Effects of dietary inclusion with rapeseed cake containing high glucosinolates on nitrogen metabolism and urine nitrous oxide emissions in steers

Jian Gao, Bingbing Cheng, Yanfeng Sun, Yuchao Zhao, Guangyong Zhao*

State Key Laboratory of Animal Nutrition, College of Animal Science and Technology, China Agricultural University, Beijing 100193, China

1. Introduction

Nitrous oxide (N\textsubscript{2}O) is a potent greenhouse gas with a global warming potential about 296 times greater than carbon dioxide (CO\textsubscript{2}) (WMO, 2017). Livestock farming results in approximately 53\% of the anthropogenic N\textsubscript{2}O emissions, which are equal to 39.3\% of the total agricultural N\textsubscript{2}O emissions (FAO, 2015). The N\textsubscript{2}O emissions from livestock are considerably emitted from the excreta deposition, particularly the urine from grazing animals (Di and Cameron, 2002).

N\textsubscript{2}O is produced from the excreta of animals during storage and fertilization in the processes of nitrogen (N) transformation by microorganisms (Clough et al., 2020). Four pathways including nitrifier nitrification, nitrifier denitrification, denitrification, and nitrification coupled denitrification by denitrifiers are identified for N\textsubscript{2}O formation in soil (Zhu et al., 2013). Nitrification is the metabolic pathway by which microorganisms oxidize...
ammonium (NH$_4^+$) to produce nitrate (NO$_3^-$) with several intermediate products including hydroxylamine and nitrite (NO$_2^-$), while denitrification is the pathway by which microorganisms reduce NO$_3^-$ to nitrogen gas (N$_2$) with several intermediate products including NO$_2^-$, nitric oxide (NO) and N$_2$O (Levy-Booth et al., 2014). The N$_2$O emissions from urine are generally higher than emissions from feces in cattle because urea accounts for the major part of urinary N (Dijkstra et al., 2013) which could be easily degraded into NH$_4^+$–N and used as the precursor of N$_2$O in soil (Whitehead et al., 1989).

Approaches to mitigate N$_2$O emission from animal excreta include decreasing the total N excretion, regulating the fecal N-to-urinary N ratio, and supplementing tannins and tannic acids to rations (Zhao, 2017; Zhao et al., 2020; Zhou et al., 2019). A recent method to mitigate the N$_2$O emissions from the urine patches of grazing ruminants is to use dicyandiamide (DCD) which is an exogenous nitrification inhibitor (NI). It was reported that DCD loading within urine patches at 10 to 30 kg DCD/ha reduced the N$_2$O emission factor (EF3, % N applied) by 34% to 64% (Minet et al., 2018). However, it is difficult to achieve a synchronism between the urinary N loading and the DCD application (Clough et al., 2020) because DCD is easily degraded in soil (McGeough et al., 2016). Supplemeting DCD in the ration of dairy cows effectively reduced the urine N$_2$O–N emissions because part of DCD was excreted into urine (Minet et al., 2018). However, about 1% of orally administered DCD to lactating dairy cows was recovered in milk (Welten et al., 2016), suggesting the potential negative effects of feeding DCD on milk quality and human health. Thus, it is necessary to find efficient endogenous NI that could be excreted into ruminant urine.

It was reported that the N$_2$O emission from the urine of sheep fed fresh forage rape (Brassica napus L.) was much lower than fed fresh perennial ryegrass (Lolium perenne L.) (EF3 0.11% vs. 0.27%) and it was inferred that the effect could be caused by glucosinolates (GLS) in forage rape (Luo et al., 2015). In a laboratory static incubation, it was found that adding different types of iso-thiocyanates (ITC) from GLS hydrolysis decreased the N$_2$O emissions from the soil applied with urea to different extents, while adding phenethyl ITC reduced the N$_2$O emission by 51% (Balvert et al., 2017), indicating direct addition of ITC effectively inhibited the soil microbes such as NH$_4^+$-oxidizing bacteria (Bending and Lincoln, 2000; Aires et al., 2009). These results suggested that the metabolites excreted in urine from brassica forages had inhibitive effects on the urine N$_2$O emissions in ruminants. However, Hoogendoorn et al. (2016) reported that the EF3 of N$_2$O from the urine of sheep grazing on forage rape (Brassica napus L.) was higher than on the perennial ryegrass/white clover pasture (L. perenne L./Trifolium repens). Balvert (2018) also reported that the total N$_2$O emissions of urine from cattle fed kale (Brassica oleracea L.) were higher than fed the perennial ryegrass/white clover pasture (L. perenne L./T. repens). The reasons for the contradictory results are unclear and the effects of Brassica forages on N$_2$O emissions are inconclusive.

Rapeseed cake (RSC), which is the by-product of rapeseeds after oil extraction, is an important protein supplement for livestock and also contains high levels of GLS. The objectives of this study were to investigate the effects of dietary inclusion of RSC containing high GLS on the N metabolism and urinary nitrogenous components in steers, to clarify if the metabolites of GLS in RSC could be excreted into steer urine, to explore the effects of the metabolites on the urine N$_2$O emissions, and to elucidate the mechanisms of the effects of GLS and metabolites on the urinary composition and animal health using plasma metabolome.

