ABSTRACT: In recent years extensive studies on the Earth’s climate system have been carried out by means of advanced complex network statistics. The great majority of these studies, however, have been focusing on investigating correlation structures within single climatic fields directly on or parallel to the Earth’s surface. Here, we develop a novel approach of node weighted coupled network measures to study correlations between ocean and atmosphere in the Northern Hemisphere extratropics and construct 18 coupled climate networks, each consisting of two subnetworks. In all cases, one subnetwork represents monthly sea-surface temperature (SST) anomalies, while the other is based on the monthly geopotential height (HGT) of isobaric surfaces at different pressure levels covering the troposphere as well as the lower stratosphere. The weighted cross-degree density proves to be consistent with the leading coupled pattern obtained from maximum covariance analysis. Network measures of higher order allow for a further analysis of the correlation structure between the two fields and consistently indicate that in the Northern Hemisphere extratropics the ocean is correlated with the atmosphere in a hierarchical fashion such that large areas of the ocean surface correlate with multiple statistically dissimilar regions in the atmosphere. Ultimately we show that this observed hierarchy is linked to large-scale atmospheric variability patterns, such as the Pacific North American pattern, forcing the ocean on monthly time scales.

1. Introduction

In the last years, complex network analysis has been established as a powerful tool to study statistical interdependencies in the climate system (Donges et al., 2009a; Donges et al., 2015a; Tsonis and Roebber, 2004; Tsonis et al., 2006; Tsonis et al., 2008). Links in the so-called climate networks represent functional interdependencies indicated by significant correlations (Donges et al., 2009a, 2009b; Palùs et al., 2011; Radebach et al., 2013) or the synchronous occurrence of extreme events (Malik et al., 2010; Malik et al., 2011; Boers et al., 2013; Boers et al., 2015; Stolbova et al., 2014) in climatic time series taken at different grid points or measurement sites on or parallel to the Earth’s surface.

In addition to studies on observational data of climate dynamics, climate networks have also been applied successfully to hindcast extreme events, such as extreme precipitation in South America (Boers et al., 2014), or to predict the occurrence of El Niño episodes (Ludescher et al., 2013; Ludescher et al., 2014) and discriminate between different event types (Tsonis and Swanson, 2008; Yamasaki et al., 2008; Radebach et al., 2013; Wiedermann et al., 2016).

So far, most studies conducted within the framework of climate networks focused solely on the dynamics within a single climatic field or layer. Besides atmospheric characteristics like surface air temperature, sea level pressure, or precipitation, recent studies have also addressed ocean dynamics represented by ocean temperature variability at the surface (Feng and Dijkstra, 2014; Tantet and Dijkstra, 2014) or different depths (van der Mheen et al., 2013) as well as the spatio-temporal variability in the strength of the Atlantic meridional overturning circulation (Feng et al., 2014).

It is well known, however, that the dynamics within the two major subcomponents of the Earth’s climate system, ocean and atmosphere, are closely entangled (Trenberth and Hurrell, 1994; Frankignoul et al., 2001). Examples for these interrelationships include the North Atlantic...
eddy-driven jet stream (Woollings et al., 2010) or the Pacific ocean forcing to the atmosphere which is closely related to the dynamics of the El Niño Southern Oscillation (Wyrtek, 1975). Further, it has been shown that on time scales of up to one month the ocean is forced by atmospheric circulation, prominently manifested in terms of long-term variability patterns like the Pacific North American pattern (e.g. Frankignoul and Sennchael, 2007) and the North Atlantic Oscillation (Czaja and Frankignoul, 1999; Gastineau and Frankignoul, 2015).

Inspired by approaches to investigate the interaction structure between different mutually coupled subsystems such as infrastructure networks (Bulyrev et al., 2010; Vespignani, 2010; Boccaletti et al., 2014) a novel set of coupled network measures has been proposed by Donges et al., (2011) which provides a general tool to quantify interdependencies between subcomponents in complex coupled climate networks. The latter framework has been successfully applied to investigate interactions between different layers of geopotential height fields (HGT), where each isobaric surface forms a subcomponent of a larger climate network. Similarly, coupled climate networks have been constructed to study ocean–atmosphere interactions in the tropical Pacific (Feng et al., 2012) or over the South Atlantic Convergence Zone (Tirabassi et al., 2015).

Following upon these previous studies, in this work we extend the approach by Donges et al., (2011) and present an exploratory study to understand and quantify ocean–atmosphere interactions in the Northern Hemisphere mid-to-high latitudes during boreal winter at monthly scales. This temporal restriction is chosen, since previous studies by means of lagged maximum covariance analysis (MCA) have already revealed that the statistical interrelationship between atmosphere and ocean is strongest and most significant at lags of zero or one month during late fall and winter (e.g. Czaja and Frankignoul, 1999; Wen et al., 2005; Liu et al., 2006; Frankignoul and Sennchael, 2007; Gastineau and Frankignoul, 2015).

To investigate further the spatial structure of these complex interaction patterns, we construct here in total 18 coupled climate networks consisting of two layers each, one layer representing sea surface temperature (SST) anomalies and the other geopotential height fields (HGT) at different pressure levels from 1000 to 10 mbar covering the entire troposphere as well as the lower stratosphere.

Our area of study covers the whole Northern Hemisphere north of 30°N so that the density of grid points in the considered data sets increases rapidly towards the poles and induces some bias in the unweighted network measures (Tsonis et al., 2006; Radebach et al., 2013). Therefore, the standard coupled network approach by Donges et al., (2011) is not sufficient in the present case. To overcome the problem associated with the heterogeneous spatial density of grid points interpreted as nodes of the climate network, Heitzig et al., (2012) introduced a novel set of network measures that takes into account the different sizes or weights of nodes in the network. By following an axiomatic approach, each standard (unweighted) network measure can be transformed into its weighted counterpart, the so-called node splitting invariant (n.s.i.) network measure. Corresponding n.s.i. measures have also been derived by Zemp et al., (2014) for edge-weighted and directed networks.

To quantify the topology of coupled climate networks, we rely in this work on the previously defined versions of local (i.e. node-wise) n.s.i. coupled network measures (Feng et al., 2012; Wiedermann et al., 2013) and additionally derive further weighted global network measures following the approach introduced by Heitzig et al., (2012). This allows us to assess and compare the macroscopic correlation structure in each of the 18 coupled climate networks.

