The ability to engineer the thermal conductivity of materials allows us to control the flow of heat and derive novel functionalities such as thermal rectification, thermal switching and thermal cloaking. While this could be achieved by making use of composites and metamaterials at bulk length-scales, engineering the thermal conductivity at micro- and nano-scale dimensions is considerably more challenging. In this work, we show that the local thermal conductivity along a single Si nanowire can be tuned to a desired value (between crystalline and amorphous limits) with high spatial resolution through selective helium ion irradiation with a well-controlled dose. The underlying mechanism is understood through molecular dynamics simulations and quantitative phonon-defect scattering rate analysis, where the behaviour of thermal conductivity with dose is attributed to the accumulation and agglomeration of scattering centres at lower doses. Beyond a threshold dose, a crystalline-amorphous transition was observed.
he thermal conductivity of bulk materials can be engineered by various means such as the use of composite materials or metamaterials. This allows the manipulation of heat flow with precision and inspires various functionalities, like thermal inverter, thermal concentrator, thermal cloak and so on. However, the realization of such concepts at the nanoscale is difficult because engineering the thermal conductivity of materials at small dimensions is much more difficult. The thermal conductivity of nano-sized material systems can be tuned by phonon-boundary scattering, interfacial thermal resistance, and/or by exploiting phononic crystals, but to engineer the thermal conductivity locally with precision is challenging from both fabrication and theoretical-prediction aspects. In particular, in the case of Si nanowires—a versatile building block for nano electronic, photovoltaic, thermoelectric, and photonic devices—it has been shown experimentally that the thermal conductivity of an individual Si nanowire can be reduced by shrinking its diameter and by introducing surface roughness. These prior works only demonstrated the tuning and measurement of the local thermal conductivity of a nanowire as a whole between its ends. Significantly, in terms of mechanical robustness for practical device design, ultra-thin or highly roughened silicon nanowires are extremely fragile, apart from the fact that making reliable ohmic contacts to such silicon nanowires is also a major issue. Moreover, the use of physical structuring means that post-fabrication tuning of thermal conductance by this method is not possible.

Another approach to engineer the thermal conductivity of a Si nanowire without affecting its surface morphology is through ion implantation. By introducing impurity atoms into the crystalline silicon nanostructures, the thermal conductivity can be tuned due to enhanced phonon-defect scattering and the damage can be annealed away (at CMOS process-compatible thermal budgets) as well. Even though heavy-ion irradiation (for example, using gallium and uranium ions) has been observed to change the thermal conductivity in nanostructures by defect engineering, point defect generation is inevitably accompanied by cluster amorphization along the ion trajectory. For less heavy ions, like silicon ions, the process of continuously elastic collision would make it difficult to generate a spatially uniform defect profile, and a complicated region containing simple defects as well substantial cluster formation results. It is thus desirable to adopt a technique that can produce different concentrations of simple point defects in a well-controlled manner to establish unequivocally the role of such defects on the thermal conductivity.

In this paper, we show that the thermal conductivity of an individual Si nanowire can be locally changed by irradiating it with helium ions with well-defined doses at different positions along its length (see Methods section for detailed sample preparation). Because of the small nanowire diameter (~160 nm) and moderately high helium ion energy (30–36 keV), the helium ions pass through the nanowire with minimal forward scattering and energy loss, and their effect is reasonably uniformly distributed over the nanowire cross-section, unlike the case of a much thicker Si substrate. The thermal conductivity of each irradiated nanowire segment was then measured by an electron beam heating technique that is capable of spatially resolving the thermal conductivity along the nanowire’s length (Methods section present the detailed measurement and calculation procedure). Using this technique, the effect of different helium ion dose can be measured conveniently along a single nanowire, thereby eliminating potential discrepancies that could arise from sample-to-sample variations in the nanowire diameter and from uncertainty in the thermal contact resistance between the nanowire ends and the thermometers. From the measurement, we observed a reproducible thermal conductivity versus ion irradiation dose curve, from which a clear crystalline-to-amorphous transition is seen. The effect of defects created by helium ions below the transition dose threshold on the nanowire thermal conductivity is discussed with theoretical support from the kinetic theory of phonon gas model and non-equilibrium molecular dynamics (NEMD) simulations. We also show that the thermal conductivity of the irradiated nanowire can be further tuned by annealing. The ability to tune the thermal conductivity along silicon nanowires with high spatial resolution by a well-controlled helium ion irradiation, and to measure the local thermal conductivity thereafter, provides a new platform to study nanoscale thermal transport.

