Abstract

We develop a discrete-time version of the blended dynamics theorem for the use of designing distributed computation algorithms. The blended dynamics theorem enables to predict the behavior of heterogeneous multi-agent systems. Therefore, once we get a blended dynamics for a particular computational task, design idea of node dynamics for individual heterogeneous agents can easily occur. In the continuous-time case, prediction by blended dynamics was enabled by high coupling gain among neighboring agents. In the discrete-time case, we propose an equivalent action, which we call multi-step coupling in this paper. Compared to the continuous-time case, the blended dynamics can have more variety depending on the coupling matrix. This benefit is demonstrated with three applications; distributed estimation of network size, distributed computation of the PageRank, and distributed computation of the degree sequence of a graph, which correspond to the coupling by doubly-stochastic, column-stochastic, and row-stochastic matrices, respectively.

Key words: discrete-time heterogeneous multi-agent system; multi-step coupling; blended dynamics

1 Introduction

Over the past decades, many distributed algorithms have been actively studied for their benefits. The benefits include lessened computational burden of one node as the burden is distributed over many nodes in the network, improved reliability against faults as a fault on one node can be compensated by redundancy of many nodes, and preserved privacy as private information need not be transferred to a central node for computation. Examples that enjoy the aforementioned benefits include distributed optimization (Nedić & Ozdaglar, 2009; Nedić & Liu, 2018) and distributed computation of PageRank (Ishii & Tempo, 2010; Suzuki & Ishii, 2018).

On the other hand, constructive design methods for general distributed algorithms, except the distributed optimization, are not well developed yet. One potential approach towards the constructive design is the blended dynamics approach (Lee & Shim, 2020), which is inspired by (Kim, Yang, Shim, Kim, & Seo, 2015; Panteley & Loría, 2017). This approach is based on the blended dynamics theorem, which, briefly speaking, asserts the following. Consider a multi-agent system

\[ \dot{x}_i = f_i(t, x_i) + \kappa \sum_{j \in N_i} (x_j - x_i), \quad i \in \mathcal{N}, \quad (1) \]

where \( x_i \in \mathbb{R} \) are the states, \( f_i : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{R} \) are heterogeneous vector fields, \( \mathcal{N} := \{1, \ldots, N\} \) is the set of node indices, and \( N_i \) is the index set of nodes that send information to node \( i \). The individual node dynamics are represented by \( \dot{x}_i = f_i(t, x_i) \), which is coupled with neighboring nodes by the coupling term \( \sum_{j \in N_i} (x_j - x_i) \) with a common coupling gain \( \kappa \). Then, under the assumption that the communication graph is undirected and connected, every agent in (1) behaves like the blended dy-
namics defined as
\[
\dot{s}(t) = \frac{1}{N} \sum_{i=1}^{N} f_i(t, s(t)) \quad \in \mathbb{R}
\]  
(2)

where \( s \) is the state of the blended dynamics, if the coupling gain \( \kappa \) is sufficiently large and if the blended dynamics are contractive, i.e., incrementally stable (Kim et al., 2015). More precisely, for any \( \epsilon > 0 \), there exists \( \kappa_{\text{min}} \) such that, if \( \kappa > \kappa_{\text{min}} \),
\[
\limsup_{t \to \infty} |x_i(t) - s(t)| \leq \epsilon, \quad \forall i \in N.
\]  
(3)

Since the blended dynamics are a simple average of individual node dynamics, it has been utilized as a design tool for many distributed algorithms; that is, one designs a desired algorithm as the blended dynamics (2) first, and then, splits it into different node dynamics (1) with couplings. This philosophy has been successfully employed in many applications such as distributed economic power dispatch problem (Yun, Shim, & Ahn, 2018), distributed state estimator (Kim, Lee, & Shim, 2019), secure estimation by distributed median computation (Lee, Kim, & Shim, 2020), distributed optimization without convexity of each node (Lee & Shim, 2022), decentralized controller design (Kim, Lee, & Shim, 2023), and analysis of coupled oscillators (Trunnel, Liu, & Stursberg, 2023). See (Lee & Shim, 2021) for more comprehensive summary of these applications. The distributed algorithms designed by the blended dynamics theorem does not require each node dynamics to be stable, as long as their average (i.e., the blended dynamics) is contractive, which yields flexibility of the design. Moreover, as long as the blended dynamics remain contractive, a new node can join the network or an existing node can leave the network during the operation, which is called as a plug-and-play feature. This is because the designed distributed algorithms are initialization-free, i.e., the proposed algorithms do not rely on any specific initial values (Lee & Shim, 2020).

While all the above results are in the continuous-time domain, it is however required to implement the designed algorithm in the discrete-time domain so that it operates on digital devices in practice. A naive idea is to use simple discretization methods such as forward difference. However, in the discrete-time case of (4), increasing \( \kappa \) unboundedly yields instability of the network unless \( \Delta_t \) is decreased with the same ratio \(^1\). Therefore, the discrete-time algorithm (4) is not suitable for a discrete-time version of the blended dynamics approach.

In this paper, we propose a new form of a multi-agent system (which is given by (5) in Section 2). We note that the meaning of using a large coupling gain \( \kappa \) in the continuous-time case of (1) is that consensus is taken more care of than the progress through the node dynamics. Based on the observation, and motivated by (Wang, Liu, Morse, & Anderson, 2019), the proposed form repeats a weighted averaging action many times before progressing through the node dynamics, which we call ‘multi-step coupling.’

This approach still maintains the advantages of the continuous-time case, such as the initialization-free benefit or the plug-and-play operation, and that the individual node dynamics need not be stable as long as the blended dynamics are stable. The latter benefit is useful for a distributed algorithm because, without it, the algorithm must be re-initialized whenever a change occurs in the network such as addition of new nodes or removal of existing nodes, and immediate detection of a change in a distant node is not easy for a large scale network. In particular, the initialization-free feature is beneficial for a distributed estimation of relative importance of each node in the network, i.e., the PageRank score. While there have been various studies for the distributed estimation of the PageRank scores such as (Ishii & Tempo, 2010; Lei & Chen, 2014; Suzuki & Ishii, 2018), they assume the initialization process. On the contrary, the proposed approach provides a design method for initialization-free distributed algorithms. An initialization-free algorithm for PageRank will appear in Section 3.2. Now, the latter benefit that not all node dynamics have to be stable, has been successfully utilized in a few applications. Distributed state estimator in the continuous-time (Kim et al., 2019) or in the discrete-time (Wang et al., 2019) is one example because individual observers at each agent can not be stable due to lack of observability. But, with strong couplings in some sense, their collective behavior becomes a stable one. Another example can be found in Section 3.1, where individual node dynamics are not stable, but their blended dynamics are stable so that they can estimate the size of the network asymptotically.

Moreover, while the continuous-time approach predicted collective synchronization behavior of the multi-agent

\(^1\) One can verify it with, e.g., \( f_i(t, x_i) = -x_i \) so that \( x^+ = \{(1 - \Delta_t) I - \kappa \Delta_t \mathcal{L}\} x \) where \( x = [x_1^\top, \ldots, x_N^\top]^\top \) and \( \mathcal{L} \) is the Laplacian matrix of a connected graph. With \( \kappa \) sufficiently large, some eigenvalues of the system matrix lie outside of the unit circle unless \( \kappa \Delta_t \) remains small.
system in (Kim et al., 2015; Lee & Shim, 2020), this discrete-time approach estimates not only emergent but also individually scaled behavior, i.e., each agent behaves similarly to the solution of the blended dynamics with an agent-wise scaling factor. For example, in Section 3.2, we will introduce an application example where each node estimates its relative importance which is possibly agent-wise scaling factor. For example, in Section 3.2, we propose the following discrete-time algorithm:

1. Keeping in mind that $t \in [0, 1]$, the time $t$ will often be written as $\frac{1}{K} \cdot t$.
2. A directed graph $G$, its adjacency matrix $A$, and its binary adjacency matrix $A$, the following statements are equivalent: (a) $G$ is strongly connected and aperiodic, (b) $A$ is primitive, and (c) $A$ is primitive.