### Table 1

**Ingredients and nutritional composition of the experimental rations (DM basis).**

| Item                             | Dietary levels of RSC, % DM |
|----------------------------------|-----------------------------|
|                                 | 0   | 2.7 | 5.4 | 8.0 |
| **Ingredients, %**              |     |     |     |     |
| Corn                            | 27.50 | 28.30 | 28.90 | 29.15 |
| Corn gluten meal                | 5.60  | 3.73  | 3.00  | 0.10  |
| Soybean meal                    | 5.35  | 4.32  | 3.20  | 2.20  |
| RSC                             | 0.00  | 2.65  | 5.35  | 8.00  |
| Sodium chloride                 | 1.00  | 1.00  | 1.00  | 1.00  |
| Sodium bicarbonate              | 1.00  | 1.00  | 1.00  | 1.00  |
| Premix                          | 2.00  | 2.00  | 2.00  | 2.00  |
| Cereal silage                   | 57.55 | 57.00 | 56.55 | 56.55 |
| Total                           | 100.00 | 100.00 | 100.00 | 100.00 |
| **NUTRITIONAL COMPOSITION**     |     |     |     |     |
| NEmf, MJ/kg                     | 5.42  | 5.50  | 5.48  | 5.48  |
| OM, %                           | 89.52 | 89.42 | 89.41 | 89.68 |
| CP, %                           | 11.96 | 12.06 | 12.04 | 11.93 |
| RDP, % CP                       | 64.53 | 63.52 | 61.42 | 58.18 |
| RUP, % CP                       | 35.47 | 36.48 | 38.58 | 41.82 |
| ADIP, % CP                      | 7.85  | 8.45  | 9.11  | 10.09 |
| Neutral detergent fiber, %      | 44.85 | 44.14 | 44.52 | 44.91 |
| Acid detergent fiber, %         | 25.54 | 25.49 | 25.99 | 26.46 |
| Ether extract, %                | 1.49  | 1.80  | 1.82  | 2.05  |
| GLS and metabolites, mmol/g     | 0.00  | 0.59  | 12.10 | 18.09 |
| SCN                             | 0.00  | 0.01  | 0.02  | 0.03  |
| Total                           | 0.00  | 6.00  | 12.12 | 18.12 |

**DM** – dry matter; **RSC** – rapeseed cake; **NEmf** – net energy for maintenance and fattening; **OM** – organic matter; **CP** – crude protein; **RDP** – rumen degradable protein; **RUP** – rumen undegradable protein; **ADIP** – acid detergent insoluble protein; **GLS** – glucosinolates; **SCN** – thiocyanate.

1 Provided per kilogram DM of ration: 54 mg Zn (ZnSO$_4$); 70 mg Fe (FeSO$_4$); 38 mg Mn (MnSO$_4$); 12.8 mg Cu (CuSO$_4$); 1.2 mg I (KI); 0.17 mg Se (Na$_2$SeO$_3$); 0.6 mg Co (Co$_3$O$_4$); 2.31 mg vitamin A; 75 µg vitamin D$_3$.

2 NEmf was calculated according to Feng (2000).

3 The contents of RDP and RUP were calculated according to NRC (2001) based on the nitrogenous fractions of feeds analyzed using the methods of Licitra et al. (1996).
feces from each animal was recorded, and 2% of the total was sampled and mixed with 20 mL H₂SO₄ (10%, vol/vol) per 100 g of feces to keep the pH < 3.0 to prevent the N loss. The total urine from each animal was also collected using a rubber funnel connected by polyvinyl chloride pipe to a plastic barrel surrounded by ice packs. The daily urine output was recorded and homogenized, and 1% of the total urine from each steer was sampled and mixed with 10 mL H₂SO₄ (10%, vol/vol) per 70 mL urine to keep the pH < 3.0 to prevent the N loss, while another urine sample was taken without adding H₂SO₄. The feeds were also sampled daily during the sampling periods. All the samples were stored at −20 °C for later analysis. A blood sample was taken from the jugular vein of each animal 3 h after feeding in the morning on the last day of each experimental period. The blood samples were centrifuged at 2,000 rpm, and the 2 successive sampling time points (0 and 20 min) was found to be linear (R² > 0.99) (Bao et al., 2018), 2 gas samples taken from the jugular vein of each animal were used for soil sampling. At the end of incubation, the last 3 jars of each urine sample used for determining the daily N₂O–N emissions were also used for soil sampling. All the soil samples were stored at −20 °C.

2.4. Chemical analysis

2.4.1. Feeds, feces and urine

The feeds and the corn silage were lyophilized using a LQJ-12 freeze dryer (Beijing Songyuan Huaxing Technology Development Co., Ltd, Beijing, China). The fecal samples were milled using a mortar with a pestle and the daily fecal samples from each animal during each experimental period were composited as one sample. The freeze-dried corn silage and other feeds were ground and screened through a sieve with a pore size of 1 mm.