**Results**

**Thermal conductivity measurement.** The silicon nanowire is suspended between two temperature sensors comprising platinum (Pt) loops on silicon nitride membranes, each of which is suspended by six nitride beams. Figure 1a shows the measurement result for Sample #1 for the damaged portion irradiated with the highest dose (7.5 × 10^16 cm^-2). From this figure, we can see that as the electron beam scans from the left to right across the damaged portion, the temperature rise of the left (right) sensor, ΔT_L (ΔT_R), undergoes obvious decrease (increase), indicating that the thermal resistivity of the damaged portion is much larger than that of the intrinsic portion. This is further confirmed by the increase in slope of the R(x) curve within the damaged portion, where R(x) is the cumulative thermal resistance from the left sensor to the heating spot. It is observed that the power absorption of the nanowire from the electron beam, (ΔT_L + ΔT_R)/R_b, where R_b is the equivalent thermal resistance of the sensors, does not vary significantly at the damaged portion, indicating negligible material removal from inside the nanowire. The R(x) curves for all the portions with different doses are plotted in Supplementary Fig. 3. The thermal conductivity of each portion was calculated as κ = 1/R(x)A, where A is the cross-sectional area of silicon nanowire with diameter d = 160 nm as measured in the TEM. To minimize the error, dR/dx was obtained by linearly fitting the R(x) curve of the damaged portion and the intrinsic portion, with the beginning and ending 50 nm of these portions stripped off to avoid the non-uniformity in the dose near the boundaries arising from ion forward scattering. As the thermal conductivity is derived from the gradient (dR/dx) of each portion, one can conveniently obtain the local thermal conductivity of each irradiated/non-irradiated portion in a single nanowire. Moreover, the need to contend with the unmeasurable thermal contact resistance between the ends of the nanowire and the sensors, which is a long standing problem of the conventional thermal bridge method, is avoided with our technique.

Plotted in Fig. 1b are the thermal conductivity versus dose curves for the eight samples measured at room temperature. The error bar is calculated by error propagation due to the uncertainty in dR/dx during linear fitting and the uncertainty in the diameter (~5 nm), with the former being one to two orders smaller than the latter. The intrinsic thermal conductivity of the nanowire is 50.2 ± 2.3 W m^-1 K^-1, obtained by linearly fitting several undamaged portions of the measured samples and taking the average. The amorphous limit of ~1.7 W m^-1 K^-1 (at 300 K) is taken from the literature.

Clearly two regimes can be identified in Fig. 1b—in the regime of relatively low dose (<1.5 × 10^16 cm^-2), the thermal conductivity drops rapidly initially and then tapers off as the dose increases, whereas in the regime of dose ≥3 × 10^16 cm^-2, the thermal conductivity approaches an asymptotic value.
simulation results, 98% of the helium ions penetrate the sensor, from averaging calculated ones by fitting several intrinsic portions for the plotted on a logarithmic scale. NATURE COMMUNICATIONS | DOI: 10.1038/ncomms15919 | www.nature.com/naturecommunications

The as-implanted damage was calculated by Monte Carlo simulations based on a binary collision approach (TRIM/SRM, the detailed simulation conditions and results are described in Supplementary Fig. 2 and Supplementary Note 1). The simulation shows that one helium ion can create a large number of displaced atoms (or Frenkel pairs, each of which is composed of a vacancy and a nearby interstitial) along its track; moreover, this as-produced damage is discrete and distributes relatively uniformly across the nanowire cross-section due the large range of the light and high energy (30–36 keV) incoming helium ions compared to the sample thickness (d = 160 nm); last, from simulation results, 98% of the helium ions penetrate the sample, and one helium ion can create 33 defects on average, while the number of residual (embedded) helium atoms is much smaller than the number of damaged lattice sites.

However, at room temperature, the as-produced point defects are not stable. They undergo extensive interstitial-vacancy recombination, defect clustering and pairing with impurities (for example, carbon and oxygen) during and after the irradiation process at room temperature. As a result, only 1–10% of the defects survive at room temperature for bulk materials. For the case of nanowires, annihilation at the surface may also enhance this annealing effect given the high surface-to-volume ratio.