2.1. Discrete-time Blended Dynamics Theorem

For a discrete-time version of the blended dynamics theorem, we propose the following discrete-time algorithm: for each agent $i \in N$,

\[
x_{i}[t] = f_{i}(x_{i}[t]), \quad \text{if } k = 0,
\]
\[
x_{i}[t+1] = \sum_{j \in N_{i}} w_{ij} x_{j}[t], \quad \text{if } k = 1, \ldots, K - 1,
\]

where $x_{i} \in \mathbb{R}^{n}$ is the state, the function $f_{i} : \mathbb{Z} \times \mathbb{R}^{n} \rightarrow \mathbb{R}^{n}$ is continuously differentiable and represents the time-varying heterogeneous node dynamics (5a), and the co-efficient $w_{ij}$, called coupling weight, determines the behavior of the coupling dynamics (5b). Here, $t_{k}$ is the symbol defined by

\[
t_{k} = t + \frac{k}{K},
\]

where $K \in \mathbb{N}$, and we call $t_{k}$ by fractional discrete-time index. In particular, we call $t \in \mathbb{Z}$ as integer count and $k \in \mathbb{Z}$ as fraction count. The fraction count $k$ varies from 0 to $K - 1$. Keeping in mind that $t_{K} = t + K/K = (t + 1) + 0/K = (t + 1)_{0}$, we see that the fractional discrete-time $t_{k}$ advances as $t_{0}, 0_{1}, \ldots, 0_{K-1}, 1_{0}, 1_{1}, \ldots$. The time $t_{0}$ will often be written as $t$ for convenience. The fractional discrete-time has nothing to do with real time, and can be implemented in practice just as a sequential order in an algorithm.

We will choose $K$ sufficiently large, which determines how many times the coupling dynamics (5b) are executed before the next node dynamics (5a) are executed. It will be shown that, in this way, the effect of strong...
coupling \( \kappa \) in the continuous-time blended dynamics theorem can be similarly reflected in discrete-time. To emphasize the difference, we call this type of coupling in (5) by multi-step coupling.

The coupling weights \( w_{ij} \) in (5b) have the property:

\[
\begin{align*}
    w_{ij} &> 0, & j &\in N_i \cup \{i\}, \\
    w_{ij} &= 0, & \text{otherwise.} & (7)
\end{align*}
\]

Now, we assume that the matrix \( W := [w_{ij}] \in \mathbb{R}^{N \times N} \), which we call a weight matrix, satisfies the following.

**Assumption 1** The spectral radius of \( W \) is 1.

Note that the communication protocols in many discrete-time multi-agent systems in the literature have the form of linear combination like in (5b) and their weight matrices satisfy Assumption 1. Examples include (Ishii & Tempo, 2010; Le & Chen, 2014; Saber, Fax, & Murray, 2007; Ren & Beard, 2005), in which the weight matrices are given by stochastic matrices whose spectral radius is 1.

Meanwhile, the communication network under consideration is represented by the directed graph \( G \), which does not have self-connection at any node by definition, and we assume the following.

**Assumption 2** The network \( G \) is strongly connected.

Then, under Assumptions 1 and 2, the following is well-known (but we put its proof for readers’ convenience).

**Lemma 3** Let \( \lambda_i, i \in \mathcal{N} \), be the eigenvalues of \( W \) such that \( |\lambda_1| \geq |\lambda_2| \geq \ldots \geq |\lambda_N| \). Under Assumptions 1 and 2, \( \lambda_1 = 1, \lambda_2 > |\lambda_j| \) for all \( j = 2, \ldots, N \), and there exist positive vectors \( p, q \in \mathbb{R}^N \) such that

\[
Wp = p, \quad q^TW = q^T, \quad q^Tp = 1. \quad (8)
\]

**PROOF.** From (7), the associated graph of \( W \) not only contains all edges of \( G \) but also has a self-connection for every node because all diagonal entries of \( W \) are positive. Thus, the associated graph is aperiodic as well as strongly connected. This implies that \( W \) is primitive by Lemma 1, and, by Assumption 1 and Lemma 2, \( W \) has the simple Perron-Frobenius eigenvalue 1, i.e., \( \lambda_1 = 1 \) and \( \lambda_1 > |\lambda_j| \) for all \( j = 2, \ldots, N \), with positive right and left eigenvectors \( p \) and \( q \), respectively. Scaling \( p \) and \( q \) yields that \( q^Tp = 1 \).

With \( p \) and \( q \) from Lemma 3 at hand, we now introduce discrete-time blended dynamics, which are defined as a weighted average of node dynamics:

\[
s[t+1] = \sum_{i=1}^{N} q_i f_i(t, p_i s[t]) =: f_s(t, s[t]) \in \mathbb{R}^{n} \quad (9)
\]

where \( p_i \) and \( q_i \) is the \( i \)-th element of \( p \) and \( q \), respectively, and \( t \) is the integer count of the fractional time (i.e., \( t = t_0 \)). In particular, we assume the blended dynamics are stable in the sense of (Lohmiller & Slotine, 1998; Tran, Rührer, & Kellett, 2018) as follows.

**Assumption 3** The blended dynamics (9) are contractive; i.e., there exist a (symmetric) positive definite matrix \( H \in \mathbb{R}^{n \times n} \) and a positive constant \( \gamma < 1 \) such that

\[
\frac{\partial f_s(t, s)}{\partial s} (t, s)^T H^2 \frac{\partial f_s(t, s)}{\partial s} (t, s) \leq \gamma H^2, \quad \forall s \in \mathbb{R}^n, t \in \mathbb{Z}.
\]

**Remark 1** Assumption 3 does not ask each node dynamics \( x_i[t+1] = f_i(t, x_i[t]) \) to be stable. Rather it allows unstable node dynamics whose instability can be compensated by other node dynamics so that the blended dynamics become stable in the sense of Assumption 3. For example, when there are four agents with \( f_1(t, x) = f_2(t, x) = 0.1x \) and \( f_3(t, x) = f_4(t, x) = 1.5x \), the agents 1 and 2 have stable node dynamics while the agents 3 and 4 have unstable nodes. If the weight matrix has the vectors \( p = \text{1}_4 \) and \( q = \text{1}_4 \), then Assumption 3 holds because \( f_s(s) = 0.8s \).

We will see that the blended dynamics (9) allow to predict the behavior of (5) when \( K \) is large. To make the prediction effective from any initial conditions globally in the state-space, we impose the following assumption.