The DM in feeds and feces was determined in an oven at 105 °C using the AOAC method No. 934.01 (2012). The crude ash and ether extract (EE) of feeds were determined using AOAC (2012) methods No. 942.05 and 920.39, respectively. The organic matter (OM) content was calculated by DM minus crude ash. The neutral detergent fiber (aNDF) and acid detergent fiber (ADF) of feeds inclusive of residual ash were analyzed on an Ankom A200i Fiber Analyzer (Ankom Technology Corp., USA) using the methods of Van Soest et al. (1991). The rumen degradable protein (RDP) and rumen undegradable protein (RUP) of feeds were predicted according to NRC (2001) based on the nitrogenous fractions of feeds (PA, PB1, PB2, PB3, PC) analyzed using the methods of Licitra et al. (1996). The total N of feeds, feces and urine was analyzed using the Kjeldahl procedures according to AOAC (2012) method no.988.05. The CP content of feeds was calculated by the total N content multiplied by 6.25.

Urinary urea and creatinine were analyzed by colorimetric methods using commercial kits (Nanjing Jiancheng Bioengineering Institute, Jiangsu, China) on an ultraviolet spectrophotometer (UV-1801, Beijing Beifen Ruli Analytical Instrument Co., Ltd, Beijing, China). The urinary hippuric acid was analyzed according to China Hygienic Standard (WS/T 52-1996a). The urinary purine derivatives (PD) including uric acid and allantoin were analyzed according to the methods of Chen and Ørskov (2004). The urinary thiocyanate (SCN) was analyzed according to China Hygienic Standard (WS/T 39-1996b). The urinary goitrin and ITC were analyzed using the methods of Thomke et al. (1998) and Matthaus and Fiebig (1996), respectively. The GSH in RSC was extracted using the method of Tholen et al. (1989) and analyzed using the method of Wathelet et al. (1988) with slight modification.

2.4.2. Analysis of plasma biochemical indices

The plasma total protein (TP), albumin (ALB), total cholesterol (TC), triglyceride, glucose and urea were analyzed on a biochemical analyzer (A7, Beijing Shining Sun Technology Co., Ltd, Beijing, China) using commercial kits (BioSino Bio-Technology and Science Inc., Beijing, China). The plasma total antioxidant capacity (T-AOC) was analyzed using commercial kit (HY-60021, Beijing Sino-UK Institute of Biological Technology, Beijing, China) on a biochemical analyzer (A7, Beijing Shining Sun Technology Co., Ltd, Beijing, China). Considering metabolites of GSH could cause the goiter of animals (Halkier and Gershenzon, 2006), the plasma triiodothyronine (T₃) and thyroxine (T₄) were analyzed using enzyme-linked immunosorbent assay (ELISA) kits (BioSino Bio-Technology and Science Inc., Beijing, China) on a microplate reader (DR-200BS, Wuxi Hiwell Diatек Instruments Co., Ltd, Jiangsu, China). The plasma SCN was analyzed according to China Hygiene Standard (WS/T 39-1996b). The plasma goitrin and ITC were analyzed using the methods of Thomke et al. (1998) and Matthaus and Fiebig (1996), respectively.
2.4.3. Analysis of plasma metabolome

The extraction of plasma metabolites from the animals fed 0 and 8.0% RSC rations for LC/MS analysis was according to the method of Wang et al. (2019). Briefly, 100 μL of each plasma sample was mixed with 300 μL of the extracted solution (acetoniitrile:methanol = 1:1, vol/vol) and 20 μL of the internal standard (DL-o-chlorophenylalanine). The mixture was homogenized on a high throughput tissue crusher (Wondoie-96c, Shanghai Wando Biotechnology Co., Ltd, Shanghai, China) at 50 Hz for 6 min, followed by vortex treatment for 30 s and ultrasonic treatment at 40 kHz for 30 min at 5 °C. The mixture was centrifuged at 13,000 x g for 15 min at 4 °C and the supernatant was used for LC/MS analysis.

The LC/MS analysis was performed using a UPLC-TripleTOF system (AB Sciex, Framingham, MA, USA) with a Waters Acquity HSS T3 column (100 mm x 2.1 mm i.d., 1.8 μm, Waters, Milford, MA, USA) preheated to 40 °C. The volume of each sample for injection was 10 μL. The mobile phase consisted of 0.1% (vol/vol) formic acid in water (phase A) and 0.1% (vol/vol) formic acid in a mixture of acetonitrile and iso-propanol (1:1, vol/vol) (phase B) at a flow rate of 0.40 mL/min. The elution gradient was used as: 0 to 3.0 min, 5% to 20% phase B; 3.0 to 9.0 min, 20% to 95% phase B; 9.0 to 13.0 min, 95% phase B; 13.0 to 13.1 min, 95% to 5% phase B; 13.1 to 16 min, 5% phase B. The parameters of the electron spray ionization (ESI) source were set according to Liu et al. (2019). The quality control (QC) samples were prepared by mixing all extracted plasma samples and were injected at regular intervals (every 5 samples).

