Cardiovascular Risk Reduction With Liraglutide: An Exploratory Mediation Analysis of the LEADER Trial

OBJECTIVE

The Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) trial (ClinicalTrials.gov reg. no. NCT01179048) demonstrated a reduced risk of cardiovascular (CV) events for patients with type 2 diabetes who received the glucagon-like peptide 1 receptor agonist liraglutide versus placebo. The mechanisms behind this CV benefit remain unclear. We aimed to identify potential mediators for the CV benefit observed with liraglutide in the LEADER trial.

RESEARCH DESIGN AND METHODS

We performed exploratory analyses to identify potential mediators of the effect of liraglutide on major adverse CV events (MACE; composite of CV death, nonfatal myocardial infarction, or nonfatal stroke) from the following candidates: glycated hemoglobin (HbA1c), body weight, urinary albumin-to-creatinine ratio (UACR), confirmed hypoglycemia, sulfonylurea use, insulin use, systolic blood pressure, and LDL cholesterol. These candidates were selected as CV risk factors on which liraglutide had an effect in LEADER such that a reduction in CV risk might result. We used two methods based on a Cox proportional hazards model and the new Vansteelandt method designed to use all available information from the mediator and to control for confounding factors.

RESULTS

Analyses using the Cox methods and Vansteelandt method indicated potential mediation by HbA1c (up to 41% and 83% mediation, respectively) and UACR (up to 29% and 33% mediation, respectively) on the effect of liraglutide on MACE. Mediation effects were small for other candidates.

CONCLUSIONS

These analyses identify HbA1c and, to a lesser extent, UACR as potential mediators of the CV effects of liraglutide. Whether either is a marker of an unmeasured factor or a true mediator remains a key question that invites further investigation.

Liraglutide is a glucagon-like peptide 1 receptor agonist (GLP-1 RA) approved for the management of hyperglycemia in type 2 diabetes and for reduction of cardiovascular (CV) risk in patients with type 2 diabetes and clinical CV disease (CVD) (1,2). It is also approved at a higher dose for the treatment of obesity (3,4). The Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) trial was initiated to assess the CV safety of liraglutide in patients with type 2 diabetes and...
showed that it reduced the risk of CV events, all-cause mortality, and renal events compared with placebo (5,6).

Typical CV risk factors associated with type 2 diabetes (glycemic control, body weight, blood pressure, and lipid profiles) are improved by GLP-1 RAs, including liraglutide (7). During the LEADER trial, liraglutide reduced glycated hemoglobin (HbA1c) and body weight, along with small but significant reductions in systolic blood pressure (6). Liraglutide has also shown multiple direct anti-inflammatory and antiatherosclerotic effects in non-clinical studies (7,8). Given these numerous effects of GLP-1 RAs, it is a challenge to pinpoint the relevant mechanisms underlying the CV benefit of liraglutide (7,9). Mediation analyses allow investigation of the associations among known, measured variables, such as the aforementioned risk factors, and outcomes, but do not necessarily identify causality.

In the present exploratory analyses, we sought to identify potential mediators for the CV benefit observed with liraglutide using data from the LEADER trial. We explored these with several mediation methods, including a new statistical methodology designed to integrate sequential confounders (a limitation of existing methods for mediation analysis) (10).

RESEARCH DESIGN AND METHODS

Trial Design
The double-blind, randomized, placebo-controlled LEADER trial assessed the CV safety of liraglutide in the context of standard care in patients with type 2 diabetes, HbA1c ≥7% (≥53 mmol/mol), and a high risk for CVD (aged ≥50 years with established CVD or chronic kidney disease stage 3 or greater or ≥60 years with at least one risk factor for CVD, defined fully in the protocol available as supplementary material to the primary publication [6]). Patients were randomly assigned double-blind, 1:1 to once-daily injections of liraglutide (1.8 mg or maximum tolerated dose) or placebo, both in addition to standard-of-care treatment for type 2 diabetes and other CV risk factors, with a follow-up period of 3.5–5 years (6).