We compare the results of MCA (e.g. von Storch and Zwiers, 2001), a well-established standard tool from statistical climatology, with the cross-degree density of nodes in the different subnetworks and confirm expected similarities between the two measures (Donges et al., 2015a). By utilizing network measures of higher order such as the n.s.i. local cross-clustering coefficient, we find that the statistical interrelation between ocean and atmosphere exhibits a hierarchical structure, in which individual parts or areas of the ocean surface correlate strongly with multiple statistically dissimilar parts of the atmosphere. Building upon previous studies by, e.g. Czaja and Frankignoul, 1999; Frankignoul and Sennchael, 2007, and Gastineau and Frankignoul, 2015 we relate the observed hierarchy to dominant atmospheric patterns forcing the ocean on the time scales investigated in this study.

The remainder of this paper is organized as follows. Section 2 introduces the data sets and all methods, i.e. MCA and coupled climate network analysis, that are applied in this study. Section 3 presents all results of the analysis followed by conclusions and an outlook discussing future research tasks in Section 4.

2. Data and methods

2.1. Data description

We construct coupled climate networks from two different climatic observables in order to investigate their interaction structure. One subnetwork is based on monthly anomalies of HGT fields obtained from the ERA40 reanalysis project of the European Centre for Medium-Range Weather Forecast (Uppala et al., 2005). The data is given on a regular latitude/longitude grid with a spatial resolution of \( \Delta \lambda = \Delta \phi = 2.5^\circ \). In total, we investigate 18 layers of HGT fields. The corresponding pressure values at each isobaric surface as well as the average HGT are given in Table 1. The second subnetwork is constructed from the monthly averaged SST field (HadISST1) provided by the Met Office Hadley Centre (Rayner et al., 2003) with a resolution of \( \Delta \lambda = \Delta \phi = 1^\circ \). All grid points with corresponding time series containing missing values are removed from the data set as they represent areas which have been at least temporarily covered by sea-ice.

For our analysis we investigate all grid points north of \( \lambda = 30^\circ \)N excluding the North Pole itself. Both data sets

Int. J. Climatol. 37: 3821–3836 (2017)
are cropped in their temporal extent to cover the same time span from January 1958 to December 2001 and, hence, each time series consists of $T = 528$ temporal sampling points. We obtain a total number of $N_i = 6201$ grid points for the SST data and $N_j = 3456$ grid points for each isobaric surface $i$ of HGT. For both data sets, we remove the annual cycle by subtracting the climatic mean for each month from each time series. Since we focus on the spatial structure of strong statistical interrelationships between ocean and atmosphere during boreal winter months (DJF), we use only the corresponding values which yields a length of each time series of $\tau = 132$ data points.

2.2. Maximum covariance analysis

Consider two sets of time series \( \{X_{i_n}(t)\}_{n=1}^{N_i} \) and \( \{X_{j_m}(t)\}_{m=1}^{N_j} \) representing two different climatic fields, which in the scope of our application are the SST field (in what follows indicated by the index $i$) and one layer $i$ of HGT (see also Table 1). Further assume each individual time series in both fields to be normalized to zero mean and unit variance. The linear lag-zero cross-correlation matrix $C_{sl}$ with entries $C_{s_{i_n}l_{j_m}}$ is then defined as

$$ C_{s_{i_n}l_{j_m}} = \frac{1}{\tau} \sum_{t=1}^{\tau} X_{i_n}(t) X_{j_m}(t) $$

where $n = 1, \ldots, N_i$, $m = 1, \ldots, N_j$, and $\tau$ denotes the total number of temporal sampling points in the two time series. Owing to the heterogeneous spatial distribution of grid points in the present data sets all matrix entries $C_{s_{i_n}l_{j_m}}$ are additionally multiplied by the square roots of the cosine of latitudinal positions $\lambda_i$ to ensure equal weighting. This then yields the weighted cross-correlation matrix $C_{sl}^{w}$ with entries

$$ C_{s_{i_n}l_{j_m}}^{w} = \sqrt{\cos \lambda_i \cos \lambda_m} C_{s_{i_n}l_{j_m}} $$

Analogously to empirical orthogonal function (EOF) analysis (e.g. Ghil et al., 2002; Hannachi et al., 2007), MCA identifies orthonormal pairs of coupled patterns \( p_{s_{im}}^{(m)} = (p_{s_{i1}}^{(m)}, \ldots, p_{s_{in}}^{(m)}) \) and \( p_{l_{jm}}^{(m)} = (p_{l_{j1}}^{(m)}, \ldots, p_{l_{jn}}^{(m)}) \) for $m = 1, \ldots, R$ (with $R$ being the rank of $C_{sl}$) which explain as much as possible of the covariance between pairs of time series taken from the two different climatic fields (e.g. Bretherton et al., 1992; von Storch and Zwiers, 2001). The coupled patterns are obtained by solving the singular value problem of the weighted cross-covariance matrix,

$$ C_{sl}^{w} \overline{p}_{s_{im}}^{(m)} = \sigma_m \overline{p}_{s_{im}}^{(m)} $$

$$ (C_{sl}^{w})^T \overline{p}_{l_{jm}}^{(m)} = \sigma_m \overline{p}_{l_{jm}}^{(m)} $$

They are ordered according to their respective singular values $\sigma_m$ with $\sigma_1 \geq \sigma_2 \geq \ldots \geq \sigma_R$. Hence, $\sigma_1$ denotes the largest among the $R$ singular values that can be found to solve the above equations. Therefore, $\overline{p}_{s_{im}}^{(1)}$ and $\overline{p}_{l_{jm}}^{(1)}$ are referred to as the leading coupled patterns representing the largest fraction of squared covariance between the two climatic fields given by $\sigma_1^2$.