2.4.4. Processing of metabolome data

The LC/MS raw data were generated by Waters MassLynx Software (version 4.1, Waters Corporation, Milford, MA, USA). The Progenesis QI (version 2.3, Nonlinear Dynamics, Newcastle, UK) was used to process the raw data for peak detection and alignment. The human metabolome database (HMDB, http://www.hmdb.ca/) and the Metlin database (http://metlin.scripps.edu/) were used to identify the metabolites. The multivariate statistical analyses including the principal component analysis (PCA) and the orthogonal partial least squares discrimination analysis (OPLS-DA) were performed using the ropls package (version 1.6.2, R software) from Bioconductor on Majorbio Cloud Platform (https://cloud.majorbio.com). The differential metabolites between treatments were identified based on the variable importance (VIP) from the OPLS-DA analysis and the student’s t-test (VIP > 1 and P < 0.05). The fold-change (FC) value of each metabolite was calculated by comparing the means of the peak area, and the log2FC value was used to indicate the specific variable quantity in the comparison.

2.4.5. Analysis of N2O in gas and NO3-N and NH4+-N in soil

The N2O concentration of the gas samples was analyzed according to the method of Bao et al. (2018) on a gas chromatograph (3420A, Beijing Beifen Tianpu Instrument Technology Co. Ltd, Beijing, China) equipped with an electron capture detector (ECD). 2 Porapak Q columns (2 m in length, 3 mm in internal diameter, Beijing Beifen Tianpu Instrument Technology Co. Ltd, Beijing, China). The NO3−-N and NH4+-N of soil samples were analyzed according to China National Standard (GB/T 32737-2016) and China National Environmental Protection Standard (HJ 634-2012) on a spectrophotometer (K5500, Beijing Kaiao Technology Development Co., Ltd, Beijing, China), respectively.

2.5. Calculations

The rumen microbial N flow was predicted according to the method of Chen and Orskov (2004) based on the total urinary PD output including uric acid and allantoin:

\[ Y = 0.85X + 0.147BW^{0.75}, \]

where \( Y \) refers to the total urinary PD (mmol/d); \( X \), the absorbed PD (mmol/d); \( BW^{0.75}, \) the metabolic body weight of steers (kg); 0.85, the recovery rate of absorbed purines as PD in urine; 0.147, the endogenous PD excretion (mmol/kg BW^{0.75} per d).

Microbial N flow = \((X \times 70)/(0.116 \times 0.83 \times 1.000)\)

= 0.727X,

where the unit for microbial N flow is g/d; \( X \) refers to the absorbed PD (mmol/d); 70, the N content of purines (mg N/mmol); 0.116, the ratio of purine N/total N in mixed rumen microbes; 0.83, the digestibility of microbial purines.

The daily N2O—N flux was calculated according to the method of Watanabe et al. (1997):

\[ F = 273/\{273 + T\} \times 28 \times 1440 \times 10^{-3} \times (V/22.4) \times (dc/dt)/W, \]

where \( F \) refers to the N2O-N flux (μg N2O-N/kg soil DW per d); 273, the Kelvin temperature; \( T \), the incubation temperature (°C); 28, the mass of N in N2O (g/mol); 1,440, the total minutes of 1 d (min); \( V \), the volume of each jar over soil (L); \( dc/dt \), the average changing rate of N2O concentration with time (nL/L per min); 22.4, the molar volume of gas at 273 K (L/mol); \( W \), the DW of soil in each jar (kg).

The 15 d-cumulative N2O-N fluxes (FCumulative) of 10-mL urine sample was calculated as:

\[ FCumulative = F_1 + F_2 + \ldots + F_{15}, \]

where \( F_1, F_2, \ldots, F_{15} (\text{μg} \text{N}_2\text{O}-\text{N/kg soil DW per d}) \) refer to the N2O-N emissions of d 1, 2, \ldots, 15, respectively and the unit of FCumulative is μg N2O-N/kg soil DW.

The estimated steer urine N2O-N emissions (E, µg) was calculated as:

\[ E = FCumulative \times U/10 \times W, \]

where FCumulative refers to the 15 d-cumulative N2O-N flux of 10 mL urine sample applied to soil, μg N2O-N/kg soil DW; U, the daily urine volume of each steer, mL; W, the DW of soil in each jar, kg.

The ratio of N2O-N to applied urine-N was calculated as:

\[ N_2O-N \text{ to applied urine-N ratio} = \text{(Urine sample N2O-N emissions - Blank N2O-N emissions)}/\text{Urine sample-N} \times 100\%, \]

where the unit for N2O-N emissions and urinary sample-N is micrograms.

