Abstract
The Lead-free solders (SAC) with low Ag content have been identified as crucial solder to replace the traditional Sn–Pb solder. The main discussion was presented in two major area of microstructural investigation and mechanical properties of SAC305 and SAC405. Composition and microstructure of SAC solder alloys were investigated by an optical microscope and SEM (Scanning Electron Microscopy). Mechanical properties such as tensile tests and hardness test of the lead-free solder alloys have been tested in this research. Different Ag content and constant Cu content of lead-free solder has been considered in this investigation and compare the mechanical properties of SAC305 and SAC405 solders. From this investigation, tensile strength and hardness have been increased with increased of Ag content.

Keywords: Lead-free solder; Sn–Ag–Cu alloys; Microstructure; Mechanical properties.

Introduction
Soldering is the essential joining process in the electronics industry. Environmental and health hazards studies of Pb-Sn solders with focus on lead-free alternatives are meet in reliability [1]. It is important to ensure that the thermal, mechanical and physical properties of lead-free solders are superior to those of Sn-Pb solders. Since the portable electronic products increased to high speed, lightweight, continual miniaturization, and multi-functionality of integrated circuits, the transition to Pb-free solders occurred to compact with the increase in portable electronic products. So, in the reliability condition, both the thermal cycling loading and drop performance are essential for portable electronic products. The most important for electronic industry appears to be the Sn-Ag-Cu (SAC) alloys eutectic or near eutectic alloy system. These

* Corresponding author: Manoj Kumar Pal, manojsantosh2002@gmail.com
alloys can offer an excellent combination of better thermal, mechanical and wettability compared to Pb-Sn solders. Moreover, the SAC solders alloys have a good quality joint with different substrates, i.e., chip scale package as well as ball grid array (BGA) interconnect. The main reason for weak mechanical properties of the solder joint is the extensive formation of Ag$_3$Sn and Cu$_6$Sn$_5$ IMC, so these problems need to be resolved. For that reason, the industries mostly use the low-Ag SAC solder alloys such as SAC105, SAC205 and, SAC305, which have low cost and better performance than eutectic or near-eutectic SAC alloys in drop impact reliability [1-7].

With the requirement of lead-free solders, it is necessary to understand that how different lead-free solders affect the reliability of microelectronic assembly when subjected to different loading conditions such as thermal cycling, bending, vibration and drop impact. The Sn–Ag–Cu solder is one commonly used lead-free solder in surface mount technology (SMT) assembly for microelectronics. Many studies were conducted on Sn–Ag–Cu lead-free solders. Results showed that the Ag content affects the mechanical properties and microstructures with Sn–xAg–Cu lead-free solder joint [2-4].

Pb-free solders are good alternatives to traditional Sn-Pb solders alloys, and their existence is significant efforts in course. The traditional Sn–Pb solder alloy is the dominant solder material in the industry because of their shallow melting temperature.

In the context of the environmental and human precaution, Sn-Pb has not been widely promoted. Since 2006 the environmental protection agencies (RoHS and WEEE) have banned the lead-containing portable electronic products because lead and lead-containing products are toxic substances and it would be very harmful to the well-being of humans and the environment. So, the researchers are trying to find the other alternatives without Pb, and lead-free solders are good alternatives because lead-free solders are non-toxic [3-8].

Sn–Ag alloys have three different Ag$_3$Sn morphologies during solidification. Various researchers have been shown IMCs, i.e. spheroids, needles and platelets type intermetallic (Ag$_3$Sn) particles. Regarding the mechanical strength, the Ag$_3$Sn IMC is brittle when compared with the Sn-rich matrix. Under stressed loading conditions, serious problems can be carried by the brittle nature of the Ag$_3$Sn intermetallic. It has been described that Sn–Ag solder having a coarse dendritic microstructure with the shape of fiber-platelets Ag$_3$Sn particle has lower corrosion resistance when compared with that of the same alloy having a microstructure characterized by finely and homogeneously distributed spheroids like fiber Ag$_3$Sn IMC particles. This paper aims to develop a comparative analysis of the mechanical properties of different lead-free solder alloys with those of the traditional Sn–Pb alloy. Experimental results are characterizing the microstructural and mechanical properties of SAC305 and SAC 405 alloys. These two SAC solder alloys have been selected due to two main reasons: (i) to determine the effect of silver content on the microstructure and mechanical behavior and (ii) these alloys have been subjected a contradiction in the research [8].

For higher density packages, flip-chip interconnects are increasingly used in daily life. Eutectic Sn–Pb alloy is one of the most popular solders used in flip chip today. Lead-free solder balls are environmentally friendly technology at this time for the electronics industry. Many researchers have been proposed for lead-free solders for material characteristics in manufacturing, reliability, and performance, such as melting temperature, solderability, cost, and long-term reliability. As SAC solders (3 to 4 wt. %
of Ag) having lower melting points and good solderability with excellent reliability, these solders are the original lead-free solder compositions for flip-chip solder [4-9].