2.3. Coupled climate network construction

In climate networks, each node represents a climatic time series and links indicate strong correlations between two series. Hence, the $N \times N$ ($N = N_i + N_j$) correlation matrix contains the pairwise linear statistical relationships between all time series considered for the network construction. Here, we independently construct coupled climate networks for all combinations of the SST field and each of the 18 isobaric surfaces of HGT and rely on the linear Pearson correlation coefficient as an appropriate measure of statistical association. Hence, the correlation matrix has the form

$$ C = \begin{pmatrix} C_{ss} & C_{si} \\ C_{is} & C_{ii} \end{pmatrix} $$

The two block matrices $C_{ss}$ ($N_i \times N_i$) and $C_{ii}$ ($N_j \times N_j$) represent the (internal) correlation matrices of the SST and HGT fields, respectively, which consist of elements

$$ C_{s_{i_n}s_{i_n}} = \frac{1}{\tau} \sum_{t=1}^{\tau} X_{i_n}(t) X_{i_n}(t), \quad n, m = 1, \ldots, N_i \quad (6) $$

$$ C_{j_mj_m} = \frac{1}{\tau} \sum_{t=1}^{\tau} X_{j_m}(t) X_{j_m}(t), \quad n, m = 1, \ldots, N_j \quad (7) $$

The elements of $C_{ij} = C_{ij}^T$ are derived according to Equation (1). Note, that (in contrast to the computation of the leading coupled patterns) we construct the coupled climate networks from the unweighted correlation matrix $C$, while the correction for the heterogeneous spatial distribution of nodes is implemented into the corresponding network measures (see Section 2.4).

From the correlation matrix $C$ one generally derives the network’s adjacency matrix $A^*$ by setting a fixed threshold $T$ such that only a certain fraction (i.e. the link density $\rho$) of
strongest correlations is represented by links in the resulting climate network. For obtaining the adjacency matrix $A^+$ of coupled climate networks, we refine this procedure by fixing a desired link density $\rho_s = \rho_i = 0.01$ for the structure of internal links within the two subnetworks representing SST and HGT fields, respectively. This means that only nodes with a correlation above the empirical 99th percentile of correlations between all time series within each field are connected. This condition then leads to internal correlation thresholds $T_s = 0.8101$ for the SST field and $T_i$ for each isobaric surface of HGT (Table 1). Usually, the dynamics within the different climatic fields shows much higher cross-correlations than between them. We account for this fact by assuming the fraction of significant interactions between the climatic fields to be lower than those within them. Specifically, we request a cross-link density of $\rho_{si} = 0.005 < \rho_s = \rho_i$, which is lower than the internal ones, and derive a cross-threshold $T_{si}$ for each layer of HGT individually (Figure 1). All internal thresholds $T_s$ and $T_i$ are significantly larger than the obtained cross-thresholds $T_{si}$. Thus, setting a global link density or threshold would cause no or few cross-links to be present between the two fields or respective subnetworks. We further note that all links in each of the coupled climate networks represent correlations that are significant at least at the 95% confidence level of a standard t-test, where the degrees of freedom are determined by the total number of temporal sampling points $\tau$ in each of the time series (with $\tau = 132$ we thus obtain 130 degrees of freedom when neglecting the presence of serial correlations in the individual time series).

The different values of $T_{si}$ already give an impression of the strength of correlation between the SST field and the different isobaric layers: low thresholds generally indicate weaker correlations while high thresholds imply stronger similarity between both fields. Further we note that the resulting cross-thresholds vary smoothly with the choice of cross-link density (Figure 1) and we thus consider the construction mechanism to be sufficiently insensitive to the actual choice of cross-link density.

Using the different thresholds introduced above, we obtain the coupled climate network’s adjacency matrix by individually thresholding the absolute correlation values between and within both fields as

$$A^+ = \Theta \left( |C_{si}| - T_s \right) \Theta \left( |C_{si}| - T_i \right)$$

where $\Theta(\cdot)$ denotes the Heaviside function. Note that in most recent studies on climate networks self-loops (resulting in a non-vanishing trace of the adjacency matrix) have been excluded. In this case the adjacency matrix is usually denoted as $A$. Since we aim to apply node splitting invariant network measures (see below) to quantify the network’s topology we specifically demand each node to be connected with itself. The resulting matrix $A^+$ is referred to as the extended adjacency matrix (Heitzig et al., 2012). Further note, that the usage of the term coupled in coupled climate networks does not imply the notion of any directionality or causal influence between the two fields under study. It is simply meant to indicate the fact that the network under study is composed of more than a single climatic field.

2.4. Coupled network characteristics

The local (point-wise) and global structure of a climate network can be quantified by a variety of network measures (Albert and Barabási, 2002; Newman, 2003; Donges et al., 2009a), which can generally be interpreted as specific operations on the adjacency matrix. The climate networks in this study are constructed from climate data sets where the density of grid points and, hence, the density of nodes in the network, rapidly increases towards the North pole. In order to avoid a bias in the evaluation of the climate network’s structure, we account for this effect by relying on node-weighted network measures and value nodes with a gradually decreasing weight as one moves from the equator towards the pole. To quantify the correlation structure between ocean and atmosphere at each node we focus on two previously defined node weighted local network measures (the n.s.i cross-degree (Feng et al., 2012) and the n.s.i. local cross-clustering coefficient (Wiedermann et al., 2013). In addition, we utilize the construction mechanism introduced by Heitzig et al., (2012) to convert global interacting network measures (Donges et al., 2011) into their weighted counterparts.

2.4.1. Preliminaries

Consider a coupled climate network $G = (V, E)$ with a set of nodes $V$, links $E$ and the number of nodes $N = |V|$. Following the general naming convention in the climate network framework we identify every node $v \in V$ with a natural number $p = 1, \ldots, N$, such that $p$ serves as the label of the node as well as an index to corresponding entries in the network’s adjacency matrix. The network $G$ is represented by its adjacency matrix $A$ with $A_{pq} = 1$ if $(p, q) \in E$, $A_{pq} = 0$ if $(p, q) \not\in E$. In this study, each coupled climate network is composed of two subnetworks,
\( G_s = (V_s, E_{ss}) \) representing the ocean and \( G_t = (V_t, E_{tt}) \) representing a specific atmospheric layer. The set of nodes \( V \) divides into subsets \( V_s \) and \( V_t \) such that each node belongs to exactly one subnetwork (i.e. \( V = V_s \cup V_t \) and \( V_s \cap V_t = \emptyset \)). Likewise, the set of links \( E \) splits into internal link sets \( E_{ss} \) and \( E_{tt} \) (connecting nodes within a subnetwork) and cross-link sets \( E_{st} \) connecting nodes \( v \in V_s \) with nodes \( q \in V_t \) in the subnetworks \( G_s \) and \( G_t \), respectively (Donges et al., 2011).