2.6. Statistical analysis

The data were subjected for statistical analysis using PROC MIXED procedure of SAS (version 9.4; SAS Inst. Inc., Cary, NC) using the following model:

\[ Y_{ijk} = \mu + T_i + P_j + C_k + e_{ijk}, \]

where \( Y_{ijk} \) is the dependent variable, \( \mu \) is the overall mean, \( T_i \) is the \( i \)th effect of ration, \( P_j \) is the \( j \)th effect of period, \( C_k \) is the \( k \)th random effect of animal, and \( e_{ijk} \) is the residual experimental error. The statistical model included the random effect of animals (\( n = 8 \)) and periods (\( n = 4 \)) and fixed effects of rations (\( n = 4 \)) for some variables. Linear and quadratic contrasts were used to test the effect of
increasing levels of RSC. Multiple linear regression analysis between the estimated steer urine N\(_2\)O–N emissions and the outputs of urinary constituents was performed using the stats package of R software (version 3.3.3). The fitted curve equation for all values of the cumulative N\(_2\)O–N in each treatment was analyzed by the basicTrendline package of R software (version 3.3.3). The data were declared significant when \(P < 0.05\) and trends were indicated of means \(\pm\) standard errors of means (SEM).

3. Results

3.1. Animal experiment (trial 1)

3.1.1. N utilization and liveweight gain

Dietary inclusion with RSC decreased the digested N (\(P = 0.003\)) and increased the fecal N excretion (\(P < 0.001\)) in a linear manner and did not affect the urinary N excretion (\(P = 0.452\)), resulting in a linear increase in the ratio of fecal N to urinary N (\(P = 0.035\)). Dietary inclusion with RSC did not affect the total N excretion, N retention, N retention rate and daily liveweight in steers (\(P > 0.10\), Table 2).

3.1.2. Plasma indices

Dietary inclusion with RSC did not affect the plasma concentrations of T\(_3\) and T\(_4\) (\(P > 0.10\), Table 3), and the TP, ALB, urea, glucose, TC, triglyceride, and T-AOC (\(P > 0.10\)). Dietary inclusion with RSC linearly increased the plasma concentration of SCN (\(P < 0.001\)) while goitrin and ITC were undetectable at the limits of detection in each treatment was analyzed by the OPLS-DA analysis, 12 different metabolites that were identified (\(P < 0.05\), FC > 1.20 or < 0.83, VIP > 1, Table 4). Compared with 0 RSC, adding RSC at 8.0% DM downregulated the plasma relative concentrations of 4-aminohippuric acid, 3α,7α-dihydroxypropanoic acid, phosphatidylserine (14:0/16:0), 6β-hydroxyprogesterone, pyrrhoxanthinol, tattatin B, mandelonitrile, rutinoside and taraxacoside (\(P < 0.05\)), and upregulated the plasma hypoglycin B, neumedin N (1–4), dhurrin and 5-deoxykivitone (\(P < 0.05\)).

3.1.3. Plasma metabolome indices

The LC/MS detected 687 valid peaks that were unique and non-overlapping in plasma samples. After quality control, 578 compounds were obtained from the peaks. No obvious separation of the PCA plot was detected between treatments of adding RSC at 0 and 8.0% DM (Fig. 1). Clear separation of the plasma metabolites was found between treatments of adding RSC at 0 and 8.0% DM, as shown in the OPLS-DA score plots (Fig. 1). The \(R^2\)Y intercepts (0.90 and 0.91 > 0.50) and the \(Q^2\) intercepts (–0.28 and –0.12 < 0.00) of the permutation test in Fig. 1 showed that the model had no overfitting, and it was effective and satisfactory to identify the plasma differential metabolites based on the VIP values of OPLS-DA analysis.

Combined with the statistical analysis and the VIP values obtained from the OPLS-DA analysis, 12 different metabolites that differentiate between treatments of adding RSC at 0 and 8.0% DM were identified (\(P < 0.05\), FC > 1.20 or < 0.83, VIP > 1, Table 4). Compared with 0 RSC, adding RSC at 8.0% DM downregulated the plasma relative concentrations of 4-aminohippuric acid, 3α,7α-dihydroxypropanoic acid, phosphatidylserine (14:0/16:0), 6β-hydroxyprogesterone, pyrrhoxanthinol, tattatin B, mandelonitrile, rutinoside and taraxacoside (\(P < 0.05\)), and upregulated the plasma hypoglycin B, neumedin N (1–4), dhurrin and 5-deoxykivitone (\(P < 0.05\)).

3.1.4. Urinary nitrogenous components and GLS metabolites

Dietary inclusion with RSC linearly decreased the daily urine volume (\(P = 0.046\)), the urinary urea excretion (\(P = 0.001\)) and the urea-N-to-urinary N ratio (\(P = 0.004\)), linearly increased the urinary excretions of allantoin (\(P = 0.023\)) and the total urinary PD (\(P = 0.027\)), the ratios of allantoin-N-to-urinary N (\(P = 0.043\)) and the PD-N-to-urinary N (\(P = 0.048\)), and the predicted rumen microbial N flow (\(P = 0.028\)), whereas it did not affect the urinary excretions of hippuric acid, creatinine and uric acid (\(P > 0.10\)). Dietary inclusion with RSC tended to increase the urinary N concentration (\(P = 0.072\)).