The primary end point was the time to first occurrence of a major adverse CV event (MACE), including CV death, non-fatal myocardial infarction, or nonfatal stroke (6). Secondary end points included the individual components of the primary composite end point and all-cause death (6). Other variables assessed during the trial included: HbA1c, body weight, waist circumference, fasting lipids, systolic blood pressure, diastolic blood pressure, pulse rate, biochemical and hematological parameters, calcitonin levels, anti-liraglutide antibodies, urinary albumin-to-creatinine ratio (UACR), the occurrence of hypoglycemia, adverse events, and concomitant medication use.

Mediation Analyses
Exploratory analyses were conducted to divide the total effect of liraglutide on time to first MACE, and other time-to-event outcomes, into an indirect effect (also known as mediated effect) and a direct effect (also known as remaining effect). The indirect effect may be interpreted as the difference in time to event between liraglutide and placebo that could be explained by a difference in another variable such as body weight or HbA1c, which we will refer to as the mediator. The direct effect is, in contrast, the effect that remained after controlling for the mediator.

Analyses were performed using methods based on a Cox proportional hazards model, which we refer to hereafter as Cox methods, and a new, more complex method, termed the Vansteelandt method (10).

Cox Methods
Preliminary analyses were performed using two variants of a Cox proportional hazards model to estimate the direct effect:

1. Analysis including the change from baseline in the potential mediator over time as a time-dependent covariate. At any given time point, the most recent change from baseline in the mediator, before the occurrence of the outcome in question, was included as a covariate. Until the first mediator assessment after baseline, the change was 0. This was one of two approaches used by Inzucchi et al. (11) to evaluate mediated effects on CV death in the BI 10773 (Empagliflozin) Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients (EMPA-REG OUTCOME) trial.

2. Analysis including the updated mean value of the potential mediator (before the occurrence of the outcomes in question), calculated as the trapezoidal area under the curve divided by time, as a time-dependent covariate. This was the other approach used by Inzucchi et al. (11) with the intention of capturing the cumulative effect of all prior values of the mediator on the outcome, in contrast to the acute effect in the first approach above.

These two approaches were performed as separate Cox regression analyses for each potential mediator with randomized treatment as a factor and the baseline mediator value as an additional covariate to estimate the direct effect as a log hazard ratio (HR). The total effect was estimated using a model with only treatment as a factor, and the indirect (mediated) effect was estimated as the difference between total and direct effects.

Vansteelandt Method
The Cox analyses have shortcomings in that they may not capture the full complexity of the mediator and prohibit adequate control for confounding. Furthermore, they do not immediately lend themselves to a counterfactual interpretation (conceiving outcomes in conditions altered from those that were observed) as used in the modern theory of mediation analysis (12). As the main approach for our mediation analysis, we applied a new statistical method proposed by Vansteelandt et al. (10) that addresses these shortcomings and is tailored for time-to-event end points with repeatedly measured mediators.

With this new method, the direct treatment effect was estimated as the difference between probabilities of event-free survival (i.e., proportions of patients without any event) in liraglutide and placebo groups, instead of an HR. It involved estimation of the counterfactual probability that a patient in the liraglutide group would be event-free at a given time if their mediator values changed to the levels that would have been seen if the patient had been assigned to placebo. Alternatively, this may be interpreted as the survival curve for the liraglutide group after adjusting the mediator values to match those observed in the placebo group. Similar to the Cox method using the updated mean, the Vansteelandt method is based on a dynamic model that incorporates new values of the mediator as they become
available over time. However, with the Vansteelandt method, mediator values are not summarized into a mean, but are added to the model as separate covariates. The method is therefore more likely to detect a mediated effect if present. All analyses undertaken allowed adjustment for baseline covariates. However, the Vansteelandt method may also adjust for postbaseline confounders, such as concomitant medication, by including them as covariates in the models. Further details of this method have been published separately (10).

The direct effect was estimated as the difference between adjusted survival curve for the liraglutide group (mediator values adjusted to match those in the placebo group) and the actual survival curve for the placebo group. The actual curve was estimated by the same method but using each patient’s actual mediator values as covariates.

To estimate the indirect (mediated) effect, the adjusted survival curve for the liraglutide group was compared with the actual curve for the same group. The total effect was estimated by comparing the actual curve for the liraglutide group with the actual curve for the placebo group.

