To understand the origin of the dynamical transition, between high temperature exponential relaxation and low temperature nonexponential relaxation, that occurs well above the static transition in glassy systems, a frustrated spin model, with and without disorder, is considered. The model has two phase transitions, the lower being a standard spin glass transition (in presence of disorder) or fully frustrated Ising (in absence of disorder), and the higher being a Potts transition. Monte Carlo results clarify that in the model with (or without) disorder the precursor phenomena are related to the Griffiths (or Potts) transition. The Griffiths transition is a vanishing transition which occurs above the Potts transition and is present only when disorder is present, while the Potts transition which signals the effect due to frustration is always present. These results suggest that precursor phenomena in frustrated systems are due either to disorder and/or to frustration, giving a consistent interpretation also for the limiting cases of Ising spin glass and of Ising fully frustrated model, where also the Potts transition is vanishing. This interpretation could play a relevant role in glassy systems beyond the spin systems case.

PACS numbers: 75.50.Nr, 02.70.Lq, 05.70.Fh

Experiments on glassy systems like structural glasses, ionic conductors, supercooled liquids, polymers, colloids and spin glasses (SG) show that precursor phenomena occur at some temperature $T^*$ well above the static transition. In particular, the density-density or spin-spin autocorrelation function in glasses or spin glasses has a transition from a high temperature exponential behavior to a low temperature nonexponential behavior at $T^*$. Many attempts to relate these dynamical transitions to thermodynamic or, alternatively, percolation transitions are present in literature, each one supported by numerical simulations. In particular for SG models, where random distributed ferromagnetic and antiferromagnetic interactions give rise to frustration, Randeria et al. suggested that $T^*$ should be smaller than the Griffiths temperature $T_G$, i.e. the critical temperature of an Ising ferromagnet. Intuitively the reason is that the randomness of the model allows the presence of exponentially rare large unfrustrated regions that reach an ordered state at $T_c$, each one with a characteristic length and a characteristic relaxation time. The distribution of relaxation times below $T_c$ gives rise to a nonexponential global relaxing correlation for the system, therefore $T^* \leq T_c$. Numerically it is found that $T^*$ is close to $T_c$.

It has also been suggested that a mechanism which would lead to nonexponential relaxation in frustrated systems is associated to percolation of the Fortuin-Kasteleyn-Coniglio-Klein (FK-CK) clusters, which can be proved occur at a temperature $T_p \leq T_c$. Since it is argued that above the percolation transition the available phase space become rather ramified, enough to slow down the dynamics, this percolation mechanism implies that nonexponential relaxation should occur also in fully frustrated (FF) Ising systems where, due to absence of disorder, there is no Griffiths phase while the percolation temperature $T_p$ is finite. Recent simulations on two dimensional (2D) and 3D FF Ising model in fact show the existence of nonexponential relaxation below a temperature equal within the numerical precision to $T_p$.

One might wonder whether also in spin glasses $T^* = T_p$ or instead $T^* = T_c$, since both results would satisfy Randeria’s criterion. Unfortunately it is found that $T_p$ is less but close to $T_c$ and it is very difficult numerically to locate precisely $T^*$ to distinguish between $T_p$ and $T_c$.

![FIG. 1. Qualitatively phase diagram for the PSG model in 3D as function of s. Solid lines mark real thermodynamic phase transitions, while dotted line marks the vanishing Griffiths transition. Cross marks Potts vanishing transition in the s = 1 (±J Ising SG) case. An analogous phase diagram holds for the PFF model with a FF Ising phase at the place of the SG phase [17,18] and without the G phase.](image)

In order to better understand the role of the percolation transition and the location of $T^*$ in the spin glass model in this Letter we consider a frustrated model in presence of disorder, where $T_c$ is quite larger than $T_p$, so that can be easily distinguished. The numerical results allow to conclude that $T^* \sim T_c$. Moreover, in absence of disorder, i.e. in the FF case (without $T_p$), the relevant role of $T_p$ in the dynamical transition is confirmed, giving a scenario consistent with all the previous results. In
particular, the model considered here clarifies the physical meaning of \( T_p \), relating it to a Potts transition that vanishes in the SG case and in the FF Ising case. Therefore in the SG case there are two vanishing transitions (the Griffiths at \( T_c \) and the Potts transition at \( T_p \)) in the paramagnetic phase which give rise to nonexponential relaxation. However since \( T_c > T_p \) the first transition dominates hiding the effects of the lower transition at \( T_p \). In the FF Ising model instead there is only the vanishing transition at \( T_p \) which now can be manifested, marking the onset of nonexponential relaxation.