An upper bound for the concentration of defects can be roughly estimated by assuming that 10% of the Si vacancies created by helium ions survive. For calculation purposes, we take it that the Si nanowire is circular with a diameter of 160 nm, based on our experimentally imaged and measured cross-section. The number of vacancies remaining is a function of dose and this relation is finally described as 2.0 × 10^5 (cm⁻²) × dose (cm⁻²), with details discussed in detail in Supplementary Note 1.

As there are 5 × 10^22 Si atoms per cm², for a dose of 1 × 10^16 cm⁻², around 4% of the Si atoms are displaced, acting as scattering centres for phonons. This value provides an upper bound of the phonon scattering centres because we use the upper bound of the survival rate (10%). Moreover, there is a consensus view that the stable defects left in the room-temperature silicon are predominantly divacancies, which are formed by two nearby vacancies. It has also been shown experimentally that at room temperature, divacancy is the dominant defect for the near-surface region of the helium ion damaged Si. Regarding its impact on the thermal conductivity, this means two displaced sites combine and act as one phonon scattering centre. Besides the vacancy-type defect, there is also a small amount of helium ions left; however, the quantity is limited as most of the helium ions penetrate the nanowire during irradiation. There may also be interstitial or interstitial-like defects in the nanowire, because although Si interstitials can follow athermal migration even at 4.2 K and the migration distance is long in high-purity material, they can also form clusters or complexes which are stable at room temperature.

The inverse phonon life time (phonon relaxation rate) contributed by substitutional point defects for a simple cubic lattice is τ^{-1}_d = Dκω, with

\[ D = \frac{\sigma}{4\pi v^3} \left( \frac{\Delta M}{M} \right)^2 \]

where \( \sigma \) is the point defect concentration per atom, \( \Delta M \) the mass difference between the substitutional atom and the host atom, \( M \) the mass of host atom, \( a \) the lattice constant and \( v \) the phonon group velocity. For the case of vacancy defect, as it removes the mass of one atom and also the force constants of two atomic sites, it can be treated as for complex lattices. Hence, compared with the substitutional point defects, the vacancy defect has a much stronger phonon scattering effect and is highly effective in reducing the lattice thermal conductivity. Indeed, experiments by Pei et al. showed that a small amount of vacancy defects (3%) in the \( \text{In}_2\text{Te}_3 \) lattice introduced by alloying with InSb can substantially reduce the lattice thermal conductivity (by ~80%).

To investigate the effect of point defects on the phonon scattering rate, we first consider a simple Debye formula for the thermal conductivity: \( \kappa = \frac{1}{3} C v^2 \tau \), where \( C \) is the specific heat,
The legend is the same as that in curve of kinetic theory of phonon gas. The fitting model, utilizing measured thermal conductivities within the framework of the assumption and extract the value of parameter towards saturation.

For dose \( \frac{1}{C0} \) dependence on dose in the low-dose regime and becomes saturated in the high-dose regime. The relationship between \( D \) and dose can be well fitted by a simple function, \( D = E(1 - e^{-F \cdot dose}) \), where the dose is small, the parameter \( D \) scales linearly with dose, namely, \( D = E \cdot F \cdot dose \). Considering the fact that the phonon-defect scattering rate depends linearly on the concentration of point defects (Eq. 1), we may infer that for doses less than \( 1 \times 10^{15} \) cm\(^{-2} \) in our experiment, the point defects created by helium ion irradiation is linearly proportional to the helium ion dose. However, as the dose increases the parameter \( D \) converges gradually to some asymptotical value, which suggests that the effective number of scattering centres does not increase significantly with further increases in dose. One possible reason is that for higher dose (from \( 2 \times 10^{15} \) to \( 1 \times 10^{16} \) cm\(^{-2} \)), the point defects agglomerate due to room temperature annealing. Last, the parameter \( D \) is about 1–3 orders of magnitude larger than the corresponding parameter for isotope scattering, which indicates the dominant role of point defects in suppressing the thermal conductivity of Si nanowire.