In the present case (as for all regularly gridded climate data sets) the share on the entire area of the surface that is represented by each node is governed by its latitudinal position \( \lambda_v \) on the grid. Following Tsonis et al., (2006), we therefore assign to each node \( v \) in the climate network a weight

\[
w_v = \cos \lambda_v. \tag{9}\]

Note that, by following this convention the climate networks’ node weights \( w_v \) exhibit the same dimension as the weights of the cross-covariance matrix in Equation (2).

Heitzig et al., (2012) introduced a novel set of node splitting invariant (n.s.i.) network measures to quantify the topology of a climate network with such a heterogeneous spatial node density for the case of a single-layer network and, hence, only one climate variable under study. In fact, the n.s.i. network measures are not restricted to climate networks but can be utilized to study any type of single-layer complex network where nodes represent entities of different weights. Heitzig et al., (2012) further showed that each complex network measure can be transformed into its weighted counterpart by using a four-step construction mechanism:

(a) Sum up weights \( w_v \) whenever the unweighted measure counts nodes.

(b) Treat every node \( v \in V \) as connected with itself.

(c) Allow equality in summations over indices \( v \) and \( q \) wherever the original measure involves a sum over distinct nodes \( v \) and \( q \).

(d) ‘Plug in’ n.s.i. versions of measures wherever they are used in the definition of other measures.

From the definition of the adjacency matrix \( A^+ \) in Equation (8) we note that step (b) of the above scheme is in our case already fulfilled. Wiedermann et al., (2013) and Zemp et al., (2014) recently utilized the proposed scheme to convert local interacting network measures as well as measures for directed networks into their weighted counterparts. Here, we additionally derive n.s.i. versions of some global cross-network measures that were introduced by Donges et al., (2011).

2.4.2. Local measures

For quantifying local cross-network interactions in coupled climate networks we rely on two measures, n.s.i. cross-degree \( k^+_v \) and n.s.i. local cross-clustering coefficient \( C^+_v \), that were introduced by Wiedermann et al., (2013) and (for the case of the n.s.i. cross-degree) by Feng et al., (2012). These two measures are defined as

\[
k^+_v = \sum_{q \in V_t} w_q A^+_{vq} \tag{10}\]

\[
C^+_v = \frac{1}{(k^+_v)^2} \sum_{p,q \in V_t} A^+_{vp} A^+_{qp} A^+_{pq} w_q w_p \in [0,1] \tag{11}\]

In contrast to the unweighted cross-degree

\[
k^+_v = \sum_{q \in V_t} A^+_{vq} \tag{12}\]

which simply counts nodes \( q \in V_t \) that are connected with \( v \in V \), \( k^+_v \) is proportional to the share on the considered overall ice-free ocean or isobaric surface area, respectively, that is connected with nodes \( v \in V_t \) in the other subnetwork. It therefore gives a notion of how similar the dynamics at a node \( v \in V_t \) is to that of the other climate variable observed at all available grid points.

Analogous to \( k^+_v \), \( C^+_v \) no longer relies on the counting of distinct fully connected node triples in the network (as for the classical local clustering coefficient (Newman, 2003)) but on the weighted sum of occurrences of triples of connected areas within the two subnetworks. It gives the probability that an area represented by a node \( v \in V_t \) is connected with two mutually connected and, hence, dynamically similar, areas in the opposite subnetwork. In this spirit, \( C^+_v \) estimates how likely areas in two different climatic fields or subsystems form clusters of statistical equivalence between them. A local accumulation of such connected triples represents clusters of closely connected nodes and, in the spirit of climate networks, strongly correlated regions.

In order to make the n.s.i. cross-degree \( k^+_v \) comparable between the two subnetworks, we normalize it by the maximum possible weight that nodes \( v \in V_t \) can be connected with,

\[
\kappa^+_v = \frac{\sum_{q \in V_t} \sum_{q \in V_t} w_q A^+_{vq}}{W_j} \in [0,1] \tag{13}\]

In the spirit of earlier work by Donges et al., (2012) and Donner et al., (2010), we refer to this quantity as the n.s.i. cross-degree density. Here, \( W_j = \sum_{q \in V_t} w_q \) denotes the total weight of all nodes \( q \in V_t \) in a respective subnetwork. For the case of a single-layer network, a measure similar to the n.s.i. cross-degree density has been introduced by Tsonis et al., (2006) in terms of the area weighted connectivity, which quantifies the share on the subdomain of interest represented by the entire network \( G \) that is connected with any nodes \( v \in V \).

Generally, Wiedermann et al., (2013) and Zemp et al., (2014) showed that the weighted local cross-network measures improve the representation of a network’s topology with inhomogeneous node density within the domain of interest in comparison with its unweighted counterparts.

Donges et al., (2015a) showed that for the unweighted case cross-degree and leading coupled patterns display
strong similarity if the first coupled patterns explain a high fraction of the system’s covariance. A similar assessment can be made for the similarity between the leading coupled patterns obtained from a weighted crosscovariance matrix and the n.s.i. cross-degree (see Appendix S1, Supporting information).

2.4.3. Global measures

In addition to local (per node) network measures we also aim to characterize the macroscopic interaction structure of each pair of coupled climate networks by means of global network properties. For coupled climate networks a variety of unweighted measures have been proposed by Donges et al., (2011). Here, we utilize the construction mechanism by Heitzig et al., (2012) to convert two of them into their weighted counterparts as well.

2.4.3.1. N.s.i. global cross-clustering coefficient: The global cross-clustering coefficient $C_{ij}^\star$ of a subnetwork $G_j$ gives the probability that for a randomly chosen node $v \in V_i$ one finds neighbours $p, q \in V_j$ that are mutually linked. It is defined as the arithmetic mean of all local cross-clustering coefficients $C_{ij}^\star$.

$$C_{ij}^\star = \frac{1}{N_i} \sum_{v \in V_i} C_{ij}^\star$$

(14)

This measure can be converted into its n.s.i. counterpart by calculating the weighted mean of all values of $C_{ij}^\star$.

$$C_{ij} = \frac{1}{W_i} \sum_{v \in V_i} w_v C_{ij}^\star.$$  

(15)

Again, analogously to the interpretation of the local n.s.i. measures, $C_{ij}$ no longer only measures pure node-wise triangular structures but takes into account the share on the Earth’s surface areas involved in the formation of triangular structures. Generally, large values of $C_{ij}$ (which are induced by a dominance of connected triples between the two subnetworks under consideration) indicate strong transitivity in the underlying correlation structure.