**Assumption 4** The function \( f_i(t, x) \) is uniformly bounded in \( t \) and globally Lipschitz with respect to \( x \) uniformly in \( t \); i.e., \( \exists M : \mathbb{R} \rightarrow \mathbb{R} \) and a constant \( L \geq 0 \) such that, \( \forall x, y \in \mathbb{R}^n, t \in \mathbb{Z}, \) and \( i \in \mathcal{N} \),

\[
\begin{align*}
    \|f_i(t, x)\| &\leq M (\|x\|), \\
    \|f_i(t, x) - f_i(t, y)\| &\leq L \|x - y\|.
\end{align*}
\]

**Theorem 1** Under Assumptions 1–4, for any \( \epsilon > 0 \), there exists \( K^\min \) such that, for all \( K > K^\min \), the solution \( x_i \) of (5) and the solution \( s \) of (9) with arbitrary initial conditions satisfy

\[
\limsup_{t \rightarrow \infty} \|x_i[t] - p_i s[t]\| \leq \epsilon, \quad \forall i \in \mathcal{N}. \quad (10)
\]

In addition, for each \( k \in \{1, 2, \ldots, K - 1\} \) and \( i \in \mathcal{N} \),

\[
\limsup_{t \rightarrow \infty} \|x_i[t_k] - p_i s[t+1]\| \leq \frac{\epsilon}{2} \left( 1 + \frac{1}{|\lambda_N|^{K-t}} \right)^k. \quad (11)
\]
Theorem 1 states that, with sufficiently large number of steps for the coupling (5b), the behavior of node dynamics (5a), which is represented by the state \( x_i \) at the integer count \( t \), can be approximately predicted by the solution \( s \) of the blended dynamics with the scaling factor \( p_i \), and the approximation error can be made arbitrarily small by increasing \( K \). Moreover, the behavior of \( x_i \) over the fraction counts is also bounded with respect to the scaled trajectory of \( s \).

**Remark 2** From proof of Theorem 1 in Appendix B, \( K^\text{min} \) can be explicitly defined as the smallest integer such that

\[
K^\text{min} \geq \log_{|\lambda_2|} \left( \frac{1 - \sqrt{7}}{2M_1} \max \left\{ \frac{1}{1 + \sqrt{2}} \frac{1}{2M(\|p\|M_2)^{\sqrt{N}}} \right\} \right),
\]

where \( M_1 \) and \( M_2 \) are some constants which will be induced from (B.5) and (B.6). This expression yields a reasonable interpretation in the sense that \( K^\text{min} \) increases as the second largest eigenvalue \( \lambda_2 \) of the weight matrix \( W \) approaches to 1, the performance index \( \epsilon \) decreases, or the Lipschitz constant \( L \) and the network size \( N \) get larger, while it decreases as the degree of stability of the blended dynamics, \( 1 - \sqrt{7} \), gets larger. Note that the network topology implicitly affects \( K^\text{min} \) through \( \lambda_2 \). In practice, a suitable \( K \) is chosen by repeated simulations, or by a maximal value if an upper bound of the right-hand side for all possible cases can be computed (like in (Lee, Lee, Kim, & Shim, 2018)).

**Remark 3** Selection of the eigenvectors \( p \) and \( q \) as (8) is not unique, but the result of Theorem 1 remains the same. To see this, we note that different selection of \( p' \) and \( q' \) from \( p \) and \( q \), respectively, should satisfy \( p' = cp \) and \( q' = (1/c)q \) for some \( c > 0 \) because of the Perron-Frobenius theorem (Lemma 2). In addition, we note that the new blended dynamics become

\[
s'[t + 1] = \frac{1}{c} \sum_{i=1}^{N} q_i f_i(t, cp, q'[t]) =: f_{p'}(t, q'[t]).
\]

Comparing it with (9), it is seen that \( s[t] = (1/c)s'[t], \) and thus, we have \( \|x_i[t] - p'[s'[t]]\| = \|x_i[t] - cp, (1/c)s'[t]\| = \|x_i[t] - ps'[t]\|. \) Finally, it is also seen that the new blended dynamics satisfy Assumption 3 because \( \partial f_{p'}/\partial s' \)(t, \( s' \)) = \( \partial f_{p}/\partial s \)(t, \( s \)) with \( s = cs' \).

**Remark 4** In (11), the state \( x_i[t_k] \) is compared not with \( s[t] \) but with \( s[t + 1] \). One may find this is natural considering the behavior of the overall system. At each integer time \( t = t_0 \), each \( x_i \) obeys the heterogeneous node dynamics (5a), which potentially updates \( x_i[t] \) in different directions from the updated \( p_i s[t + 1] \) (even if \( x_i[t_0] \) is close to \( p_i s[t] \)). Instead, repeated execution of (5b) drives \( x_i[t_k] \) to \( p_i s[t + 1] \), which is well reflected in (11).

We now present intuitive explanations for Theorem 1, whose rigorous proof continues in the Appendix. For simplicity, define \( \tilde{x} := [x_1^T, \ldots, x_N^T]^T \in \mathbb{R}^{N \times N} \). Then, (5) is simply written as

\[
\tilde{x}[t_k] = W_k^{-1} \begin{bmatrix} f_1(t_0, x_{1}[t_0]) \\ \vdots \\ f_N(t_0, x_N[t_0]) \end{bmatrix} =: W_k^{-1} F(t_0, \tilde{x}[t_0]),
\]

for \( k = 1, \ldots, K - 1 \) and \( t \in \mathbb{Z} \), where \( W_{k+1} = W \otimes I_n, \) and, since \( t_K = (t + 1) = t + 1, \) we have

\[
\tilde{x}[t + 1] = W_{k}^{-1} F(t, \tilde{x}[t]).
\]

Similar to (13), the blended dynamics (9) are written as

\[
s[t + 1] = \sum_{i=1}^{N} q_i f_i(t, p_i s[t]) = q_i^T F(t, p_i s[t]).
\]

By Lemma 3, there exist \( R, Z \in \mathbb{R}^{N \times (N - 1)} \) such that

\[
W = \begin{bmatrix} p^T R \\ I \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & \Lambda \end{bmatrix} \begin{bmatrix} q^T \\ Z^T \end{bmatrix},
\]

\[
Z^T R = I_{N-1}, \quad \text{and} \quad Z^T p = R^T q = 0_{N-1},
\]

where \( \Lambda \in \mathbb{R}^{(N-1) \times (N-1)} \) is a matrix whose eigenvalues are \( \lambda_2, \ldots, \lambda_N \). With them, we consider the coordinate transformation

\[
\xi = \begin{bmatrix} \xi_1 \\ \xi \end{bmatrix} = \begin{bmatrix} q_i^T \\ Z_i^T \end{bmatrix} \tilde{x}
\]

whose inverse is

\[
\tilde{x} = p_i \xi_1 + R_i \xi.
\]

The overall dynamics (13) at each integer time \( t \) become

\[
\xi_1[t + 1] = q_i^T W_{k}^{-1} F(t, p_i \xi_1[t] + R_i \xi[t]),
\]

\[
\tilde{x}[t + 1] = Z_{i}^T \cdot W_{k}^{-1} F(t, p_i \xi_1[t] + R_i \xi[t]),
\]

\[
= (\Lambda^{K-1} Z_{i}^T) \cdot F(t, p_i \xi_1[t] + R_i \xi[t]).
\]

Define the error variable \( e := \xi - s \). Then the above dynamics are rewritten by

\[
e[t + 1] = q_i^T F(t, p_i (e[t] + s[t]) + R_i \xi[t]),
\]

\[
\tilde{x}[t + 1] = (\Lambda^{K-1} Z_{i}^T) \cdot F(t, p_i (e[t] + s[t]) + R_i \xi[t]).
\]

Since the spectral radius \( p(\Lambda) = |\lambda_2| < 1 \), it may be inferred that \( ||\xi|| \) gets small if \( K \) is sufficiently large. On the other hand, if \( \xi \) happens to be identically zero, then
In fact, if $\tilde{\xi} \geq 1$, the states $x \in \mathbb{R}^n$ are in a known compact set, then $K_{\text{mix}}$ can be computed (see the proof in the Appendix).