Let us consider the following frustrated model with 2\( s \) states spin variables whose Hamiltonian is given by:

\[
H = -sJ \sum_{\langle i,j \rangle} [\delta_{\sigma_i \sigma_j} (\epsilon_{i,j} S_i S_j + 1) - 2]
\]  

where to each lattice site is associated an Ising spin \( S_i = \pm 1 \) and a \( s \)-states Potts \( \sigma_i \) spin \( \sigma_i = 1, \ldots, s \). The sum is extended over all nearest neighbor sites, \( J > 0 \) is the strength of interaction and \( \epsilon_{i,j} = \pm 1 \) is a quenched variable (the sign of the interaction).

When the \( \epsilon_{i,j} \) are randomly distributed the model is a superposition of a ferromagnetic \( s \)-states Potts model and a \( \pm J \) Ising SG and we will refer to it as the Potts spin glass (PSG) when the \( \epsilon_{i,j} \) configuration is ordered in such a way that every elementary cell of the lattice has an odd number of -1 signs (i.e. is frustrated) the Potts model is superimposed to a FF Ising model, and we will refer to it as the Potts FF (PFF) model. For \( \delta_{\sigma_i \sigma_j} = 1 \) (i.e. \( s = 1 \)) we recover, respectively, the \( \pm J \) Ising SG and the FF Ising model.

Both the PSG and the PFF models exhibit [15] [18], for every \( s > 1 \) a thermodynamic transition at \( T_p(s) \) in the same universality class of the ferromagnetic \( s \)-state Potts transition (see Fig.1). This transition corresponds to the percolation transition of FK-CK clusters. For example, for \( s = 2 \) at \( T_p \) there is a second order phase transition in the universality class of the Ising transition [16]. Therefore \( T_p \) for \( s > 1 \) marks the Potts thermodynamic transition, that disappears for \( s = 1 \) [19]. Both the models exhibit also a lower transition in the same universality class of the SG transition and of the FF Ising model, respectively for the PSG [13] and the PFF model [17]. The PSG model has also a higher Griffiths temperature at \( T_c(s) \) which is the transition of the model without disorder, namely with all \( \epsilon_{i,j} = 1 \). It is easy to recognize that in this case the model corresponds to the ferromagnetic 2s-Potts model therefore the Griffiths temperature \( T_c(s) \) corresponds to the ferromagnetic 2s-Potts model [24].

For \( s = 1 \), that is the \( \pm J \) Ising SG, Oginski [1] showed that nonexponential relaxations appear below \( T_c \), separating the paramagnetic (PM) phase in a high temperature PM phase and a low temperature Griffiths (G in Fig.1) PM phase. An analogous phase diagram holds for the 2D case, with the SG phase suppressed to \( T = 0 \).

Here we will analyze the dynamical behavior of the 2s-state PSG and PFF models, with \( s = 2 \) in 2D, simulated by standard Monte Carlo (MC) spin-flip dynamics.

**PSG model** We have studied the normalized autocorrelation function

\[
f(t) = \frac{\chi_{SG}(t) - \chi_{SG}(t \to \infty)}{\chi_{SG}(0) - \chi_{SG}(t \to \infty)}
\]

of the time dependent nonlinear susceptibility

\[
\chi_{SG}(t) = \frac{1}{N} \left\langle \left( \sum_{i=1}^{N} S_i(t + t_0) S_i(t_0) \right)^2 \right\rangle
\]

where \( N \) is the total number of spins, \( t_0 \) the equilibration time, \( \chi_{SG}(0) = N \) and where the bar stands for the average over the disorder and the angular brackets for the thermal average. Following Ref. [3] the infinite size behavior of \( f(t) \) has been extrapolated at every \( t \) plotting the data for finite linear sizes \( L \) vs \( 1/L \). To test the form of \( f(t) \) we fitted the data \( a) \) with a simple exponential, finding good fits only asymptotically for long time and for high temperatures, \( b) \) with a stretched exponential \( f_0 \cdot \exp([t/\tau]^{\beta}) \), finding that it fails to fit the data only for short times, and \( c) \) with the form \( f_0 \cdot t^{-\sigma} \exp([t/\tau]^{\beta}) \) suggested by Oginski [1], finding that it fits very well the data over all the time’s range and the temperature’s range (see Fig.2.A) [22]. The parameters \( \beta, \tau \) and \( x \) used in the fit \( a) \) and \( c) \) are plotted in Fig.2.B. In both types of fit the correlation functions turn to be nonexponential for \( T \leq T_c \). The results shows that \( T^* \approx T_c \). Since here the difference \( T_c - T_p \) is quite large [22] it is possible to exclude \( T^* \leq T_p \) [24].