2.4.3.2. N.s.i. cross-transitivity: The cross-transitivity $T_{ij}$ gives the probability that two randomly drawn nodes $p, q \in V_j$ are connected if they have a common neighbour $v \in V_i$. It is given as

$$T_{ij} = \frac{\sum_{v \in V_i} \sum_{p, q \in V_j} A_{vp} A_{pq} A_{qv}}{\sum_{v \in V_i} \sum_{p, q \in V_j} A_{vp} A_{qv}}.$$  

(16)

Like $C_{ij}$, the cross-transitivity is a measure of organization with respect to the cross-correlation structure in a coupled network (Donges et al., 2011). However, in contrast to $C_{ij}$, $T_{ij}$ takes into account the increasing influence of nodes with high cross-degree and weighs them more heavily than nodes with low cross-degree. More importantly it ignores nodes with no links into the opposite layer, since these nodes display a zero cross-degree. The node-weighted variant of $T_{ij}$ can be written as

$$T_{ij}^w = \frac{\sum_{v \in V_i} \sum_{p, q \in V_j} w_v A_{vp} A_{pq} A_{qv}^+}{\sum_{v \in V_i} \sum_{p, q \in V_j} w_v A_{vp}^+ A_{qv}^+} = \frac{\sum_{v \in V_i} w_v (k_v^*)^2}{\sum_{v \in V_i} w_v} C_{ij}^\star$$  

(17)

We note that both $C_{ij}$ and $T_{ij}^w$ similarly evaluate the transitivity of correlations between the two climatic variables under study and, hence, quantify a similar network property. They are derived, however, in a disjoint manner. One measure, $C_{ij}$, is computed as the weighted average taken over $C_{ij}^\star$. In contrast, despite suggestions by Radebach et al., (2013) to decompose the global transitivity into local contributions, the n.s.i. cross-transitivity $T_{ij}^\star$ is defined solely as a global network measure with no direct local counterpart. It is important to note that n.s.i. cross-transitivity and n.s.i. global cross-clustering coefficient are commonly asymmetric in the sense that $T_{ij}^\star \neq T_{ji}^\star$ and $C_{ij}^\star \neq C_{ji}^\star$.

3. Results

3.1. Maximum covariance analysis

We start our analysis by computing the leading coupled patterns between the SST field and the 18 HGT layers for boreal winter (DJF). Figure 2 displays the results for three representative layers of HGT at 50 mbar, 100 mbar and 500 mbar.

By applying MCA, we detect coherent large-scale patterns of winter SST, which co-vary with the winter atmospheric circulation structures instantaneously. The leading MCA patterns explain rather large amounts of 42%, 63% and 70% (for the 500, 100 and 50 mbar pressure level, respectively) of the squared covariance. At all levels, the leading MCA mode displays significant SST anomalies over the North Pacific with maximum values along the sub-Arctic front near 40°N, and anomalies of the opposite sign along the western coast of North America (Figure 2(a), (c), and (e)) (An and Wang, 2005; Frankignoul and Sennachael, 2007). Over the North Atlantic, a dipole structure is seen between the northern part of the Gulf Stream and the Atlantic Ocean south of Greenland including parts of the Davis Strait and the North Atlantic current. This pattern resembles the first SST EOF for the Northern Hemisphere during boreal winter (not shown).

This general SST pattern is co-varying with a pressure anomaly pattern showing a hemispheric annular-like structure in the upper troposphere and lower stratosphere (Figure 2(b) and (d)). In the mid-troposphere (Figure 2(f)), this pattern displays wave-like deviations from the annular structure, which show distinct similarities with the wave-train structure of the Pacific North American (PNA) pattern. Therefore, the leading MCA mode relates negative SST anomalies along the sub-Arctic front with a positive PNA phase.
Figure 2. Leading coupled patterns obtained from MCA between the SST field and three layers of geopotential height at 50 mbar (a and b), 100 mbar (c and d) and 500 mbar (e and f) in winter (DJF). The left column (a, c and e) displays the component in the SST and the right column (b, d and f) that in the respective HGT field. All spatial patterns are shown as regression maps obtained by regressing SST anomalies and geopotential height anomalies onto associated time series for the geopotential height field for the respective MCA mode. Statistically significant areas at the 95% confidence level based on a two-tailed Student’s t-test are shown as solid contours. Dashed lines indicate the climatic mean geopotential height fields.

[Colour figure can be viewed at wileyonlinelibrary.com].
The second MCA mode (not shown, explaining 13%, 17% and 21% of the squared covariance fraction for the 500, 100 and 50 mbar pressure level, respectively) displays the strongest SST anomalies over the North Atlantic. Over that region, the SST pattern resembles the northern part of the North Atlantic SST tripole pattern which is related with the North Atlantic Oscillation (NAO; e.g. Czaja and Frankignoul, 1999; Czaja and Frankignoul, 2002; Gastineau and Frankignoul, 2015). Accordingly, the co-varying atmospheric pattern in the middle troposphere shows the cold ocean/warm land (COWL) pattern (introduced by Wallace et al., 1996) including a NAO-like dipole over the North Atlantic. At higher levels, the co-varying atmospheric patterns display a pronounced wave-number-2 pattern.

By applying lagged MCA between SST and mid-tropospheric circulation fields, several studies for the North Atlantic and the North Pacific have shown that the squared covariance fraction is strongest and most significant at lags of 0 and 1 month during late fall and winter (e.g. Czaja and Frankignoul, 1999; Wen et al., 2005; Liu et al., 2006; Frankignoul and Sennchael, 2007; Gastineau and Frankignoul, 2015). This points to the forcing of the SST by the dominant atmospheric pattern, which is the PNA pattern over the Pacific-North American sector (e.g. Frankignoul and Sennchael, 2007) and the North Atlantic Oscillation (NAO) over the North Atlantic-European region (Czaja and Frankignoul, 1999; Gastineau and Frankignoul, 2015). On the other hand, results of lagged MCA analyses with the ocean leading by 1 to 4 months in Frankignoul and Sennchael (2007) and Gastineau and Frankignoul (2015) suggest that the SST anomalies have a substantial influence on the large-scale atmospheric circulation at these time-scales.