Dietary inclusion with RSC linearly increased both the urinary concentration and the excretion of SCN (\(P < 0.001\) (Table 5)) whereas other metabolites of GLS including goitrin and ITC were undetectable in urine at the limits of 1 mg/L and 7 mg/L, respectively.

3.2. Static incubation experiment (trial 2)

3.2.1. Urine N\(_2\)O–N fluxes

The urine N\(_2\)O–N fluxes increased from d 1 to 4 and decreased after d 4 during incubation (Fig. 2A). The peak N\(_2\)O–N fluxes were observed on d 3 or 4 and came to zero after d 13 during incubation. The cumulative N\(_2\)O–N fluxes increased from d 1 to 9 and nearly reached the maximum levels after d 9 (Fig. 2B). Close exponential correlations were found between the cumulative N\(_2\)O–N flux (Y) and the incubation days (X) (Fig. 2B). Results in Table 6 showed that dietary inclusion with RSC linearly increased the 15 d-urine sample N\(_2\)O–N flux, the ratio of N\(_2\)O–N to N application, and the estimated steer urine N\(_2\)O–N emissions (\(P < 0.001\)).

3.2.2. NH\(_4\)-N and NO\(_3\)-N in soil

Dietary inclusion with RSC tended to linearly increase the soil concentrations of NH\(_4\)-N on d 0 (\(P = 0.056\)) and 6 (\(P = 0.051\), Fig. 3) and linearly increased the average soil concentrations of NH\(_4\)-N (\(P = 0.031\)), while it did not affect the soil concentrations of NO\(_3\)-N and the average soil concentrations of NO\(_3\)-N (\(P > 0.10\), Fig. 3).

PC = principal component; Comp = component.
3.2. Correlations between N₂O−N emission and urinary constituents

The estimated steer urine N₂O−N emission was positively correlated with the daily urinary excretions of urea-N (P = 0.045) and SCN (P < 0.001), and negatively correlated with the urinary excretion of creatinine-N (P = 0.041, Table 7) whereas no correlations were found between the estimated steer urine N₂O−N emission and the urinary excretions of hippuric acid-N, uric acid-N or allantoin-N (P > 0.10). A multiple linear correlation was found between the estimated steer urine N₂O−N emission and the urinary excretions of urea-N, hippuric acid-N, creatinine-N, uric acid-N, allantoin-N and SCN (R² = 0.617, P < 0.001, Table 7).

4. Discussion

4.1. Effects of RSC containing high GLS on N excretion and urinary nitrogenous compounds in steers

The RSC used in the present study was from rapeseeds after oil extraction by hot-pressing. Therefore, the RUP content of the rapeseed cake; DM dry matter; VIP variable importance; FC fold-change.

Means in the same row with different superscripts differ (P < 0.05, n = 8).
Since dietary inclusion with different levels of RSC increased the fecal N excretion and did not affect the urinary N excretion, the fecal N-to-urinary N ratio was increased linearly. However, the dietary inclusion with different levels of RSC did not affect the total N excretion and the N retention. The reason for this behavior could be that the variability in urinary N is higher than that of fecal N and the higher variability could be resulted from the effects of some metabolites originated from RSC. The results were in accordance with the unchanged daily liveweight gains among different treatments. The results indicated that dietary inclusion with RSC up to 8.0% DM did not depress the N utilization in steers even though RSC contained high level of GLS.

Urea is the major nitrogenous compound in the urine of cattle and urea-N accounts for about 52.1-93.5% of urinary N (Dijkstra et al., 2013). The urinary urea was from the blood synthesized in the liver by using ammonia-N (NH$_3$–N) absorbed from the rumen. Our previous results showed that dietary inclusion with hot-pressed RSC decreased the ruminal concentration of NH$_3$–N (Gao et al., 2021). Hence, dietary inclusion with RSC should have reduced the amount of NH$_3$–N absorbed from the rumen, resulting in less urea synthesis in the liver and less urinary excretion of urea in steers. Since dietary inclusion with RSC did not affect the total urinary N excretion, the urea-N-to-urinary N ratio was decreased. The results were in agreement with Maxin et al. (2013) and Broderick et al. (2015) who reported that replacing soybean meal by rapeseed meal in the ration of dairy cows decreased the urinary excretion of urea and the urea-N-to-urinary N ratio. The results of the present study also showed that dietary inclusion with RSC increased the urinary excretions of allantoin and total PD and the predicted rumen microbial N flow. The results indicated that dietary inclusion with RSC improved the efficiency of rumen microbial N synthesis. Since the rumen microbial N synthesis is affected by many dietary factors, the exact mechanism for the results needs to be investigated in further research.