To further examine the role of point defect scattering, and to incorporate the effect of phonon-boundary scattering, NEMD simulation was carried out for qualitative comparisons with the experimental results. In the simulation, Si nanowires with various cross-sections of \( 3 \times 3 \), \( 6 \times 6 \) and \( 9 \times 9 \) unit cells (0.543 nm per unit cell) and fixed length of 20 unit cells were considered (Supplementary Fig. 6). Point defects are in the form of vacancies modelled by randomly removing some Si atoms (up to 20%) and then removing the single-bonded atom pairs (Supplementary Fig. 7). The details of the NEMD simulation are given in Supplementary Note 3.
Compared to the pristine Si nanowires, the simulated thermal conductivity of the defective Si nanowires is reduced, and decreases with the increase of vacancy concentration due to the enhanced phonon scattering by vacancy (Fig. 2c). At low vacancy concentration (smaller than 5%), the thermal conductivity of defective Si is further reduced by boundary scattering, while it is almost the same for different diameters at high vacancy concentration (greater than 15%), indicating the dominant role of vacancy scattering in this regime. We also plotted the $1/k$ curve as a function of vacancy concentration (Fig. 2d). As the Si nanowire diameter used in the simulation increases, $1/k$ shows no trend of saturation as the isolated vacancy concentration increases; on the other hand this corroborates the model of point defect agglomeration in the real situation under helium ion irradiation at room temperature.

From the experimental and simulation results, we can see that in the low-dose regime, point defects are effective in changing the thermal conductivity of the helium-irradiated Si nanowire. First, the thermal conductivity initially decreases drastically as the dose (and the corresponding density of point defects) increases; however further increasing the dose yields diminishing return on reducing thermal conductivity, that is, to obtain the same marginal decrease of thermal conductivity, one has to at least double the dose (inset of Fig. 1b). Second, at most 4% displaced Si atoms (corresponding to a dose of $1 \times 10^{16}$ cm$^{-2}$) is capable of decreasing the nanowire thermal conductivity by nearly 70%. It should be noted that under our experimental conditions of high helium ion energy, thin sample and same dose rate and temperature, the thermal conductivity for a particular dose is repeatable for all the samples measured.

**Effect of annealing.** It has been shown in the literature that point defects that are stable at room temperature such as divacancies can be annealed out at higher temperatures$^{37,47}$. This annealing effect on the thermal conductivity was investigated using Sample #3. Upon annealing, the total thermal resistance ($R_T$) of the nanowire became progressively smaller. The results from spatially resolved thermal conductance measurement show that this decrease of $R_T$ is due to the increase of the irradiated portion’s thermal conductivity, while the thermal conductivity of the non-irradiated portion remained the same (Fig. 3a) as expected.

The before- and after- annealing results are plotted in Fig. 3b. From this figure, we can see that for annealing at 120 °C, the thermal conductivity of the irradiated portion increases noticeably after 20 h. To further improve the nanowire thermal conductivity at 120 °C, a long annealing time, for example, 160 h, is required. On the other hand, merely 2 h of annealing at 300 °C improved the thermal conductivity substantially, and for the lowest dose ($2.5 \times 10^{14}$ cm$^{-2}$), the thermal conductivity had almost recovered to that of the non-irradiated portions. This is further illustrated by Fig. 3c, in which the $R_i(x)$ curve becomes a straight line, and the irradiated and non-irradiated potions are indistinguishable from each other.

It has been shown that the predominant point defects—divacancies—become mobile only at 200–300 °C, but at lower temperatures, divacancies could be annihilated by interstitials that have dissociated from clusters and diffused through the lattice. It was previously found that by annealing a proton-irradiated Si substrate at 150 °C for ~60 h, the divacancy concentration can be reduced by 54% (ref. 48). This annihilation of divacancies by interstitials explains the increase in the thermal conductivity upon annealing at 120 °C. On the other hand, at 300 °C, divacancies become mobile and migrate to sinks (primarily to the surface in the case of a nanowire), and if their concentration is high enough, they also agglomerate to form small clusters that are stable up to 500 °C (ref. 37). This explains the experimental results of the 300 °C annealing at low doses ($2.5 \times 10^{14}$ cm$^{-2}$), nearly all the divacancies migrate to sinks and disappear, so that the thermal conductivity has practically fully recovered, while at

higher doses, divacancies agglomerate, forming clusters which continue to act as scattering centres, so that the thermal conductivity of these portions could not be recovered. Figure 3b shows that the thermal conductivity of the irradiated Si nanowire can be further tuned through annealing.