### 3.2. Local coupled network measures

In order to first demonstrate the general consistency of coupled climate network analysis in comparison with MCA, we continue by generating coupled climate networks between the SST field and the three previously considered layers of HGT (500 mbar, 100 mbar, 50 mbar). The n.s.i. cross-degree densities $\kappa_{vi}^s$ and $\kappa_{vi}^s$ are expected to display similar spatial structures as the corresponding leading coupled patterns (Donges et al., 2015a) since the latter explain a high share of the cross-covariance between both fields (see Appendix S1).

As demonstrated in Figure 3, the results for $\kappa_{vi}^s$ and $\kappa_{vi}^s$ indeed match well the results obtained from the MCA when comparing the locations of maximum values in the coupled networks’ n.s.i. cross-degree densities to those of maximum or minimum values in the leading mode of the MCA. Note, that the n.s.i. cross-degree densities $\kappa_{vi}^s$ and $\kappa_{vi}^s$ take, per definition, only positive values, while coupled patterns display both, positive and negative values. Hence, $\kappa_{vi}^s$ and $\kappa_{vi}^s$ only reproduce structures that coincide with the absolute values of the leading coupled patterns. However, as only a certain percentage of squared covariance is explained by the leading coupled patterns, we also note differences between the patterns revealed by the two methods.

In particular, the negative center of action around the North Pole that is detected by MCA is only weakly present in the cross-degree density fields $\kappa_{vi}^s$ for the 50 and 100 mbar HGT fields (compare Figure 2(b) and (d) with Figure 3(b) and (d)). For the ocean, preferably the marked structures in the leading coupled patterns in both the Atlantic and the Pacific are well recovered by the cross-degree density $\kappa_{vi}^s$ while some of the weaker structures, e.g. in the Black Sea, are missing.

Network analysis, however, allows us to undertake a further in-depth analysis of the correlation structure between the different layers beyond the information provided by MCA. The n.s.i. local cross-clustering coefficients $C_{vi}^s$ and $C_{vi}^s$ (Equation (11)) give the probabilities that the dynamics at two grid points in the HGT (SST) field behave statistically similar if they are both similar to that at the considered grid point in the SST (HGT) field. Note that in the scope of this work we do not account for any possible effects induced by a common external forcing of the fields, which might artificially induce correlations and, hence, cause the presence of spurious links between nodes or triples of nodes. We also do not account for indirect (partial) correlations or common driver effects within each of the fields when constructing the coupled climate networks. Conditioning out these possible influences by means of information theoretic approaches (Runge et al., 2012; Runge et al., 2014) and causal effect networks (Runge et al., 2015; Kretschmer et al., 2016) thus remains as a subject of future research.

Figure 4 presents the results for the n.s.i. local cross-clustering coefficients $C_{vi}^s$ for nodes in the SST field (Figure 4(a), (c), and (e)) and $C_{vi}^s$ for nodes in the HGT fields (Figure 4(b), (d), and (f)). Most nodes in the SST field tend to display a low n.s.i. local cross-clustering coefficient $C_{vi}^s < 0.2$ (Figure 4(a), (c), and (e)) and, thus, preferentially correlate with nodes in the HGT fields that are mutually dissimilar and therefore disconnected (Figure 5). In contrast, many nodes in the HGT fields exhibit a comparatively high or intermediate n.s.i. local cross-clustering coefficient $0.4 < C_{vi}^s < 1$ (for one of the most prominent examples compare nodes located at or above the Pacific in Figure 4(b) and (d)). Quantitatively, for the combination of the SST and the 500 mbar HGT field we find an n.s.i. global cross-clustering coefficient (Equation (15)) of $C_{vi}^s = 0.16$ for SST nodes and $C_{vi}^s = 0.28$ for 500 mbar HGT nodes. Ignoring those nodes in the averaging that display zero n.s.i. cross-degree density we obtain values of $C_{vi}^s = 0.42$ and $C_{vi}^s = 0.52$ (note that this definition is different from the one presented in Equation (15) as we specifically exclude the contribution of nodes with no links to the opposite subnetwork). The n.s.i. cross-transitivity (Equation (17)) which weighs nodes according to their n.s.i. cross-degree density gives values of $T_{vi}^s = 0.2$ and $T_{vi}^s = 0.25$ for nodes in ocean and atmosphere, respectively. For all three measures, the values computed for the atmospheric subnetwork exceed those for the ocean and thus consistently imply that nodes in the ocean are less likely to connect...
with mutually connected nodes in the atmosphere than vice versa.

To further quantify the asymmetries in the correlation structure between ocean and atmosphere, we investigate for each node with a given n.s.i. cross-degree density its corresponding n.s.i. local cross-clustering coefficient in a coupled climate network composed of the SST and 500 mbar HGT fields (Figure 6). This layer is chosen as it provides a good indication of the atmospheric circulation over the area of study (Kushnir et al., 2002; Gastineau and Frankignoul, 2015). Furthermore, it displays among the highest values of Ti according to Figure 1, which has similarly been described as a strong statistical signal by Frankignoul et al., (2007).

For nodes in the SST field (Figure 6(a)), we find that C\text{i} (k\text{i} *) tends to follow a power-law, C\text{i} * \sim (k\text{i} *)^{-\alpha}, which indicates a hierarchical network structure (Ravasz et al., 2002; Ravasz and Barabási, 2003) which, in contrast, is absent for nodes in the HGT field (Figure 6(b)). Here, the term hierarchical implies that nodes in the SST field strongly correlate with disconnected clusters of statistically similar nodes in the HGT field as depicted in Figure 5. This deduction is further supported by the fact that for the HGT field, the distribution of combinations of C\text{s} * and k\text{s} * is more widely spread and C\text{s} * generally takes higher values than C\text{i} *. This implies that nodes in the HGT field show a stronger tendency to correlate with mutually connected nodes in the SST field, which can be assumed to display a strong statistical similarity among themselves (Molkenthin et al., 2014; Tupikina et al., 2014). To test for the robustness of our results we have carried out the same analysis as presented in Figure 6 for internal link densities of \rho = 0.02 and \rho = 0.05, and corresponding cross-link densities \rho = 0.01 and \rho = 0.025 (see Figures

S1 and S2 in the Supporting information. Even though the power-law exponent $\alpha$ slightly decreases towards zero with increasing link densities, we find that the qualitative findings remain unchanged. We thus consider our results to be sufficiently robust with respect to the actual choice of link densities.