In the electronics industry, the solder joint reliability is a prime concern under thermal and mechanical loading. For the reliability assessment, reliability testing and computational modeling are conventional methods. Compare to actual reliability tests, the modeling is more efficient than actual, which are time-consuming, expensive, and require more workforce for failure analysis and measurement.

The material properties of the solder joint are needed for modeling. Therefore, for a reliable numerical model, it is critical to characterize material properties accurately. Various researchers have been reported on the characterization of mechanical properties of lead-free solders and lead solders. Tensile and compressive tests are the conventional techniques used for characterization. Compare to the bulk solder bars, the material properties of the small solder joints are different which used in electronics assembly because they have different microstructures and different intermetallic compound layers. It is necessary to perform characterization on actual solder joints for the effects of microstructures and intermetallic compound distribution. For the characterization of mechanical properties of actual solder joints, the conventional techniques, nanoindentation can be used. However, these techniques provide only the properties of the individual phases in the solder joints and do not provide a value for the Poisson’s ratio [5-10].

In recent years, the portable electronics products are highly demanded because of the shrinking in size of electronic components and solder joint dimensions. Furthermore, by the government legislation, the electronics industry has been adopted to lead-free solders due to environmental and health concerns issues from the use of Pb-based solders. In the recent time, several lead-free solders have been developed such as Sn-Bi, Sn-Ag, Sn-Cu, and Sn-Ag-Cu alloys. Sn-Ag-Cu (SAC) is nontoxic solder alloy, and it has excellent mechanical properties and wettability. It the most widely used lead-free solders this time. However, according to the literature, Sn-Pb solders are less brittle than SAC solder alloys with high Ag content because, in SAC solder, the intermetallic compounds (IMC) Ag3Sn IMC formed at the SAC solder/Ag interface and Cu6Sn5 and Cu3Sn are formed at the SAC solder/ Cu interface. Also, the high Ag content SAC solder increases the cost of the products compared to the low Ag content SAC solder alloy. Thus, it is mandatory to choose the low-Ag-content SAC alloys. Reducing the Ag content can improve the reliability of SAC solder joints in dynamic environments. Addition of alloying elements such as SiC, Bi, Ni, and Ce will enhance the properties of SAC solder alloys in lead-free solder alloys [3-11].

**Experimental procedures**

Before the start, the experiment, composition of lead-free solder had to check by the inductively coupled plasma mass spectrometry (ICP-MS). Table1 shown the composition of SAC305 and SAC405 which provided by the HENKEL and also checked by inductively coupled plasma mass spectrometry (ICP-MS).
Table 1. The composition of SAC305 and SAC405 provided by HENKEL (wt. %).

| Alloy name by Henkel | Sn  | Ag Henkel | Ag ICP | Cu  | Cu Henkel | Cu ICP |
|----------------------|-----|-----------|--------|-----|-----------|--------|
| SAC305               | 96.5| 2.9524    | 3.03   | 0.5 | 0.5955    | 0.76   |
| SAC405               | 95.5| 3.9918    | 3.81   | 0.5 | 0.5992    | 0.52   |

Five specimens had to be cast of SAC 305 and SAC 405, and furnace temperature was 400 °C. These specimens had to be cast at room temperature and holding time was 45 minutes in the furnace. The solder alloys were melted in the furnace and maintained 100 °C above their respective melting point for 45 minutes. The solder specimens were cast inside the designed mold. Then, the specimens were naturally air-cooled at room temperature. The specimen was annealed at 100 °C for 2 h to reduce the residual stress, induced in the sample preparation before the testing. Then, the solder bars were fixed onto a testing grip at two ends of a specimen using a universal testing machine.

Tensile tests were conducted on bulk solder cylindrical dog bone SAC305 and SAC405 solder specimens. Figure 1 shown, the dog-bone-shaped bulk solder specimens for the uniaxial tensile test were prepared by machining from casted lead-free solder bar SAC305 and SAC405. The specimens had a total length of 60 mm and a gage length of 30 mm. The diameter of the gage length was 5mm.

Fig. 1. Dog-bone-shaped tensile test specimen.

This investigation focuses on the effect of Ag content on the mechanical properties of lead-free solders. Five samples were tested under the same testing condition for each specimen to obtain the reliable and repeatable results. Then, the mechanical properties were obtained by averaging testing data. The tensile tests were conducted at room temperature (25 °C) for SAC305 and SAC405. The microstructures of solders (SAC305 and SAC405) were investigated based on the microscope and scanning electron microscope (SEM) images. The SEM samples were prepared by dicing, resin molding, grinding and polishing processes. The effects of Ag content on IMCs (Ag₃Sn and Cu₆Sn₅) distribution and Sn dendrite were examined to understand the effect of Ag content on the mechanical properties of solders.
Results and discussion

Effect of strain on mechanical properties of solder

Figure 2 shows the ductile failure mode of SAC305 and SAC405 solder alloys. Necking and surface coarsening analysis were analyzed for the tested solder before complete failure.

![Figure 2](image)

**Fig. 2. Typical ductile failure of (a) SAC305 and (b) SAC405 solder.**

The tensile stress-strain curves of Sn–3.0Ag–0.5Cu and Sn–4.0Ag–0.5Cu solder alloys are shown in figure 2(a) and figure 2(b). The strain affects the mechanical properties significantly. The solder has been effected on the ductility with substantial elongation and plastic deformation before fracture. UTS and elongation increase with increasing tensile strain.