Corollary 1 \textit{Under Assumptions 1–4, for any $\epsilon > 0$ and compact set $C \subset \mathbb{R}^n$, there exists $K_{\text{mix}} > 0$ such that, for all $K > K_{\text{mix}}$, the solution $x_i$ of (5) with $x_i[0] \in C$, and the solution $s$ of (9) with $s[1] = \sum_{i=1}^N q_i f_i(0, x_i[0])$ satisfy}

\[ \|x_i[t] - p_i s[t]\| \leq \epsilon, \quad \forall t \geq 1, \; i \in \mathcal{N}. \] \tag{19}

\text{In addition, for all $k \in \{1, 2, \ldots, K - 1\}$, $i \in \mathcal{N}$, and $t \geq 1$,}

\[ \|x_i[t_k] - p_i s[t + 1]\| \leq \epsilon \left( 1 + \frac{1}{\|N - 1\|} \right). \] \tag{20}

Remark 5 \textit{In Corollary 1, the solution $s[t]$ of the blended dynamics is initiated not at $t = 0$ but at $t = 1$. One may find this is natural because the state $s'[1] = f_0(0, s'[0])$ with $s'[0] = \sum_{i=1}^N q_i x_i[0]$ (i.e., $s'[1] = \sum_{i=1}^N q_i f_i(0, x_i[0])$) can be very different from the considered state $s[1] = \sum_{i=1}^N q_i f_i(0, x_i[0])$. In fact, the states $x_i[0]$, $j \in \mathcal{N}$, may be very different from each other, but they converge with sufficiently large $K$ towards $\sum_{i=1}^N q_i x_i[0]$ with the scaling factor $p_j$, which is $s[1]$ (not $s'[1]$).}

3 \textit{Network Synthesis with Examples}

As mentioned before, the proposed approach is useful as a design method for distributed algorithms by first designing suitable blended dynamics such that they behave as desired and then synthesizing each heterogeneity of the multi-agent system such that it has the pre-designed blended dynamics. Moreover, comparing with the continuous-time approach, the discrete-time version handles more general protocols as long as the spectral radius of its weight matrix is 1. In fact, many studies on discrete-time multi-agent system including PageRank (Ishii & Tempo, 2010; Lei & Chen, 2014) or consensus (Saber et al., 2007; Ren & Beard, 2005) have used the communication protocol which can be represented as a linear combination of agents’ state information like (5b) with the weight matrix of unit spectral radius. Thus, in this section, some of the protocols are chosen to be considered as the coupling dynamics (5b) and the behaviors of corresponding multi-step coupling systems are illustrated using the results in previous section. Based on this, the design process for each application example is also provided.

3.1 \textit{Distributed Network Size Estimation with Metropolis-Hastings Coupling}

In this subsection, we assume that the network is undirected and connected, and consider the following Metropolis-Hastings coupling weight $w_{ij}^\text{MH}$ in (Schwarz, Hannak, & Matz, 2014):

\[ w_{ij}^\text{MH} := \begin{cases} \frac{1 - \mu}{\max\{d_i, d_j\}} & (j, i) \in \mathcal{E} \text{ and } i \neq j, \\ 0, & (j, i) \notin \mathcal{E} \text{ and } i \neq j, \\ 1 - \sum_{l \neq i} w_{ii}^\text{MH}, & i = j, \end{cases} \]

where $\mu \in (0, 1)$. Note that $w_{ij}^\text{MH}$ depends on both $d_i$ and $d_j$, so that each agent should additionally exchange its degree information with neighbors to update its coupling weights online, and this will enable the plug-and-play operation to the multi-step coupling framework.

It can be easily seen that $w_{ij}^\text{MH}$ satisfies (7) and Assumption 1 holds for $W^{\text{MH}} := \{w_{ij}^\text{MH} \}$ because it is doubly-stochastic. Hence, we can choose $p = \mathbb{1}_N$ and $q = (1/N)\mathbb{1}_N$ from Lemma 3. Then, the blended dynamics are obtained as a simple average of $f_i$s as follows:

\[ s[t + 1] = \frac{1}{N} \sum_{i=1}^N f_i(t, s[t]). \] \tag{21}

Since all $p_i$s are chosen evenly as 1, by Theorem 1 or Corollary 1, the behavior of every trajectory $x_i[t]$ is approximately synchronized to the solution $s$ of...
the blended dynamics (21). It should be emphasized that this collective synchronized behavior comes from $p = 1_{N}$ and this choice of $p$ is always possible for any row-stochastic (not necessarily to be doubly-stochastic) weight matrices. In Section 3.3, we will consider the row-stochastic weight matrix whose column-sums are not 1.

As an application example for the Metropolis-Hastings coupling, we can design a distributed algorithm for network size estimation as follows. In fact, many distributed algorithms such as (Ishii & Tempo, 2010; Nedić & Ozdaglar, 2009) are often assumed to know the network size $N$. The insight of the proposed algorithm is to make its blended dynamics converge to $N$. For example, if the blended dynamics are designed as the following scalar dynamics

$$s[t + 1] = \left(1 - \frac{1}{N}\right) s[t] + 1,$$

such that it has the stable equilibrium point at $N$, then each state $x_i[t]$ will also approach $N$ under the Metropolis-Hastings coupling. Thus, by increasing $K$ until the synchronization error $\epsilon$ in (10) or (19) gets smaller than 0.5, each agent can find the exact network size through the round-off to the nearest integer.

One idea to design the heterogeneous dynamics $f_i$ is whose average becomes (22) comes from

$$\frac{1}{N} \left(\left(1 + \sum_{i=2}^{N} (s[t] + 1)\right)\right) = \left(1 - \frac{1}{N}\right) s[t] + 1,$$

this is, one agent has $f_i = 1$ and all others have $f_i(s) = s + 1$. For this, we intentionally add one specific node which does not leave the network during the operation of the algorithm. Without loss of generality, let an index of this node be 1 and it runs the following dynamics:

$$x_1[t+1] = \begin{cases} 1, & \text{if } k = 0, \\ \sum_{j \in N_1 \cup \{1\}} w_{ij}^{MH} x_j[t_k], & \text{otherwise.} \end{cases}$$

(23)

On the other hand, all the other nodes of $i = 2, \ldots, N$ run the following dynamics:

$$x_i[t+1] = \begin{cases} x_i[t] + 1, & \text{if } k = 0, \\ \sum_{j \in N_1 \cup \{i\}} w_{ij}^{MH} x_j[t_k], & \text{otherwise.} \end{cases}$$

(24)

Note that, even though the individual dynamics of $(N - 1)$ nodes for $i = 2, \ldots, N$ are (marginally) unstable, the overall networked system becomes stable and the trajectories of individual agent approach close to $N$ (less than the distance of 0.5 with sufficiently large $K$). In addition, this distributed algorithm can be applied even when some agents might join or leave the network during the process of the algorithm, because it does not rely on the initial condition of agents. This idea is motivated by (Lee et al., 2018) which proposed continuous-time distributed network size estimation algorithm.

3.2 Initialization-free Distributed PageRank Estimation with PageRank Coupling

Now, we turn our attention to a different type of the weight matrix whose column-sums are all one. In this subsection, we consider the multi-step coupling framework whose coupling dynamics are the following iterative power method of PageRank (Brin & Page, 1998):

$$x_i[t+1] = mx_i[t] + (1 - m) \sum_{j \in N_i} \frac{x_j[t_k]}{d_{ij}^{out}},$$

(25)

where $x_i \in \mathbb{R}$ is the state, the parameter $m \in (0, 1)$ is typically chosen as 0.15, $N_i$ is the in-neighbors of node $i$, and $d_{ij}^{out}$ is the out-degree of node $j$. In fact, PageRank score provides an information on relative importance of each node in the network, so it has been widely utilized in diverse areas such as informatics (Chen, Xie, Maslov, & Redner, 2007), bibliometrics (Lin, Bollen, Nelson, & de Sompel, 2005), and biology (Zaki, Berenguieres, & Elimov, 2012).