The percentage mediation was calculated as the ratio between the indirect and total effects. Complete mediation would be indicated by a percentage mediation of 100%. The percentage mediation was evaluated and presented at 3 years because this time point corresponds to the last scheduled visit, which all patients should have attended. Thereafter, the number of patients under observation for MACE decreased over time, leading to an increased statistical uncertainty of the estimated survival curves. A CI for the percentage mediation was estimated using a bootstrap resampling procedure. Because the calculation was highly computer intensive, a CI was only calculated for the strongest candidate for mediation.

**Identifying Potential Mediators**

Potential mediators examined in all methods included candidate variables on which liraglutide had a clear treatment effect and that could be related to MACE (HbA1c, body weight, UACR, confirmed hypoglycemic episodes, sulfonylurea use, and insulin use) and candidate mediators on which liraglutide had a modest treatment effect and that could be related to MACE (systolic blood pressure and LDL cholesterol) (Table 1). These previously published treatment effects were evaluated at month 36 (6), but the mediation analyses undertaken in this study are based on the mediator values indicated in the preceding sections, such as the value at 6 or 12 months, the most recent value, or all values updated over time before the event in question. Each candidate was analyzed separately using the two Cox methods and the Vansteelandt method to explore if it was a potential mediator for MACE.

Additional analyses were performed using the Vansteelandt method for the candidate with the highest apparent degree of mediation as the mediator:

1. Analysis of time to first MACE including the other candidate mediators as confounders.
2. On-treatment analysis of time to first MACE (i.e., an analysis excluding events occurring while the patient was off treatment for >1 day).

### RESULTS

In the LEADER trial, 9,340 patients were randomized to liraglutide (N = 4,668) or placebo (N = 4,672), in addition to standard-of-care therapy, with a median follow-up of 3.8 years and a median exposure to study drug of 3.5 years (6). To begin this mediation analysis, the published LEADER results were examined (6). Several risk factors were improved in patients in the liraglutide versus placebo groups (Table 1) and hence were analyzed as potential mediators of the previously reported benefit of liraglutide treatment for MACE (HR 0.87 [95% CI 0.78; 0.97]) (6).

| Systolic blood pressure, mmHg     | ETD: −1.2 (−1.9; −0.5)*                         | −3.3 |
| LDL cholesterol                   | ETR: 0.98 (0.96; 0.99)*                         | −3.0 |
| Patients who initiated insulin use during the trial, n (%) | 1,336 (28.8) vs. 2,019 (43.2)                   | —    |
| Patients who initiated SU use during the trial, n (%) | 349 (7.5) vs. 505 (10.8)                        | —    |

ETD, estimated treatment difference; ETR, estimated treatment ratio; SU, sulfonylurea. *Change from baseline to 36 months (ETR was used when the data were log-transformed, due to their known distributions).
Cox Methods to Determine Potential Mediators of MACE
Mediation analyses using the Cox methods indicated a mediation effect of HbA1c (Table 2). While there was only a very small mediation effect using the change from baseline as a time-dependent covariate, analysis with the updated mean indicated that HbA1c could be a substantial mediator for the treatment effect of liraglutide on MACE (Table 2). The same analyses with the other potential mediators demonstrated at most a small effect size, with the possible exception for UACR (Table 2).

Vansteelandt Method to Determine Potential Mediators of MACE
Mediation analysis using the Vansteelandt method (10) also indicated that HbA1c was the most promising candidate among those studied as a potential mediator (Fig. 1 and Table 3). When adjusted for HbA1c, the survival curve (proportion of patients without MACE) for patients randomized to liraglutide treatment shifted down toward the placebo curve. This indicated a reduced CV benefit in the liraglutide group when the difference in HbA1c between the liraglutide and placebo groups was modeled as a mediator for the MACE results (Fig. 1 and Table 3). A potential small mediation effect was observed with UACR (Table 3), but the estimated mediation was relatively small for the other candidates (~<20%) (Table 3).

The estimated contribution of HbA1c as a mediator to the effect of liraglutide on MACE at 3 years was 82.0% (95% CI 11.7; 449.3), with the direct effect of liraglutide accounting for the remaining 18% of the total observed CV benefit (Fig. 1 and Table 3). Because there was no clear mediation through any other candidate variable, none of them would be likely to confound the mediation through HbA1c. Nevertheless, the analysis was repeated with body weight, UACR, systolic blood pressure, LDL cholesterol, confirmed hypoglycemic episodes, sulfonylurea use, and insulin use included as confounders in the model. The indirect effect of liraglutide on MACE mediated by HbA1c was estimated to be 69.2%, which is consistent with the analysis without confounders considering the uncertainty in the estimates (Supplementary Fig. 1).