**PFF model** We have studied the autocorrelation function defined by Eqs. [2] [3] without the average over the disorder, since there is no disorder in the model in this case. The data, shown in Fig.3.A, are fitted with the above mentioned fitting forms \( a) \), \( b) \) and \( c) \). The fit parameters and the integral autocorrelation time [21] are presented in Fig.3.B and show that the onset of nonexponential behavior is \( T^* \approx T_p \) within the numerical precision [24].

This dynamical behavior is still present in the \( s = 1 \) case [13], where the Potts variables are not present anymore and the thermodynamic transition at \( T_p \) disappears. If there was no frustration the spin variables would become critical at \( T_p \), like the Potts variables, giving rise in the free energy to two minima separated by an infinite barrier. However due to frustration in the spin variables the two minima in the free energy will evolve into a corrugated landscape. It is this corrugated landscape which gives rise to the nonexponential behavior in the dynamics.

In the disordered case one expects that the free energy starts to appear corrugated in phase space at the Griffiths temperature \( T_c \) due to the effect of the disorder. As the
temperature is lowered at $T_p$ the frustration induces more roughness in the free energy landscape, however its effect will be hard to be detected experimentally or numerically, being masked by the effect of the disorder.

In conclusion, we have compared the dynamical behavior of 2s-states PSG and PFF models, with $s = 2$. These models has two thermodynamic transitions, the lower temperature transition being a SG (or FF Ising) transition and the higher at $T_p$ being an Ising transition. In the disordered (PSG) model nonexponential relaxations start to appear at $T^* \approx T_c$, i.e. at the the Griffiths temperature, excluding the controversial possibility $T^* \approx T_p$ [5,6], thus extending to $s=2$ the previous results for $s=1$ [7,8]. In the PFF model, where there is no disorder and the Griffiths phase is not present, the effect of frustration which occur at $T_p$ can be manifested. In fact, we find nonexponential relaxation starting at $T_p$ for both $s = 2$ and $s = 1$ [13], where a real and, respectively, a vanishing transition occur.

This scenario gives a consistent interpretation of all the existing results about frustrated spin systems in literature, and could be relevant in general to understand the high temperature behavior of glassy systems. In particular, we suggest that the relation of the precursor phenomena with the Griffiths phase and the Potts vanishing transition should be experimentally studied in regular crystals, like cuprates, with doping induced disorder, where both the SG case and the FF case can be reproduced.

We would like to thank the referees for very important comments; the CINECA (Bologna - Italy) for the CPU time on the Cray T3D parallel computer used to do part of the numerical work. Partial support was given by the European TMR Network-Fractals c.n.FMRXCT980183.

[18] G. Franzese, unpublished.
[19] For non integer $s$ the Hamiltonian in Eq.(1) is not defined, but its partition function, written in a percolation approach [A. Coniglio, F. di Liberto, G. Monroy, and F. Peruggi, Phys. Rev. B 44, 12605 (1991)], is well defined for every values of $s$. In this sense one can consider $s$ as a continuous variable and the $s = 1$ case as the limiting case for the $s > 1$ cases [14].
[20] Data are averaged over a number of random interaction configurations $n \in [8, 96]$. For each temperature and each interaction configuration, after $10^5$ MC steps (defined as the update of the whole system) of equilibration, we have recorded the data for a number of MC steps that goes from $m = 3 \cdot 10^5$ for $L = 20$ to $m = 12 \cdot 10^5$ for $L = 40$, always with $n \cdot m \in [2 \cdot 10^5, 6 \cdot 10^5]$, using an annealing procedure, i.e. with a slow cooling of the system at each temperature. To verify that the statistics is sufficient for the considered temperatures we compared the data obtained starting from a random configuration with those obtained from the annealing method, observing the same results.
[21] The integral correlation time is defined as $\tau_{int} = \lim_{t_{max} \to \infty} \left[ \frac{1}{2} + \sum_{t=0}^{t_{max}} f(t) \right]$.
[22] In the case c) it is possible to do fits with only two free parameters, fitting linearly the short time behavior (described by $f_0$ and $x$) and separately the long time behavior (described by $\beta$ and $\tau$) with $f_0$ and $x$ fixed.
[23] In 2D is $T_p/(2s a) = 1/\ln(1 + \sqrt{2s a})$ with $a = 0.0803 \pm 0.003$ [16] while is $T_c/(2s) = 1/\ln(1 + \sqrt{2s})$ [16], therefore $T_c - T_p$ increases with $s$.
[24] Same qualitatively results are seen for $\beta$ and $x$ fit parameters associated to autocorrelation functions of energy or Potts magnetization, while for these critical quantities $\tau$ exponent diverges near the transition temperature $T_p$.