Then, the coupling weight $w_{ij}^{PR}$ is given by

$$w_{ij}^{PR} = \begin{cases} m, & i = j, \\ (1 - m) \frac{a_{ij}}{d_{ij}^{out}}, & i \neq j, \end{cases}$$

where $a_{ij}$ is the $ij$-th element of the binary adjacency matrix $A$. It can be easily seen that $w_{ij}^{PR}$ satisfies (7) and its weight matrix $W^{PR} := [w_{ij}^{PR}]$ is obtained as

$$W^{PR} = mI + (1 - m)AD_{out}^{-1},$$

where $D_{out}$ is a diagonal matrix whose diagonal components are $d_{1}^{out}, \ldots, d_{N}^{out}$ in sequence. Since $W^{PR}$ is column-stochastic, it has the spectral radius of 1 with the left eigenvector $q = 1_{N}$. By Lemma 3, there exists a positive right eigenvector $p \in \mathbb{R}^N$ for the eigenvalue 1 such that

$$W^{PR} p = p, \quad 1_{N} p = 1.$$
By the results in Section 2, the \( i \)-th agent’s trajectory over the integer count \( t \) is approximated by \( p_i s[t] \), i.e., PageRank-scaled solution \( s \) of the blended dynamics (26). Therefore, if one is interested in solving the PageRank score each node, then the blended dynamics can be designed to have a stable equilibrium of 1.

In fact, when the network has a large number of agents, these PageRank scores are not easy to be computed in a centralized manner. Thus, the distributed PageRank algorithms have been proposed in (Ishii & Tempo, 2010; Lei & Chen, 2014; Suzuki & Ishii, 2018). Unfortunately, most of them commonly assume an initialization. However, when nodes are added to or removed from the network during the process of the algorithm, the whole algorithm must be re-initialized whenever a change occurs in the network, and this is not easy to be achieved in a distributed manner.

On the contrary, we can design an initialization-free distributed PageRank estimation algorithm by employing the proposed multi-step coupling framework. It can be easily inferred that, if the solution of the blended dynamics simply converges to 1, then every sampled state \( x_i[t] \) will approach to its PageRank score \( p_i \) under the multi-step coupling of (25). Thus, we first design the blended dynamics which have a stable equilibrium point at 1 as

\[
s[t + 1] = \nu s[t] + (1 - \nu), \tag{27}
\]

where \( \nu \in (0, 1) \) is a design parameter. Since \( \nu s[t] + (1 - \nu) = \sum_{i=1}^{N} (\nu p_i s[t] + (1 - \nu)/N) \), we can divide (27) to each node by proposing the following algorithm

\[
x_i[t_{k+1}] = \begin{cases} 
\nu x_i[t_k] + \frac{1 - \nu}{N}, & \text{if } k = 0, \\
mx_i[t_k] + (1 - m) \sum_{j \in N_i} x_j[t_k] \text{ out}, & \text{otherwise.}
\end{cases} \tag{28}
\]

Indeed, the proposed algorithm has the blended dynamics of (27). As stated in Theorem 1 or Corollary 1, the proposed distributed algorithm does not rely on a particular initialization. The algorithm (28) uses a global information of \( N \), but it can be distributively estimated by the result in Section 3.1.

3.3 Distributed Degree Sequence Estimation with Average Coupling

Average consensus protocol has been widely utilized in many discrete-time consensus problems including (Saber et al., 2007; Ren & Beard, 2005). Thus, in this subsection, we consider a multi-step coupling framework whose coupling dynamics (5b) are the following average consensus protocol

\[
x_i[t_{k+1}] = \theta x_i[t_k] + \frac{1 - \theta}{|N_i|} \sum_{j \in N_i} x_j[t_k],
\]

where \( \theta \in (0, 1) \) is a parameter which represents weight between its own state and the average of the neighbors.

Then, the coupling weight \( w_{ij}^{\text{avg}} \) is obtained as

\[
w_{ij}^{\text{avg}} = \begin{cases} 
\theta, & i = j, \\
(1 - \theta) \frac{a_{ij}}{d_i}, & \text{otherwise},
\end{cases}
\]

and the weight matrix \( W^{\text{avg}} := [w_{ij}^{\text{avg}}] \) is given by

\[
W^{\text{avg}} = \theta I + (1 - \theta)D^{-1}A,
\]

where \( D \) is the diagonal matrix whose diagonal components are \( d_1, \ldots, d_N \) sequentially. Note that \( w_{ij}^{\text{avg}} \) satisfies (7) and Assumption 1 holds because \( W^{\text{avg}} \) is row-stochastic matrix. Thus, we can choose \( p = 1_N \) and find a positive vector \( q \) by Lemma 3 such that

\[
q^T W^{\text{avg}} = q^T, \quad q^T 1_N = 1.
\]

Now, the blended dynamics are given by

\[
s[t + 1] = \sum_{i=1}^{N} q_i f_i(t, s[t]). \tag{29}
\]

Meanwhile, if the network under consideration is undirected, \( q \) is easily obtained as \( q = (1/d_{\text{sum}})d \) for \( p = 1_N \) where \( d_{\text{sum}} := \sum_{i=1}^{N} d_i \) and \( d = [d_1, \ldots, d_N]^T \in \mathbb{R}^N \) because \( d^T D^{-1}A = 1_N A = [d_1^{\text{out}}, \ldots, d_N^{\text{out}}] = [d_1, \ldots, d_N] = d^T \). From this, the blended dynamics (29) are rewritten as

\[
s[t + 1] = \frac{1}{d_{\text{sum}} \sum_{i=1}^{N} d_i f_i(t, s[t])}. \tag{30}
\]

Similarly with Section 3.1, the overall trajectories of \( x_i[t] \) are approximately synchronized to the solution of blended dynamics (29) (or (30)) for sufficiently large \( K \). The difference between the doubly-stochastic and row-stochastic weight matrix is that the former has the blended dynamics as the simple average of \( f_S \) like (21), while the latter has the blended dynamics as the weighted average like (29) whose weights \( q_i \)s are uneven in general.

For undirected graphs, a non-increasing sequence of all degrees is called as degree sequence (Diestel, 2017). Since
the degree sequence does not uniquely identify a graph, there has been much attention to obtain information of the graph structure from the given degree sequence. For example, Viger & Latapy (2005) realized the given degree sequence by a simple graph (realization problem) and Harary & Palmer (2014) estimated the number of graphs with the given degree sequence (graph enumeration). If each agent can predict possible structures of the network with the degree sequence, it could obtain global information such as the algebraic connectivity. In this section, we present simulation results\(^2\) to validate the algorithms proposed in Section 3 for estimating network size and PageRank scores. In particular, we consider an undirected network that changes over time and experiences the following scenarios:

1) Initially, the network has five agents.
2) At \(t = 100\), five new agents join the network.
3) At \(t = 200\), two agents leave the network while the others remain.

The network for each time interval is demonstrated in Fig. 1. The agents in the network can be classified into three types: red circle agents, which always remain in the network; blue rectangle agents, which join the network later; and green triangle agents, which stay for a while but eventually leave the network.

\section{Simulations}

In this section, we present simulation results\(^2\) to validate the algorithms proposed in Section 3 for estimating network size and PageRank scores. In particular, we consider an undirected network that changes over time and experiences the following scenarios:

1) Initially, the network has five agents.
2) At \(t = 100\), five new agents join the network.
3) At \(t = 200\), two agents leave the network while the others remain.