High-dose regime—crystalline-amorphous transition. There is a steep drop in thermal conductivity when the dose further increases from 2.5×10^16 cm^-2 (inset of Fig. 1b). This demarcation between the low- and high-dose regimes indicates a phase transition in the material. We believe this phase change is the crystalline-amorphous transition of the Si nanowire arising from helium ion irradiation. For defect clusters and amorphous region in crystalline silicon nanowires, the phonon would be scattered differently. The defect clusters, which can be assumed to possess inner boundary if their size is large enough, have a relatively weak scattering for the phonon transport and the projected areas of defect clusters towards the heat-flow direction usually overlap, leading to the relative insensitive dependence of phonon transport on cluster size 49. Hence the thermal conductivity tapers off as the dose increases (for dose below the critical value of amorphous region creation). In an amorphous silicon region, the phonon would be scattered significantly by disorder. For amorphous silicon, the majority of heat carriers are diffusions, which are non-propagating and delocalized modes, and their contribution is predicted to be ~1 W m^-1 K^-1, according to the calculation by Allen-Feldman theory 50,51. The rest of the contribution is from the propagating propagons, which account for the remaining half of the thermal conductivity, due to their small proportions (around 3%). Thus, the existence of an amorphous region in defect-clustered crystalline silicon, if any, would greatly impede phonon transport.

In the low-dose regime, the disorder created by helium ions is mainly point defects, which agglomerate as the dose increases and the continuous aggregation of defects would change the crystalline lattice structure gradually in the silicon nanowires. When the dose goes beyond a critical value, the high energy ion-induced disorder can build up in crystalline silicon until its local free energy overcomes the energy barrier between the crystalline and amorphous phases. At this point, the defective crystalline lattice can collapse into amorphous phases 34. Once an amorphous region is formed, it promotes the growth of damage in surrounding regions which in turn leads to further amorphization 32. Finally, the entire irradiated region is amorphized.

This amorphization process can be visualized from the diffraction pattern of an irradiated Si nanowire prepared separately on a TEM grid. Figure 4a shows the bright-field image and diffraction pattern of an individual Si nanowire irradiated at two doses (7.5×10^16 cm^-2 and 2.5×10^16 cm^-2), using a focused electron beam with a spot size of 200 nm. The non-irradiated portion of the nanowire shows diffraction spots of single-crystal Si (inset(c)); for the portion with irradiation dose of 7.5×10^16 cm^-2, the nanowire is fully amorphous, leaving only short-range order among Si atoms, as indicated by the Debye-Scherrer rings 25 (inset(b)); for the irradiated portion with dose of 2.5×10^16 cm^-2, both Debye-Scherrer rings and diffraction spots can be seen
(inset(d)), indicating the coexistence of both amorphous and crystalline phases. Similar diffraction patterns for Sample #2 can also be seen in Supplementary Fig. 4a. The coexistence of both amorphous and crystalline phases explains why the thermal conductivity for doses below \(1 \times 10^{16} \text{cm}^{-2}\) is much higher than that for larger doses at the dose of \(2.5 \times 10^{16} \text{cm}^{-2}\), where both crystalline and amorphous phases coexist. However, the amorphous region rapidly takes over the entire volume for doses above \(7 \times 10^{16} \text{cm}^{-2}\). Finally, we observed that annealing could improve the amorphous region rapidly takes over the entire volume for annealing. Moreover, the interface between the irradiated area and the non-irradiated case.

Discussion

In this paper, we have demonstrated that the thermal conductivity of an individual Si nanowire can be changed by selective helium ion irradiation. A single Si nanowire was irradiated at different positions with well-controlled helium ion doses, and an electron beam heating technique was used to measure the local thermal conductivity along the nanowire, which was then related to helium ion dose.

We observed a clear transition from crystalline Si to amorphous phase at a dose between \(1.5 \times 10^{16}\) and \(2.5 \times 10^{16} \text{cm}^{-2}\) from the thermal conductivity versus dose curve. This result suggests a novel method to amorphize a Si nanowire without affecting its morphology. Moreover, within the dose regime in which only point defects are created, the Si nanowire thermal conductivity decreases drastically as the dose increases, and merely ~4% defects could reduce the thermal conductivity by ~70%, indicating a strong phonon scattering effect by the point defects. Within this regime, the effective scattering centres, inferred from parameter \(D\), initially increase linearly with dose, and then saturates for larger dose. Finally, we observed that annealing could improve the thermal conductivity of the damaged nanowire, and at 300 °C for 2 h, the thermal conductivity of a damaged portion irradiated with a dose of \(1 \times 10^{15} \text{cm}^{-2}\) could be recovered to the value of the non-irradiated case.