As a remark, we note a general tendency of nodes at the boundaries of a cluster that links with the opposite field to display comparatively low values of n.s.i. cross-degree density and increased values of n.s.i. local cross-clustering coefficient (Figures 3 and 4). In contrast, nodes located towards the center of these clusters display increased n.s.i. cross-degree density, which is in general to be expected from the continuity of the underlying system. However, in that case we also note tendencies for decreased values of n.s.i. local cross-clustering coefficients. This observation is a result of the fact that especially those nodes with only one link to the opposite field show by definition the highest value of the n.s.i. local cross-clustering coefficient, $C^{*}_v = 1$. With increasing n.s.i. cross-degree density this measure converges to a more reasonable estimate of a node’s tendency to cluster.

One way to address this issue in the future would be to subtract the squared sum of weights $w_v$ of all neighbours of the concerned node from the numerator in Equation (11). Such procedure would, however, introduce a non-standard network measure whose properties should be assessed thoroughly in future research before applying it to climatic studies. To this end, we acknowledge that the concerned nodes do not play a crucial role for the propositions put forward in this section, since they (i) are ultimately dealt with by the assessment of n.s.i. cross-transitivity which weighs
those corresponding nodes much lower than those with a high n.s.i. cross-degree density and (ii) only manifest in the very upper left corners of Figure 6(a) and (b). In that case they do not contribute significantly to the observed relationship between n.s.i. cross-degree density and n.s.i. local cross-clustering coefficient and have no further impact on the qualitative statements put forward above.

Following upon the quantitatively observed hierarchy, Figure 7 allows for a visual inspection of some illustrative parts of the corresponding network structure. In particular, we display for two selected patches of nodes in the SST field that show high values of $\kappa^v$ with the HGT field (shaded polygons in Figure 7(a) and (b)) the corresponding neighbouring nodes in the HGT field as well as all links between those nodes (respective scatter in Figure 7(a) and (b)). While ignoring very small clusters we find in total four (three) substantial mutually disconnected patches of nodes in the HGT field that correlate with the respective ocean patches. Vice versa, by selecting the resulting two largest patches of nodes in the HGT field above both oceans (shaded polygons in Figure 7(c) and (d)) we find that each of these patches only correlates with two disconnected patches of nodes in the SST field that are of a sufficient spatial extent to have an effect on the estimation of $C^v_s$. Thus, the resulting n.s.i. local cross-clustering coefficients $C^v_i$ for nodes in the ocean exceed $C^s_i$ for nodes in the atmosphere as the ocean correlates with more mutually disconnected clusters of nodes than vice versa.

Comparing the observed node patches in the HGT field with atmospheric patterns of large-scale variability (Hendler and Dethloff, 2012), we relate the two atmospheric clusters in the HGT field that are located above the Atlantic (Figure 7(a)) with the NAO. Correspondingly, the three patches located above the Pacific (Figure 7(b)) coincide well with the spatial signature of the PNA pattern. Taking into account past studies that applied lagged correlation analysis we note that on the time scales considered in this study the atmosphere serves as a driving force of the ocean along the spatial domain that is of interest here (e.g. Czaja and Frankignoul, 1999; Frankignoul and Senncha, 2007; Gastineau and Frankignoul, 2015). Thus, the hierarchical network structure might on the one hand be a result of the aforementioned atmospheric forcing to the ocean. On the other hand, with reference to Figure 7, the framework of coupled climate networks and the methodology put forward in this work serve to resolve the corresponding induced correlation structure between the two climatic subsystems in a spatially explicit way, such that it enables to specifically detect forcing and forced areas in atmosphere and ocean, respectively.

Choosing different HGT layers up to 200 mbar yield similar results (not shown). This aligns well with previous results by Czaja and Frankignoul (1999) and Frankignoul and Senncha (2007) who observed comparable spatial statistical patterns at each tropospheric level. Thus, the observed hierarchy seems to be a generic property of the troposphere. Following the above lines of thought, future work should investigate coupled climate networks constructed from lagged cross-correlations to investigate whether the observed structures are indeed a result of short-term atmosphere-to-ocean forcing. Such procedure would, however, require the derivation of novel directed interacting network measures, which in turn would provide a valuable extension to the framework of climate network analysis.

3.3. Global measures

So far we have focused our study on three atmospheric layers, namely the 50 mbar, 100 mbar and 500 mbar HGT field. Specifically for the latter case, we have carried out a further in-depth analysis of the observed hierarchical structures by means of assessing the power-law relationship between $\kappa^v_i$ and $C^v_i$ as well as investigating the distinct spatial distribution of nodes and links in ocean and atmosphere that obey the observed hierarchical organization (Figure 7). To show that these structures...
are (i) not only present for the 500 mbar field and (ii) their observations are robust with respect to the choice of link densities we now investigate global network characteristics that provide a macroscopic description of the observed network structures.

Specifically, we study the n.s.i. cross-transitivity $T_{si}^*$ computed over nodes in the SST field and $T_{si}^*$ computed over nodes in each of the HGT fields according to Equation (17) together with the n.s.i. global cross-clustering coefficients $C_{si}^*$ and $C_{si}^*$, respectively (Equation (15)). Note again that the latter are defined as the weighted means of their local counterparts that are presented in Figure 4, where nodes with no links to the opposite field are weighted in the same fashion as those with adjacent cross-links. In contrast, the n.s.i. cross-transitivity assigns nodes a weight corresponding to their n.s.i. cross-degree (which for the case of no adjacent cross-links takes a value of zero) and, thus, excludes them from the averaging.

The corresponding results are summarized in Figure 8. We find that both $T_{si}^*$ and $C_{si}^*$ show their maximum values at around 10 km altitude (250 mbar) (Figure 8(a) and (b)). For the same quantities, distinct minima at 850 mbar (1.4 km) coincide with the transition from the atmospheric boundary layer to the lower troposphere as also found in Donges et al., (2011). For all layers above 100 mbar, $T_{si}^*$ remains almost constant at low values. Hence, $T_{si}^*$ and $C_{si}^*$ seem to naturally discriminate between three different atmospheric layers: below 850 mbar (atmospheric boundary layer), between 850 mbar and 100 mbar (free troposphere) and above 100 mbar (lower stratosphere).