The network for each time interval is demonstrated in Fig. 1. The agents in the network can be classified into three types: red circle agents, which always remain in the network; blue rectangle agents, which join the network later; and green triangle agents, which stay for a while but eventually leave the network.

\subsection{Network Size Estimation}

To estimate the network size through the algorithm in Section 3.1, we first select an agent from the red circle agents and denote it as \(i = 1\). Then, we allocate the node dynamics as \(f_i = 1\) for the selected agent and \(f_i(x_i) = x_i + 1\) for all the other agents. Note that, under the Metropolis-Hastings coupling, the blended dynamics of (5) become (22).

\(^{2}\) Codes are at https://github.com/donggil-lee/multi-agent.
Fig. 2. The values $N[t] \pm 0.5$ over time are indicated by the gray dashed lines. Colored solid curves represent the network size estimation results obtained by the proposed algorithm [(a): all the state trajectories of agents at each integer count are depicted] and by IAM and OSM [(b): the state trajectory of selected agent is depicted].

Fig. 3. Estimation results for the network size by using different values of $K$: (a) $K = 10$, (b) $K = 15$, (c) $K = 25$, and (d) $K = 30$.

Fig. 2 illustrates the comparison of the network size estimation results obtained by the proposed algorithm and other algorithms including the Initial condition Averaging Method (IAM) by (Shames, Charalambous, Hadjicostis, & Johansson, 2012) and Order Statistics Method (OSM) by (Varagnolo, Pillonetto, & Schenato, 2013). Specifically, Fig. 2 (a) depicts the estimation result obtained by the proposed algorithm, where all the state trajectories, at each integer count, i.e., $x_i[t_0]$, are shown. Here, $K$ is set to be 25 for multi-step coupling and $\mu$ to be 0.1 for the Metropolis-Hastings coupling weight. Each state converges to the total number of connected agents with a deviation no greater than 0.5, regardless of agents joining or leaving from the network. This enables every agent to obtain the network size accurately. In contrast, due to initial condition dependency, the IAM and OSM algorithms’ estimation values converge to the network size only when new agents join the network and they are no longer accurate when some agents leave the network as shown in Fig. 2 (b). Meanwhile, Fig. 3 demonstrates the estimation results of the proposed algorithm with different values of $K$. As $K$ gets larger, the convergence error to the number of total agents decreases.

4.2 PageRank Estimation

As presented in (28), the implementation of proposed algorithm for PageRank estimation requires a global information of the network size $N$. We utilize the network size estimation algorithm in Section 3.1 to replace the use of $N$ in (28), so that the algorithm becomes fully distributed.

In Fig. 4, the estimation results obtained by the proposed algorithm are compared with those obtained by other algorithms, including the Randomized Algorithm (RA) by (Ishii & Tempo, 2010), and Synchronous Algorithm based on New Interpretation (SANI) by (Suzuki & Ishii, 2018). Fig. 4 (a) shows the estimation result obtained by the proposed algorithm, where each state trajectory of the agent at every integer count is displayed. We set the parameter $\nu$ as 0.9 for the blended dynamics (27) and $m$ as 0.2 for the coupling weight $w_{ij}^{PR}$. Despite changes in network configuration, each state of the agent $i$ converges to its respective PageRank score $p_i$. On the other hand, the RA and SANI algorithms’ estimation values converge to the correct value at first, but they fail to handle changes in the network, as shown in Fig. 4 (b).

5 Conclusion

In this paper, we introduced a discrete-time blended dynamics theorem, which inherits all the benefits of the continuous-time blended dynamics theorems in (Lee &
Shim, 2020). This was achieved by the proposed multi-step coupling in the multi-agent algorithm (5). The proposed approach does not require stability of individual agents as long as the blended dynamics are stable, the plug-and-play operation is easily achieved. To illustrate utility of the proposed method as a design tool, three application examples are included.

Proof of Lemma 4

Before proving Lemma 4, we first claim that, for each \( t \in \mathbb{Z} \) and \( s_1, s_2 \in \mathbb{R}^n \), there exists \( \tilde{s} \in \mathbb{R}^n \) in the line connecting \( s_1 \) and \( s_2 \) such that

\[
\left\{ f_{s}(t, s_2) - f_{s}(t, s_1) \right\}^T H^2 \left\{ f_{s}(t, s_2) - f_{s}(t, s_1) \right\} \\
\leq (s_2 - s_1)^T \frac{\partial f_s}{\partial s}(t, \tilde{s})^T H^2 \frac{\partial f_s}{\partial s}(t, \tilde{s})(s_2 - s_1). \tag{A.1}
\]

It can be proved by the mean-value theorem with a trick. Let the left-hand side of the equality (A.1) as \( \Delta(t, s_1, s_2) \) for convenience. With a variable \( c \in \mathbb{R} \), define

\[
g_{t, s_1, s_2}(c) := \left\{ f_{s}(t, s_2) - f_{s}(t, s_1) \right\}^T H^2 \\
	imes \left\{ f_{s}(t, cs_2 + (1-c)s_1) - f_{s}(t, s_1) \right\}.
\]

Since the function \( g_{t, s_1, s_2} : \mathbb{R} \rightarrow \mathbb{R} \) is continuously differentiable, by the mean-value theorem, there exists \( \tilde{c} \in [0, 1] \) such that \( g_{t, s_1, s_2}(1) - g_{t, s_1, s_2}(0) = g_{t, s_1, s_2}(\tilde{c})(1 - 0) \), which is equivalent to

\[
\Delta(t, s_1, s_2) = \left\{ f_{s}(t, s_2) - f_{s}(t, s_1) \right\}^T H^2 \\
	imes \frac{\partial f_s}{\partial s}(t, \tilde{s})(s_2 - s_1). \tag{A.2}
\]

where \( \tilde{s} = \tilde{c}s_2 + (1 - \tilde{c})s_1 \). Using this, we have

\[
\Delta(t, s_1, s_2) = \| H \{ f_{s}(t, s_2) - f_{s}(t, s_1) \} \|^2 \\
\leq \| H \{ f_{s}(t, s_2) - f_{s}(t, s_1) \} \| \left\| H \frac{\partial f_s}{\partial s}(t, \tilde{s})(s_2 - s_1) \right\|,
\]

which in turn implies \( H \{ f_{s}(t, s_2) - f_{s}(t, s_1) \} \| \leq \| H (\partial f_{s}/\partial s)(t, \tilde{s})(s_2 - s_1) \|. \) From this, the claim (A.1) is justified. Finally, it follows from Assumption 3 that

\[
\| H \{ f_{s}(t, s_2) - f_{s}(t, s_1) \} \|^2 = \Delta(t, s_1, s_2) \\
\leq (s_2 - s_1)^T \frac{\partial f_s}{\partial s}(t, \tilde{s})^T H^2 \frac{\partial f_s}{\partial s}(t, \tilde{s})(s_2 - s_1) \\
\leq \gamma (s_2 - s_1)^T H^2 (s_2 - s_1) = \gamma \| H (s_2 - s_1) \|^2,
\]