Methods

Sample preparation. Silicon nanowires with diameter ~160 nm (Sigma-Aldrich 736466) grown along the [111] direction dispersed in 2-propanol solution were drop-casted onto a SiO2/Si substrate. A single Si nanowire was picked up from the substrate by a nano-manipulator (Klenkied M3MA-EM) with a sharp tungsten probe and placed on a prefabricated suspended METS device. The METS device comprises two silicon nitride membranes, each of which is suspended by six long suspension beams for thermal isolation. Integrated on top of the silicon nitride substrate by a nano-manipulator (Kleindiek MM3A-EM) with a sharp tungsten needle attached to the SEM chamber operated at a power of 14 W in 0.4 Torr of air for 2 h, after which it was put into a helium ion microscope (Zeiss Orion Plus) chamber and pumped overnight. It was then irradiated by helium ions (~30–36 keV, 0.2–0.7 pA) with different doses at different positions (Fig. 5a). This was achieved with the help of a nanometre pattern generation system.

Eight samples were irradiated under similar helium ion energy and current (or dose rate) at room temperature. The SEM images of samples #2 to #8 are shown in Supplementary Fig. 1 and the irradiation details are shown in Supplementary Table 1. The highest dose (\(7 \times 10^{16} \text{cm}^{-2}\)) chosen is such that there is no significant sputtering of Si atoms, and a change in the Si nanowire diameter is not observable in a transmission electron microscope (TEM). The dose was then reduced to each irradiated position. The irradiation length and irradiation distance are different for all the measured silicon nanowires, the details of which are summarized in Supplementary Table 1.

Sample #3 was annealed in air at 120 °C for cumulative periods of 20, 40, and 160 h, with measurement by an electron beam heating technique carried out for each interval. After this, it was put into a tube furnace and annealed in forming gas at 300 °C for 2 h. To check for possible oxidation during annealing, HRTEM and diffraction pattern measurements of the post-annealed nanowire were carried out and the results are shown in Supplementary Fig. 5. The nanowire is observed to remain single-crystalline and an unavoidable intrinsic oxide layer of ~2.5 nm thickness is seen, which is similar to or even slightly smaller than that found in electron-etching silicon nanowires.

Thermal conductivity measurement by electron beam technique. In the electron beam heating technique, a focused electron beam is used as a localized heating source. By moving the electron beam along the nanowire and measuring the temperature raise (\(\Delta T_i\) and \(\Delta T_o\)) of the left and right sensors corresponding to the position of the electron beam \(x\) as measured from the left sensor, the cumulative thermal resistance \(R_i(x)\) between the electron beam location and the left sensor is:

\[
R_i(x) = R_0 \left( \frac{\Delta T_i}{\Delta T_o} \right)
\]

where \(x_i(x) = \Delta T_i(x)/\Delta T_o(x)\), and \(R_0\) is the equivalent thermal resistance of the six beams that link each suspended membrane to the environment as measured by the conventional thermal bridge method in which a 10 μA DC current was passed through the left Pt loop, raising its temperature (\(\Delta T_0\)) by ~8.5 K, and the temperature rise of both sensors (\(\Delta T_i, \Delta T_o\)) were measured from the resistance change of the Pt loops. Finally, \(x = \Delta T_i/\Delta T_o\).

From the \(R_i(x)\) curve, the spatially resolved thermal conductivity of the nanowire can be calculated as:

\[
\kappa = \frac{\pi d^2}{A R_i(x)}
\]

where \(A = \pi d^4/16\) and \(d\) is the diameter of the nanowire.

Acknowledgements

The authors thank Dr Ronugo Xie for useful discussions. This work is funded by grant MOE2011-T2-1-052 from the Ministry of Education, Singapore, and grant NRF- CRP902-050 from the National Research Foundation, Singapore.

Author contributions

Y.Z., D.L. and J.T.L.T. designed the experiment; Y.Z. and D.L. made the samples and performed the measurement; Y.Z., D.L., B.L. and J.T.L.T. wrote the paper; J.C. and L.Z. conducted the simulations; Y.Z., A.B., O.S.O., M.I.B., S.K., H.H. and D.S.P. carried out the irradiation works; Y.Z. and R.R.U. performed the TEM characterization; B.L. and J.T.L.T. directed the project.