Vansteelandt Method Investigating All-Cause Death and CV Death
The same types of analyses were applied to all-cause death and CV death. The effects of liraglutide on these end points in LEADER appeared to be mediated by HbA1c to some extent (Supplementary Fig. 4).

CONCLUSIONS
These mediation analyses of the LEADER trial data, with the Cox methods and the new Vansteelandt method, suggest that HbA1c could be a significant mediator of the CV benefits observed with liraglutide. There was no evidence for a mediation effect with any other candidates that mediation the effects of liraglutide on MACE mediated by HbA1c was estimated to be 69.2%, which is consistent with the analysis without confounders considering the uncertainty in the estimates (Supplementary Fig. 1).

On-treatment analysis (excluding MACE that occurred when a patient was off treatment) showed a slightly stronger mediation effect for HbA1c of 93% than the 82% observed in the first Vansteelandt mediation analysis (without confounders) (Supplementary Fig. 2). The reversed adjustment analysis showed a lower but still substantial percentage mediation by HbA1c of 47% (Supplementary Fig. 3).

### Table 2—Cox modeling for mediation of time to first MACE with liraglutide versus placebo by HbA1c, body weight, UACR, SBP, LDL cholesterol, confirmed hypoglycemic episodes, SU use, and insulin use, assessed using two approaches

| Analysis | Risk of MACE with liraglutide vs. placebo, HR (95% CI) | Percentage mediation (95% CI)* |

were assessed in the trial, with the possible exception of UACR. A mediation effect of HbA1c on mortality was also observed. However, it is important to note that these analyses cannot distinguish between the possibilities that HbA1c could be a mediator or a marker of unmeasured factors that are also affected by treatment with liraglutide and that themselves affect CV outcomes. For example, a large change in HbA1c could be indicative of adherence to treatment, including concomitant medications. Contrary to the hypothesis that HbA1c could be acting as a marker of treatment adherence, an on-treatment analysis showed treatment adherence was unlikely to be a confounding factor, as the percentage mediation was not reduced compared with the main analysis. A related hypothesis is that HbA1c could be acting as a marker of exposure to liraglutide specifically, but this was not supported by the reversed adjustment analysis in which the association between HbA1c and CV outcomes was also apparent in the placebo group.

Modern CV outcome trials with the GLP-1 RA lixisenatide, dipeptidyl peptidase 4 inhibitors (alogliptin, saxagliptin, and sitagliptin), and insulin (insulin glargine), on a background of standard-of-care therapy, showed CV safety but failed to show benefits on CV outcomes despite improvements in HbA1c in the active- versus placebo-treatment groups (13–17). More recently, results from other CV outcome trials have shown CV benefits for the sodium–glucose transporter 2 (SGLT2) inhibitors empagliflozin and canagliflozin and the GLP-1 RAs liraglutide, semaglutide, albiglutide, and dulaglutide (6,18–22). In others, non-significant trends for reductions in CV events (MACE) were reported (for dapagliflozin: SGLT2 inhibitor; for exenatide [once weekly] and semagluate [oral]: GLP-1 RAs) (23–25). Changes in HbA1c from baseline with the study treatment versus placebo in these more recent trials ranged from −0.36% to −1.0% (6,18–22), which were marginally larger than changes in the previous trials that showed no CV benefits (range of changes in HbA1c: −0.2% to −0.36% [13–17]). These modest changes in HbA1c across all of these trials with varying CV outcome results (including variation within drug classes) suggest that mechanisms other than reductions in HbA1c account for the CV benefits with liraglutide, semaglutide, albiglutide, dulaglutide, empagliflozin, and canagliflozin (6,13–25).