which proves Lemma 4.
integer time $t$. For this, with $\xi_1$ and $\tilde{\xi}$ from (17), we introduce a Lyapunov function
\[
V(\xi_1, \tilde{\xi}, s) = \|H(\xi_1 - s)\| + \eta\|\tilde{\xi}\|
\]
where $\eta > L\|q\|\|R\|/\sqrt{\gamma}$. Then, by recalling (18),
\[
V[t + 1] = \|H(\xi_1[t + 1] - s[t + 1])\| + \eta\|\tilde{\xi}[t + 1]\|
\]
\[
\leq \|H\{q_{\otimes n}^\top F(t, p_{\otimes n}\xi_1[t]) - q_{\otimes n}^\top F(t, p_{\otimes n}s[t])\}
+ q_{\otimes n}^\top F(t, p_{\otimes n}\xi_1[t]) + R_{\otimes n}\tilde{\xi}[t]\| - q_{\otimes n}^\top F(t, p_{\otimes n}\xi_1[t])\| + \eta\|(\Lambda^{K - 1}Z_{\otimes n}^\top F(t, p_{\otimes n}s[t])\|
+ F(t, p_{\otimes n}\xi_1[t]) - F(t, p_{\otimes n}s[t])
+ F(t, p_{\otimes n}\xi_1[t] + R_{\otimes n}\tilde{\xi}[t]) - F(t, p_{\otimes n}s[t])\|
\]
\[
\leq \|H\{q_{\otimes n}^\top F(t, p_{\otimes n}\xi_1[t]) - q_{\otimes n}^\top F(t, p_{\otimes n}s[t])\}\|
+ \|H\{f_s(t, \xi_1[t]) - f_s(t, s[t])\}\| \leq \sqrt{\gamma}\|H(\xi_1[t] - s[t])\|
\]
Second, by Assumption 4,
\[
\|F(t, p_{\otimes n}\xi_1[t] + R_{\otimes n}\tilde{\xi}[t]) - F(t, p_{\otimes n}\xi_1[t])\|
\leq \|\sum_{i=1}^n f_i(t, p_i\xi_1[t]) + (R_i \otimes I_n)\tilde{\xi}[t) - f_i(t, p_i\xi_1[t])\|^{1/2}
\leq \left(\sum_{i=1}^n L^2\|(R_i \otimes I_n)\tilde{\xi}[t]\|^2\right)^{1/2}
\leq L\|R_{\otimes n}\tilde{\xi}[t]\| \leq L\|R\|\|\tilde{\xi}[t]\|,
\]
where $R_i$ is the $i$-th row of $R$, and similarly the third one is
\[
\|F(t, p_{\otimes n}\xi_1[t]) - F(t, p_{\otimes n}s[t])\|
\leq L\|p\|\|\xi_1[t] - s[t]\| = L\|p\|\|H^{-1}H(\xi_1[t] - s[t])\|
\leq L\|p\|\|H^{-1}\|\|H(\xi_1[t] - s[t])\|.
\]
Then, we have that
\[
V[t + 1] \leq \sqrt{\gamma}\|H(\xi_1[t] - s[t])\| + \|H\|\|q\|\|L\|\|R\|\|\tilde{\xi}[t]\|
+ \|\lambda_2^{K - 1}q\|Z\|L\|\|L\|\|H^{-1}\|\|H(\xi_1[t] - s[t])\|
+ \|\lambda_2^{K - 1}q\|Z\|L\|\|R\|\|\tilde{\xi}[t]\|
+ \|\lambda_2^{K - 1}q\|Z\|L\|\|F(t, p_{\otimes n}s[t])\|
\leq \sqrt{\gamma}V[t] + |\lambda_2|^{K - 1}\eta L\|Z\|M_1 V[t]
+ |\lambda_2|^{K - 1}\eta q\|Z\|F(t, p_{\otimes n}s[t])
\]
where $M_1 := \max\{\|p\|\|H^{-1}\|, \|R\|/\eta\}$.

For the given $\epsilon$, let $K_{\text{min}}$ be a positive integer such that
\[
|\lambda_2|^{K_{\text{min}}} \frac{2\eta M_1 M(\|p\|\|M_s\|)\sqrt{\gamma}}{1 - \sqrt{\gamma}} \leq \epsilon.
\] (B.5)
\[
\|\lambda_2|^{K_{\text{min}}} 2\eta M_1 M(\|p\|\|M_s\|)\sqrt{\gamma} \|Z\|F(t, p_{\otimes n}s[t])\| \leq \epsilon.
\] (B.6)

Then, for all $K > K_{\text{min}}$,
\[
V[t + 1] - V[t] \leq \frac{1 - \sqrt{\gamma}}{2} V[t]
+ |\lambda_2|^{K_{\text{min}}} 2\eta M_1 M(\|p\|\|M_s\|)\sqrt{\gamma} \| \leq \frac{1}{2} V[t + 1].
\] (B.7)

By Assumption 4 and by Lemma B.1,
\[
\limsup_{t \to \infty} \|F(t, p_{\otimes n}s[t])\| \leq \sqrt{\gamma}M(\|p\|\|M_s\|)
\leq \sqrt{\gamma}M(\|p\|\|M_s\|).
\]

Using this and (B.7), the ultimate bound of $V$ is obtained as
\[
\limsup_{t \to \infty} V[t] \leq |\lambda_2|^{K_{\text{min}}} 2\eta \|Z\| \sqrt{\gamma}M(\|p\|\|M_s\|).\] (B.8)

Therefore, for each agent $i \in \mathcal{N}$ and $K > K_{\text{min}},$
\[
\limsup_{t \to \infty} \|x_i[t] - p_is[t]\| \leq \sqrt{\gamma}M(\|p\|\|M_s\|).
\]
\[
\leq \max\left(\|p\|\|H^{-1}\|, \frac{\|R\|}{\eta}\right) \limsup_{t \to \infty} V[t]
\leq |\lambda_2|^{K_{\text{min}}} 2\eta \|Z\| \sqrt{\gamma}M(\|p\|\|M_s\|) \leq \epsilon.
\] (B.9)

where we used $\bar{x} = p_{\otimes n}\xi_1 + R_{\otimes n}\tilde{\xi}$. This completes the proof for (10) of Theorem 1.

Now, in order to inspect the behavior of the system over the fractional time, let us apply the transformation of (17) to (12), which yields, for $k = 1, \cdots, K - 1,$
\[
\xi_k[t_k] = q_{\otimes n}^\top W_{\otimes n}^{k - 1} F(t_0, \bar{x}[t_0])
= q_{\otimes n}^\top F(t_0, \bar{x}[t_0]) = q_{\otimes n}^\top \bar{x}[t + 1] \quad (B.10)
\]
\[
= \xi_1[(t + 1)0]
\]
in which, the third equality can also be seen from (13). Similarly, for $k = 1, \cdots, K - 1$,

$$
\hat{\xi}[t_k] = Z_{\otimes}^T W_{\otimes}^{-1} F(t_0, \tilde{x}[t_0]) \\
= (\Lambda^{K-1} Z^T)_{\otimes} F(t_0, \tilde{x}[t_0]) \\
= \Lambda_{\otimes}^{K-K} (\Lambda^{K-1} Z^T)_{\otimes} W_{\otimes}^{-1} F(t_0, \tilde{x}[t_0]) \\
= (\Lambda^{-1})^{K-k} \hat{\xi}(t + 1)\!.
$$

Hence,

$$
\|\hat{\xi}[t_k]\| \leq \frac{\|\hat{\xi}(t + 1)\!\|}{|\lambda_N|^{K-k}} \tag{B.11}
$$

for each $k = 1, \cdots, K - 1$.