4.2. Effects of RSC on plasma indices and metabolome

Many studies indicated that feeding monogastric animals with RSC containing high GLS was harmful to thyroid function (Bourdon and Aumaitre, 1990). Ruminants are more tolerant to GLS than monogastric animals. However, feeding ruminants with high dietary GLS for long terms also negatively affects their health (Tripathi et al., 2001) since the metabolites of GLS such as goitrin and SCN can cause the goiter in animals (Halkier and Gershonzen, 2006). Results of the present study showed that dietary inclusion with RSC up to 8.0% DM did not affect the plasma concentrations of $T_3$ and $T_4$. The results are in agreement with Veselý et al. (2009) and Tronan et al. (2018), who reported that dietary inclusion with extrudated RSC at 11.8% DM and heat-treated RSC at 8.4% DM, respectively, did not affect the plasma thyroid hormones in dairy cows. The results of present study indicated that the dietary content of GLS and metabolites up to 18.12 $\mu$mol/g DM did not affect the thyroid function of steers even though the plasma concentration of SCN was increased up to 87.07 $\mu$mol/L. It should be noted that each experimental period in the present study was only 20 d. Therefore, longer term feeding experiments are needed to be carried out to clarify the results.

The plasma metabolome analysis showed that dietary inclusion with RSC at 8.0% DM containing high GLS upregulated the plasma relative concentration of dhurrin, which was a type of cyanogenic glucoside similar to GLS. The results suggested that RSC not only contained GLS but also other secondary metabolites which could be transformed into dhurrin in metabolism, possibly because the CYP79 homologues in GLS-producing plants are able to convert amino acids (AA) into cyanogenic glucosides and GLS (Bak et al., 1998). Dhurrin could be readily hydrolyzed into hydrogen cyanide which is toxic and reduces the apparent nutrient digestibility in

### Table 6

Effects of feeding RSC containing high GLS on the urine $N_2O$ emissions in steers.

| Item                        | Dietary levels of RSC, % DM | SEM  | $P$-value |
|-----------------------------|-------------------------------|------|-----------|
|                             | 0          | 2.7 | 5.4 | 8.0 |               |       | Linear | Quadratic |

RSC = rapeseed cake; GLS = glucosinolates; DM = dry matter; $N_2O$–N – nitrous oxide; N = nitrogen; DW = dry weight.

$^{ab}$ Means in the same row with different superscripts differ ($P < 0.05, n = 8$).
livestock (Etuk et al., 2012). The plasma dhurrin could possibly be derived from some antinutritional factors in RSC which could be one of the reasons for decreasing the digested N.

The plasma metabolome analysis also indicated that dietary inclusion with RSC at 8.0% DM decreased the plasma relative concentration of 4-aminohippuric acid (an acyl glycine), and increased hypoglycin B (an AA chemically related to lysine) compared with the treatment of 0 RSC. The impact could have resulted from the differences in the AA composition between RSC and soybean meal (NRC, 2001) and the dietary GLS. However, the exact mechanisms were unclear. The 4-aminohippuric acid is a non-toxic organic anion. It is unable to bind plasma protein or moves across the erythrocyte membranes (Rodríguez-Romero et al., 2015). Hypoglycin A could be converted into hypoglycin B by γ-glutamyl transeptidase. The hypoglycin A and its metabolites can interfere with gluconeogenesis, which could result in a rapid depletion of hepatic glycogen (Gordon, 2015), suggesting that dietary inclusion with RSC could possibly depress the energy utilization in steers.

Dietary inclusion with RSC at 8.0% DM downregulated the plasma relative concentration of phosphatidylserine (14:0/16:0) in steers. The reason for the results could be that soybean meal contains phosphatidylserine (Sur et al., 2010) whereas RSC does not contain the compound. Phosphatidylserine functions as a constitutive component of membrane anionic domains that bind and thereby activate cytosolic proteins involved in neuronal signaling (Kim et al., 2000).

### 4.3. Effects of RSC containing high GLS on urine N2O emissions

The nitrogenous compounds in the urine of cattle mainly include urea, uric acid, creatinine, allantoin, hippuric acid etc., of which urea accounts for the major part of the compounds. Urea can be easily degraded into NH₃ by microbial urease in soil and NH₃ can be transformed into NH₄⁺ (Whitehead et al., 1989) which is used as the major precursor for N₂O formation during nitrification and denitrification in soil (Clough et al., 2020). Thus, urea in steer urine is the major N source for N₂O formation. The positive correlation between the estimated steer urine N₂OₑN emission and the urinary excretions of different components in steers (g/d).

| Item               | Coefficient estimate | P-value |
|--------------------|----------------------|---------|

Fitting degree of multiple linear equation: $R^2 = 0.617$, $P$-value < 0.001

N = nitrogen; SCN = thiocyanate.
inclusion with RSC linearly increased the urinary excretions of allantoin and total PD, these compounds should have not affected the urine N₂O–N emissions in the present study. It could be inferred that the GLS metabolites excreted in urine greatly affected the N₂O–N emissions.