For the global measures computed over all nodes in the HGT field, we find that the n.s.i. cross-transitivity $T_{si}^*$ shows almost constant values for all layers below 200 mbar and, hence, again separates well the dynamics within the troposphere from that inside the stratosphere (Figure 8(c)). For all layers above 200 mbar $T_{si}^*$ becomes almost independent of the cross-link density $\rho_{si}$ that is fixed when constructing the network. The same property also holds for the n.s.i. global cross-clustering coefficient $C_{si}^*$ computed over all nodes in the different HGT fields (Figure 8(d)).

In agreement with the local measures discussed in Section 3.2 we find that n.s.i. cross-transitivity and n.s.i. global cross-clustering coefficients are in most cases larger for nodes in the HGT fields than for nodes in the SST field (compare Figure 8(a) and (b) with (c) and (d)). As for the n.s.i. local cross-clustering coefficients this indicates again the hierarchical network structure, i.e. a tendency for nodes in the HGT field to form triangular structures with nodes in the SST field, that is present across all atmospheric layers ranging from the troposphere to the lower stratosphere. The detailed structure of this hierarchy, however, seems to vary with the different atmospheric layers under study.
density construct the networks for different choices of (unweighted) cross-link field. To demonstrate the robustness and consistency of the results, we display the respective measures computed over all nodes in the HGT field. In the SST field nodes tend to correlate with multiple mutually unconnected groups of similar nodes within the respective HGT fields. From investigating the interdependency between n.s.i. cross-degree density and n.s.i. local cross-clustering coefficient, we have found that the correlations between the ocean and the atmosphere exhibit a hierarchical structure in the sense of a power-law relationship between both properties. A visual inspection of the coupled climate network for the case of the 500 mbar HGT field reveals that the observed structure could be related to a forcing of the ocean by the dominant atmospheric patterns above the Atlantic and the Pacific. Ultimately, global network characteristics further support the results obtained from their local correspondents by showing that the observed structure is valid for large parts of the atmosphere ranging from the troposphere to the lower stratosphere.

4. Conclusions and outlook

We have carried out a detailed analysis of the correlation structure between atmospheric and ocean dynamics in the Northern Hemisphere extratropics from the viewpoint of coupled climate networks. A comparison between the n.s.i. cross-degree density (measuring the weighted share of significant correlations between grid points in different layers) and the leading mode of the MCA reveals an expected high congruence between both methods for the considered data sets. However, coupled network analysis, and particularly the investigation of higher-order network parameters, allows us to further disentangle the underlying correlation structure. The n.s.i. cross-degree density in combination with the n.s.i. local cross-clustering coefficient provides additional insights on areas in the ocean and the atmosphere that show strong mutual correlations as well as localized versus delocalized correlation structures with the respective opposite field. This observation further holds not only for the case of \( \rho_{si} = 0.005 \) that was used in the previous sections but also for larger values that are chosen from a reasonable range (Figure 8). Thus, we consider our results to be sufficiently robust with respect to the choice of the networks’ link densities.

In general, we observe that the quantitative and qualitative properties of the n.s.i. cross-transitivity and n.s.i. global cross-clustering coefficients vary with the different atmospheric layers. Hence, these global characteristics may serve to intercompare and distinguish between different correlation structures in a coupled climate network. An in-depth analysis of the mechanisms that cause the occurrence of this behaviour in our specific application remains as a subject of future research.

Figure 8. Global coupled network measures computed for all 18 coupled climate networks: (a) N.s.i. cross-transitivity and (b) n.s.i. global cross-clustering coefficient taken over all nodes in the SST field. (c) and (d) display the respective measures computed over all nodes in the HGT field. To demonstrate the robustness and consistency of the results, we construct the networks for different choices of (unweighted) cross-link density \( \rho_{si} \) and internal link density \( \rho_{si} = \rho_{i} = 2 \rho_{si} \). [Colour figure can be viewed at wileyonlinelibrary.com].

Besides all possible future lines of work with respect to the climatic side of this work, it is from a network-theoretic point of view worthwhile to construct climate networks using more advanced causal estimators (e.g. Runge et al., 2012; Runge et al., 2014; Runge et al., 2015) to disentangle direct from indirect or externally and internally forced correlations.

To this end, our analysis has only been performed for the pairwise correlation between one atmospheric layer and the ocean. Future studies should further explore the possibility to refine the proposed methods to also quantify interactions in a climate network consisting of more than two subnetworks. Specifically, when studying...
coupled climate networks in the Northern Hemisphere, one should also consider Arctic sea ice as an additional observable in the network construction. Its dynamics has already been discovered as an influencing factor on atmospheric teleconnections and the dynamics of land snow cover in the Northern Hemisphere (Handorf et al., 2015). The study of coupled climate networks can help here to further disentangle and quantify possible changes in correlations between ocean and atmosphere over the course of the past decades that may have been induced by processes related to the Arctic amplification (Serreze and Francis, 2006). Moreover, it is of great interest to apply our methods not only to coupled networks composed of different climatic fields (as presented in this work), but also to networks constructed from just one single climatic field that divides into dynamically distinct areas (Hlinka et al., 2014) or communities (Tsonis et al., 2010; Steinhaeuser et al., 2011). The framework presented in this work could then be utilized to study and quantify correlations between these detected or defined regions on or parallel to the Earth’s surface. This would allow for a detailed investigation of correlation structures between different climatic subsystems such as, for example, the Indian Summer Monsoon and the El Niño Southern Oscillation.

Finally, it remains to remark that the weighted network measures presented in this work provide a general framework which can be applied to quantify interdependencies in complex networks representing subjects of study taken from many other fields beyond climatology.

Supporting information

The following supporting information is available as part of the online article:

Appendix S1. Similarities between leading coupled patterns and n.s.i. cross-degree densities.

Figure S1. The same as Figure 6 in the main text for a network with an internal link density \(\rho_s = \rho_t = 0.02\) and a cross-link density \(\rho_{sl} = 0.01\). The dashed line in (a) indicates again the relationship \(C_n(k_s) \sim (k_s)^{\alpha-\gamma}\) (here with \(\alpha = 0.90\)) expected for traditional network measures \(C_n(k_s)\) in the case of hierarchical network structures (Ravasz et al., 2002; Ravasz and Barabási, 2003).

Figure S2. The same as Figure S1 for a network with an internal link density \(\rho_s = \rho_t = 0.05\) and a cross-link density \(\rho_{sl} = 0.025\). The power-law exponent for this case reads \(\alpha = 0.83\).