On the other hand, by (B.8) and (B.6), we have

$$
\limsup_{t \to \infty} \max_{t \to \infty} \{\|H(\xi_1[t] - s[t])\|, \eta\|\hat{\xi}[t]\|\} \\
\leq \limsup_{t \to \infty} V[t] \leq \frac{\epsilon}{2M_1}.
$$

Therefore, for each $k = 1, \cdots, K - 1$,

$$
\limsup_{t \to \infty} \|x_1[t_k] - p_i s[t + 1]\| \\
= \limsup_{t \to \infty} \|p_i(\xi_1[t_k] - s[t + 1]) + (R_i \otimes I_N)\hat{\xi}[t_k]\| \\
\leq \limsup_{t \to \infty} \left(\|p\| H^{-1} \|H(\xi_1[t] - s[t + 1])\| \\
+ \|R\| \eta\|\hat{\xi}[t_k]\|\right) \\
\leq \limsup_{t \to \infty} \left(\|p\| H^{-1} \|H(\xi_1[t] + 1) - s[t + 1]\| \\
+ \|R\| \eta\|\hat{\xi}[t + 1]\|\right) \\
\leq \frac{\|p\| H^{-1}_1 \frac{\epsilon}{M_1}}{2} + \frac{\|R\| \eta}{2 |\lambda_N|^{K-k}} \\
\leq \frac{\epsilon}{2} \left(1 + \frac{1}{|\lambda_N|^{K-k}}\right),
$$

where the last two inequalities come from (B.12) and the definition of $M_1$, and this completes the proof.

## C Proof of Corollary 1

In this proof, we show that, after $K - 1$ times execution of (5b), the solution of the overall system from the initial condition enters a positively invariant set, in which (19) holds. For this, let us first construct a few sets as

$$
C_1^* = \{q_{\otimes}^T F(0, \bar{x}) : x_i \in C_i, i \in \mathcal{N}\} \subset \mathbb{R}^n, \\
C_{t+1}^* = \{q_{\otimes}^T F(t, p_{\otimes} s) : s \in C_t^*\} \subset \mathbb{R}^n, \forall t \geq 1, \\
C_\infty = \bigcup_{t=1}^{\infty} C_t^* \subset \mathbb{R}^n,
$$

in which, $C_t^*$ is the set of all possible $s[t]$ for each $t \geq 1$, which is bounded. The set $C_\infty$ is also bounded by Lemma B.1. Now, for the overall state $\bar{x}$, consider two more sets:

$$
C' = \{\bar{x} : \|H(\xi - s)\| \leq \epsilon, s \in C_\infty, \|\tilde{\xi}\| \leq \delta\} \cup C_N \\
\subset \mathbb{R}^{nN}, \\
\tilde{C} = \{(\bar{x}, s) \in C' \times C_\infty : \|H(\xi - s)\| \leq \epsilon, \|\tilde{\xi}\| \leq \delta\} \\
\subset \mathbb{R}^{nN} \times \mathbb{R}^n,
$$

where $C_N$ is $N$-ary Cartesian power of $C$, i.e., $C_N = C \times C \times \cdots \times C$ and

$$
\epsilon_0 := \frac{\epsilon}{2} \max\{\|p\| H^{-1}_1\|, \|R\|\}, \\
\delta := \min\left(1, \frac{1 - \sqrt{\tau}}{L \|q\| \|R\| \|H\|}\right) \epsilon_0.
$$

Now, pick $K_{\text{min}}$ such that

$$
\|\lambda_2\|^{K_{\text{min}}} \sup_{\tilde{\xi} \in \tilde{C}} \|F(t, \bar{x})\| \leq \delta, \forall t \geq 0.
$$

We claim that the set $\tilde{C}$ is positively invariant for any $K > K_{\text{min}}$. To see this, suppose that, for any $\tau \geq 1$, $s[\tau] \in C^*_0 \subset C^*_\infty, \|\tilde{\xi}[\tau]\| \leq \delta$, and $\|H(\xi[\tau] - s[\tau])\| \leq \epsilon_0$, so that $(\bar{x}[\tau], s[\tau]) \in \tilde{C}$. Then, it follows that $s[\tau + 1] \in C^*_{\tau + 1} \subset C^*_\infty, \|\tilde{\xi}[\tau + 1]\| \leq |\lambda_2|^{K-1} \|Z\| \|F(\tau, \bar{x}[\tau])\| \leq \delta$, and

$$
\|H(\xi[\tau + 1] - s[\tau + 1])\| \\
\leq \|H(\xi[\tau + 1] - q_{\otimes}^T F(\tau, p_{\otimes} \xi[\tau])\| \\
+ \|H(\xi[\tau + 1] - q_{\otimes}^T F(\tau, p_{\otimes} \xi[\tau]) - s[\tau + 1])\| \\
\leq L \|q\| \|R\| \|H\| \delta + \|H f_x(\tau, \xi[\tau]) - f_x(\tau, s[\tau])\| \\
\leq L \|q\| \|R\| \|H\| \delta + \sqrt{\tau} \|H(\xi_1[\tau] - s[\tau])\| \leq \epsilon_0
$$

in which, we used

$$
\|\xi[\tau + 1] - q_{\otimes}^T F(\tau, p_{\otimes} \xi[\tau])\| \\
= \|q_{\otimes}^T \{F(\tau, p_{\otimes} \xi[\tau]) + R_{\otimes} \xi[\tau]\} - F(\tau, p_{\otimes} \xi[\tau])\| \\
\leq L \|q\| \|R\| \|\xi[\tau]\| \leq L \|q\| \|R\| \delta.
$$

On the other hand, the set $\tilde{C}$ is reached within $K - 1$ executions of (5b) from the initial time $t_0$. 

14
Indeed, $s[1] = q^T F(0, \bar{x}[0]) \in C_1^* \subset C_{\infty}^*$, $\|\tilde{\xi}[1]\| = \|(A^{K-1} Z^T)_{\otimes n} F(0, \bar{x}[0])\| \leq \|A_2^{K-1}\| \|F(0, \bar{x}[0])\| \leq \delta$, and $\|H(\zeta_1[1] - s[1])\| = \|H(q^T W^{K-1} F(0, \bar{x}[0]) - q^T F(0, \bar{x}[0]))\| = 0$. Therefore, $(\bar{x}[t], s[t])$ remains in $\bar{C}$ for all $t \geq 1$.

Finally, (19) is proved because, in the set $\bar{C}$,
\[
\|x_i[t] - p_i s[t]\| = \|p_i (\zeta_1[t] - s[t]) + (R_i \otimes I_n) \tilde{\xi}[t]\| \leq \max \{\|p_i\| \|H^{-1}\|, \|R_i\|\} (\|H(\zeta_1[t] - s[t])\| + \|\tilde{\xi}[t]\|) \leq \epsilon.
\]

To show (20), we note that (B.10) and (B.11) still hold. Therefore, for all $k = 1, \ldots, K - 1$, $i \in \mathcal{N}$, and $t \geq 1$,
\[
\|x_i[t_k] - p_i s[t + 1]\| = \|p_i (\zeta_1[t_k] - s[t + 1]) + (R_i \otimes I_n) \tilde{\xi}[t_k]\| \leq \max \{\|p_i\| \|H^{-1}\|, \|R_i\|\} (\|H(\zeta_1[t_k] - s[t + 1])\| + \|\tilde{\xi}[t_k]\|) \leq \max \{\|p_i\| \|H^{-1}\|, \|R_i\|\} (\|H(\zeta_1[t_{k+1}] - s[t + 1])\| + \|\tilde{\xi}[t_{k+1}]\|/|\lambda_N|^{K-k}) \leq \max \{\|p_i\| \|H^{-1}\|, \|R_i\|\} \left(\epsilon_0 + \frac{\delta}{|\lambda_N|^{K-k}}\right) \leq \frac{\epsilon}{2} \left(1 + \frac{1}{|\lambda_N|^{K-k}}\right),
\]

which completes the proof of (20).
