-2} = 0.1 \dot{M}_{\text{Edd}}$ possibly even somewhat lower in some cases. A similar conclusion was reached by Lundgren et al. (1996b). This is consistent with the findings that low-mass X-ray binaries have a range of sub-Eddington accretion rates (Bradt & McClintock 1983).

### 4.3 Magnetic field decay

Although many authors have noted that millisecond pulsars must have very long magnetic field decay times (Kulkarni 1986; Camilo et al. 1994a), the determination of a cooling age allows us to make a quantitative estimate of $t_c$ in the context of the paradigm outlined in Section 2. To get the lower limits on $t_0$ using equation (7), we must use the lower limits on both the distance and the cooling age (and assume a value for $n$; we will use $n = 3$ below). For pulsar J1713+0747 we find a lower limit of 15.6 Gyr for $t_0$ (essentially because the cooling age is restricted to be quite close to the spin-down age), which is the largest value amongst all our sample. PSR J0034–0534 also yields a strong constraint (6.5 Gyr) although most of the other systems yield weaker constraints ($\sim 1$ Gyr in most cases). These results strongly support the view that millisecond pulsar fields do not decay at all. Fig. 15 shows the limits using equation (7) for the various binary systems.

### 4.4 Nuclear equation of state

In addition to constraining evolution scenarios, we note that our models offer the possibility of determining neutron star masses and hence constraining the nuclear equation of state. If we adopt the van Kerkwijk et al. gravity in Section 3.2, then the neutron star mass is $> 1.7 M_{\odot}$. This would rule out five of the softer equations of state listed in Cook et al. (1994). This is also interesting, because it raises the value of the minimum rotation period for a neutron star. Of the surviving models, the shortest minimum spin period is 0.47 ms. However, good gravity measurements and good radial velocities are required to make this a robust calculation.

If one assumes $n = 3$, the initial spin period of J0034–0534 can also provide a useful constraint on the harder equations of state. The three parallel dotted lines indicate the spin-up lines (8) for $M/M_{\text{Edd}} = 1$, 0.1 and 0.01 respectively, and canonical neutron star values of $M = 1.4 M_{\odot}$ and $R = 10 \text{ km}$. The heavy dashed lines indicate the Eddington rate spin-up lines for different equations of state taken from Cook et al. (1994), and spanning the range from hard (L) to soft (AU). The shaded region represents the case for maximal spin-up covered by the range of equations of state (i.e. they result from the spin-up of a maximum static mass model). Many of the pulsar magnetic fields are uncertain because of the Shklovskii effect on $P$. The derivation of the limits on $P_0$ is discussed in the text. The open circles describe systems with orbital periods $> 50 \text{ d}$ while the filled circles describe those with periods $< 50 \text{ d}$. The two starred systems are the spiral-in systems containing carbon core companions.

### Table 3. Cooling ages and initial spin periods.

| Name          | $P$  | $t_P$ | $t_{\text{cool}}$ | $P_{0}^a$ | $P_{0}^b$ | $t_D$ |
|---------------|------|-------|-------------------|-----------|-----------|-------|
|               | (ms) | (Gyr) | (Gyr)            | (ms)      | (ms)      | Gyr   |

*Based on $n = 3$.

*Based on $n = 2$.
state, but this conclusion is not robust, because a braking index \( n = 2 \) will yield an upper limit that lies above all minimum spin periods.

In conclusion, we have shown that using the white dwarf cooling ages as an independent chronometer for binary pulsars can teach us a lot about both neutron star structure and binary evolution. In particular, the determination of initial spin periods provides us with new information about the final stages of pulsar spin-up and evolution. However, we must reiterate that our results should be considered as preliminary until certain uncertainties can be conclusively addressed. In particular, except in the few cases where parallaxes are available, we are forced to use dispersion measure distances. The oft-claimed 30 per cent error is a statistical statement; individual cases may be more uncertain, as is suggested by the case of PSR B1820+02. Nevertheless, the good agreement by the case of PSR B1820+02 will undoubtedly lead to even better constraints in the future.

ACKNOWLEDGMENTS

The authors thank Marten van Kerwijk for use of results prior to publication and discussion of white dwarf observational uncertainties, and Glenn Soberman for discussions about mass transfer in binaries, as well as the referee, Frank Verbunt, whose comments contributed greatly to the clarity of this paper. This work was supported by NSF grant AST93-15455 and NASA grant NAG5-2756.