Effect of Ag content on solder mechanical properties and microstructures

Figure 3 shows the stress-strain curves for SAC305 and SAC405 solders under the same loading conditions. Fig.3 shows that the tensile strength of solder increases with increasing the Ag content but ductility reduces when the Ag content increases in Sn–Ag–Cu solder. Therefore, high Ag content solder joint has lower drop lifetime in the electronic assembly when subjected to drop impact, which is the testing results given by Amagai *et al.* [12]. The low Ag content solders are mainly used in the portable electronic assembly for handheld electronic products to improve the drop performance of solder joint [12, 13].
Fig. 3. Effect of Ag content on the stress-strain curves of SAC305 and SAC405 solders.

Microstructural characterization of solder

The microstructure of the SAC305 (Sn-3.0Ag-0.5Cu) and SAC405 (Sn-4.0Ag-0.5Cu) solders having an Sn matrix phase where Ag₃Sn needles-like and Cu₆Sn₅ in the bulk form are uniformly distributed in an Sn-rich phase. To investigate the effect of Ag content on the solder mechanical properties and microstructures by the scanning electron microscopy and microscope were used to study the microstructures of lead-free solders. Figure 4 and figure 5 show the microscopic and SEM images of microstructure for different Sn–Ag–Cu solders. It can be seen that the Ag content affects the Ag₃Sn and Cu₆Sn₅ intermetallic compound (IMC) precipitate. In Sn–Ag–Cu solder amount of Ag₃Sn and Cu₆Sn₅ IMCs increases when the Ag content increases and distributed in an Sn-rich matrix. Therefore, finer Sn dendrites have been seen in the microstructure of solder which has the higher Ag content and more IMC precipitates in solder with higher Ag content such as SAC405.

The typical example of low and high-magnification microscopic images of the microstructure of SAC305 and SAC405, an alloy of IMC phases are shown in Figure 4. The show the microstructures of SAC305 and SAC405 consists of β-Sn dendrites and mixture of Ag₃Sn and Cu₆Sn₅ IMCs distributed within Sn-rich matrix. Similar microstructures were reported in other SAC studies [11]. In Figure 4 and Figure 5, the needle-like particles are identified as Ag₃Sn IMCs, whereas an irregular polygon of IMC particles are Cu₆Sn₅. These large IMCs (Ag₃Sn and Cu₆Sn₅) particles are present in near eutectic lead-free solders and could lead to failure due to the high interfacial energy between the solid solder and IMCs particles [15].
Alloys having low silver content have two distinct melting phases. One is Sn-Ag eutectic and second is high-temperature phase corresponding to Sn-Cu eutectic. DSC analysis determined the melting temperature of the SAC305 and SAC405 solders. The Sn-Ag3.0-Cu0.5 and n-Ag4.0-Cu0.5 solder were found to have a melting interval of 215-220°C and 217-219 °C.

Fig. 4. Microstructures of SAC305 (a, b) and SAC405 (c, d) at different magnifications.
General tensile and hardness test

The tensile properties of SAC305 and SAC405 solder alloys are mainly controlled by their microstructures, which depend on the amount of Ag content, shape and size of IMC particles and their distribution in alloy matrix. Table 2 shows the hardness and tensile strength of the SAC305 and SAC405 lead-free solder, and table 2 shows that hardness and tensile strength of the SAC405 were higher than SAC305 lead-free solder because of Ag content. Ag content is increases, hardness and tensile strength are also increases.

Table 2. Tensile and hardness properties of the solders SAC305 and SAC405.

| Alloy   | Hardness (HV) | Tensile strength (MPa) |
|---------|---------------|------------------------|
| SAC305  | 13.87         | 45.70                  |
| SAC405  | 14.70         | 51.65                  |

Conclusions

Silver content is significant for the soldering process and solder joint reliability. Based on the present investigations described in this work, several conclusions may have found regarding a comparative evaluation of microstructural and mechanical deformation behavior of SAC305 and SAC405 solders:

- Optical microscope and SEM images examined microstructures – needle-like Ag₃Sn and Cu₆Sn₅ intermetallic compound (IMC) precipitate were found and saw in Sn–Ag–Cu solder amount of Ag₃Sn and Cu₆Sn₅ IMCs increases when the Ag content increases and distributed in an Sn-rich matrix. Therefore, finer Sn dendrites exist in the microstructure of solder which has the higher Ag content and more IMC precipitates in solder with higher Ag content such as SAC405.
DSC analysis determined melting interval of the SAC305 and SAC405 solders – the Sn-Ag3.0-Cu0.5 and Sn-Ag4.0-Cu0.5 solder have a melting interval of 215-220°C and 217-219 °C.

- The tensile strength of SAC305 is 45.70 MPa, and SAC405 is 51.65 MPa which are higher than SAC305. The hardness of SAC305 is 13.87 HV, and SAC405 is 14.70 HV, which is higher than SAC305.