Epidemiological data support the association between HbA1c and CV and mortality outcomes (26,27). Data from >250,000 people in the Swedish National Diabetes Register found that HbA1c was a strong predictor of all-cause death, myocardial infarction, stroke, and heart failure (27). These epidemiological data appear to be supported by a meta-analysis using results from early CV outcome trials of intensive glucose control in patients with type 2 diabetes (UK Prospective Diabetes Study [UKPDS], Action in Diabetes and Vascular Disease:

SBP, systolic blood pressure; SU, sulfonylurea.
Preterax and Diamicron MR Controlled Evaluation [ADVANCE], Veterans Affairs Diabetes Trial [VADT], and Action to Control Cardiovascular Risk in Diabetes [ACCORD]—all trials with varying results for CV benefits) showing modest benefits for CV outcomes (28). Taken as a whole, the data strongly suggest that the choice of therapies used to reduce HbA1c, and not just HbA1c reduction itself, has an important impact on CV outcomes.

For SGLT2 inhibitors, it has been proposed that hemodynamic effects—reducing blood pressure and intravascular volume—and diuretic effects could be underlying mechanisms for the CV benefits (29,30). These hypotheses are supported by a mediation analysis of data from EMPA-REG OUTCOME, which identified hematocrit and hemoglobin, markers of effects on plasma volume, as potential key mediators for the effects of empagliflozin on CV death, with smaller mediation effects attributed to renal function and glycemic control (11). Though HbA1c appears to have a smaller mediation effect relative to hematocrit and hemoglobin for empagliflozin, it was identified as a potential mediator in the EMPA-REG OUTCOME trial based on simple Cox methods (11). The EMPA-REG OUTCOME analyses showed that change from baseline HbA1c mediated 3% of the effect of empagliflozin on CV death, while updated mean HbA1c mediated 23% of the effect, suggesting a greater impact of chronic exposure to elevated HbA1c during the trial (11). Similarly, our analyses of LEADER data using the same two Cox methods (but with the primary end point of time to first MACE) showed little effect of change as a time-dependent covariate, but a larger mediation effect of updated mean HbA1c.

The percentage mediation of HbA1c in LEADER is difficult to compare across different analysis methods that we used. However, the Cox analyses appeared to support the main Vansteelandt mediation analyses in identifying HbA1c as the main candidate for a mediator, among those analyzed, of the effect of liraglutide on CV outcomes.

The occurrence of hypoglycemia was shown to be associated with an increased risk of CV events in LEADER (31). However, beyond HbA1c and UACR, little to no mediation effect was identified for the other candidates analyzed, including hypoglycemia. We therefore speculated that factors such as reduction in hypoglycemia combined with a reduction in HbA1c with liraglutide might explain the apparent mediation by HbA1c. However, results were largely unchanged when hypoglycemia was included as a confounder (along with other candidates in the mediator model).

Our mediation analyses were post hoc, and, in contrast to the primary analysis of the trial, they are not protected against confounding through patient randomization. The inability to distinguish true mediators from markers is the key limitation of this present and other published mediation analyses. Our analyses are limited by the trial data; only candidate mediators that were examined or measured during the trial could be evaluated. Future trials may help to allow examination of a wider range of potential mediators through collection of biobank samples. However, even in a large trial sample like LEADER, it was not possible to estimate the percentage mediation with precision. The estimates were subject to substantial uncertainty reflected by the wide CI for the percentage mediation through HbA1c. It is important to note that there is uncertainty in the total treatment effect of liraglutide in the primary analysis that constitutes the starting point for this mediation analysis and that, based on the 95% CI, could be a 3–22% reduced risk of MACE compared with placebo (6). Furthermore, although the Vansteelandt method has the advantage that it improves the ability to detect a mediated effect, it does not allow us to distinguish what components of the mediator might contribute to the mediated effect (i.e., whether it is the early response, the average level over time within patients, the variability within patients, or a combination of several such components). Also, this analysis was limited to MACE, which is comprised of several individual CVDs, all of which have potentially different underlying pathologies and therefore mediators. These limitations emphasize that the results should be interpreted with caution and only be considered hypothesis generating.

In summary, these mediation analyses have identified HbA1c as a potential mediator of the CV effects of liraglutide. We did not identify any mediation effects for less well-studied but possible candidate mediators, which are also risk factors for CV events, including weight and hypoglycemia. Similar to all other mediation analyses, we cannot necessarily infer causality, and whether HbA1c is a marker of an unmeasured factor or a true mediator remains a key question. Based on existing evidence, we consider it unlikely that HbA1c is a true mediator of the CV benefit observed with liraglutide, and this finding warrants further investigation.