GLS are the specific compounds in brassica forages (Clarke, 2010) and can be hydrolyzed into SCN, goitrin and ITC (Oliviero et al., 2018). It was reported that the GLS in RSC was hydrolyzed into SCN in the rumen of steers whereas goitrin and ITC were undetectable (Gao et al., 2021). The results of the present study showed that dietary inclusion with RSC containing high GLS increased both the plasma and the urinary concentrations of SCN in steers. The results suggested that the SCN which was hydrolyzed from GLS in the rumen of steers, had been absorbed into the blood and partly excreted into the urine.

Snyder et al. (2010) reported that the SCN released from Brassica alba seed meal could be an important factor to inhibit the nitrification in soil. Kim et al. (2008) also reported that SCN (200 mg/L) slightly inhibited the nitrification in sludge. However, the actual effects of SCN on the nitrification in soil are unclear. Direct addition of ITC (i.e. 2-propenyl-ITC and phenylethyl ITC) also showed the impact on inhibiting the nitrification process and subsequently decreasing the N₂O emissions from soil applied with urine (Bending and Lincoln, 2000; Balvert et al., 2017). Since ITC as well as goitrin in steer urine were extremely low and undetectable in the present study, the effect of GLS metabolites on urine N₂O formation should have come from SCN.

Majak (1992) reported that the disappearance rate of ITC was about 50 times that of SCN in in vitro culture of bovine ruminal fluid. Bheemreddy and Jeffery (2007) reported that most ITC degraded from GLS existed in the conjugates of ITC and N-acetylcysteine in rat urine. The results could explain the reason that the urinary ITC was undetectable in steers fed RSC. The results suggested that the urine N₂O emission can not be reduced by increasing the urinary excretion of ITC in steers.

Hoogendoorn et al. (2016) reported that the EF3 of N₂O from the urine of sheep grazing on forage rape (Brassica napus L.) was higher than on the perennial ryegrass/white clover pasture (L. perenne L./T. repens). Balvert (2018) also reported that the total N₂O emissions of the urine from cattle fed kale (Brassica oleracea L.) were higher than fed perennial ryegrass/white clover pasture (L. perenne L./ T. repens). The results of the present study showed that the N₂O–N emissions from the urine of steers fed with different levels of RSC linearly increased rather than decreased. A close positive correlation was found between the estimated N₂O–N emission and the urinary SCN excetration in the present study. The results were in agreement with Hoogendoorn et al. (2016) and Balvert (2018) and suggested that the SCN excreted in the urine of steers fed with RSC had a positive effect on the urine N₂O–N emissions. However, Luo et al. (2015) reported that the N₂O from the urine of sheep fed fresh forage rape (Brassica napus L.) was much lower than fed fresh perennial ryegrass (L. perenne L.) (EF3 0.11% vs. 0.27%). The inconsistency in the results of different experiments could have resulted from the differences in urinary components of the animals in different experiments.

It was reported that the ammonia-oxidizing bacteria (AOB) was able to reduce NO₂ and increase the N₂O production through the nitrifier denitrification in soil (Wragie et al., 2001). In the aerobic reactor of wastewater, SCN was found to be able to increase the population of AOB (Kim et al., 2011). The results of the present study showed that SCN was the only metabolite of GLS excreted into the urine of the steers. This suggests that the urinary SCN could have increased the steer urine N₂O–N emissions through enhancing the population of AOB in the soil. The results also showed that dietary inclusion with RSC increased the concentration of NH₄⁺–N in the soil. However, it did not alter the concentration of NO₃⁻–N in the soil, suggesting that the conversion rate from NH₄⁺–N to NO₃⁻–N was decreased in the soil applied with steer urine and more NH₄⁺–N was converted into N₂O–N.

Bell (1984) reviewed that the anti-nutritional factors in rapeseeds include GLS, erucic acid, sinapine, tannins and phytate. Leung et al. (1979) reported that the tannins in rapeseeds were condensed tannins which were only found in rapeseed hulls but not in rapeseed meats. Therefore, the metabolites of rapeseed tannins could hardly be excreted in steer urine and impact the urine N₂O formation in the present study. However, it is unclear if the metabolites of erucic acid, sinapine, and phytate in RSC could be excreted in steer urine and affected the steer urine N₂O emissions. This needs to be investigated in the future.

5. Conclusions

Dietary inclusion with RSC containing high GLS decreased the CP digestibility, but did not affect the urinary N excretion or the N retention rate in steers. GLS metabolite SCN was found in the plasma and the urine of steers fed RSC containing high GLS. Feeding steers RSC containing high GLS increased rather than decreased the urine N₂O emissions although it decreased the urinary excretion of urea. The SCN excreted in urine could be the major factor increasing the urine N₂O–N emissions. Other metabolites in RSC could possibly be excreted into the urine and consequently affect the urine N₂O emissions in steers. Field trials are necessary to clarify the effects of SCN hydrolyzed from the GLS of RSC on steer urine N₂O–N emissions.
