Animal models of nonalcoholic fatty liver disease/nonalcoholic steatohepatitis

Yoshihisa Takahashi, Yurie Soejima, Toshio Fukusato

Abstract
Nonalcoholic fatty liver disease (NAFLD) is a condition in which excess fat accumulates in the liver of a patient without a history of alcohol abuse. Nonalcoholic steatohepatitis (NASH), a severe form of NAFLD, can progress to liver cirrhosis and hepatocellular carcinoma. NAFLD is regarded as a hepatic manifestation of metabolic syndrome and incidence has been increasing worldwide in line with the increased prevalence of obesity, type 2 diabetes, and hyperlipemia. NAFLD/NASH is currently regarded as the most common chronic liver disease worldwide. It is estimated that about 20% of all adults have NAFLD and 2%-3% of adults have NASH.

INTRODUCTION
Nonalcoholic fatty liver disease (NAFLD) is a condition in which excess fat accumulates in the liver of a patient without a history of alcohol abuse. NAFLD is classified into simple steatosis and nonalcoholic steatohepatitis (NASH). In NASH, not only steatosis but also intralobular inflammation and hepatocellular ballooning are present, often accompanied by progressive fibrosis. Long-standing NASH may progress to liver cirrhosis, and hepatocellular carcinoma (HCC) may be an outcome.

NAFLD is regarded as a hepatic manifestation of metabolic syndrome. NAFLD has been increasing worldwide over recent decades in line with the increased prevalence of obesity, type 2 diabetes, and hyperlipemia. NAFLD/NASH is currently regarded as the most common chronic liver disease worldwide. It is estimated that about 20% of all adults have NAFLD and 2%-3% of adults have NASH.

The pathogenesis of NASH has not been completely elucidated, and treatments for NASH other than lifestyle modification by diet and exercise have not been fully established. Studies of NAFLD/NASH using human materials have limitations, because the occurrence and progression of NAFLD/NASH require a long period of several decades, and ethical limitations exist in admin-
Fibrosis usually originates in the perisinusoidal regions of zone 3 (perisinusoidal fibrosis) and may also be present in the periportal area. As the disease progresses, bridging fibrosis and liver cirrhosis may develop. In the process, steatosis and lesion activity may resolve, resulting in a diagnosis of "cryptogenic cirrhosis" (burn-out NASH).

Brunt et al.\[^{2}\] proposed the grading and staging system of NASH, and the NASH Clinical Research Network designed and validated the NAFLD activity score\[^{13}\]. These systems are frequently used in both clinical studies and animal experiments. Intralobular changes are milder and portal inflammation is more severe in pediatric NAFLD than in adult NAFLD\[^{14,15}\]. Furthermore, steatosis in pediatric NAFLD is not necessarily predominant in zone 3\[^{9,16}\].

PATHOGENESIS OF NAFLD/NASH

The "two-hit" hypothesis proposed by Day et al.\[^{17}\] is widely accepted as the pathogenesis of NAFLD/NASH; the first hit causes fat accumulation in hepatocytes, and the second hit causes inflammation and fibrosis. Fat accumulation in the liver is closely associated with metabolic derangements that are related to central obesity and insulin resistance\[^{18}\]. The most reproducible risk factors for NAFLD/NASH are central obesity, insulin resistance, fasting hyperglycemia, and hypertriglyceridemia\[^{19}\], and NAFLD/NASH is regarded as a hepatic manifestation of metabolic syndrome\[^{8,17}\].

Hepatic steatosis occurs when the rate of import or synthesis of fatty acids by hepatocytes exceeds the rate of export or catabolism\[^{20,21}\]. Accordingly, the following 4 mechanisms are possible causes of lipid accumulation within the liver: (1) increased delivery and uptake into hepatocytes of long-chain fatty acids (LCFA) due to excess dietary intake or release from adipose tissue; (2) increased de novo hepatic LCFAs and triglyceride synthesis; (3) failure of very low-density lipoprotein (VLDL) synthesis and triacylglycerol export; and (4) failure of LCFA elimination due to impaired hepatic mitochondrial β-oxidation\[^{22}\].

Once steatosis has developed, the liver is sensitized; thus, an inflammatory response may be precipitated by a variety of stimuli\[^{22}\]. Oxidative stress, pro-inflammatory cytokine [e.g., tumor necrosis factor (TNF)-α]-mediated hepatocyte injury, altered lipid partitioning and hepatotoxicity mediated by free fatty acids, abnormal intrahepatic cholesterol loading, hyperinsulinemia, hyperleptinemia, hypoadiponectinemia, and apoptosis are all thought to be important second hits causing NASH\[^{22-24}\].

ANIMAL MODELS OF NAFLD/NASH

An ideal animal model of NAFLD/NASH should reflect hepatic histopathology and pathophysiology of human NAFLD/NASH. Accordingly, the liver of the animal model of NASH should show steatosis, intralobular inflammation, hepatocellular ballooning, and, ideally, perisinusoidal fibrosis in zone 3 and susceptibility to liver
Table 1  Biochemical and pathological characteristics of animal models of nonalcoholic fatty liver disease/nonalcoholic steatohepatitis

| Model                          | Obesity                  | Insulin resistance | Steatosis | Steatohepatitis                  | Fibrosis |
|--------------------------------|--------------------------|--------------------|-----------|----------------------------------|----------|
| SREBP-1c transgenic mice       | No (decreased adiposity) | Yes                | Yes       | Yes                              | Yes      |
| Ob/ob mice                     | Yes                      | Yes                | Yes       | No (does not develop spontaneously) | No (resistant to fibrosis) |
| Db/db mice                     | Yes                      | Yes                | Yes       | No (does not develop spontaneously) | No (does not develop spontaneously) |
| KK-A’ mice                    | Yes                      | Yes                | Yes       | No (does not develop spontaneously) | No (does not develop spontaneously) |
| PTEN null mice                | No                       | No                 | Yes       | Yes                              | Yes      |
| PPAR-α knockout mice          | No                       | No                 | No        | No (steatosis occurs in the starved state) | No       |
| AOX null mice                  | No                       | No                 | Yes       | Yes                              | No       |
| MATIA null mice                | No                       | No                 | Yes       | Yes                              | No       |
| Methionine and choline deficiency | No (decreased weight and adiposity) | Hepatic insulin resistance | Yes | Yes (severe) | Yes |
| High fat                      | Yes                      | Yes                | Yes       | Yes (mild)                        | Yes      |
| Cholesterol and cholate (atherogenic diet) | No (decreased weight) | Hepatic insulin resistance | Yes | Yes | Yes |
| Fructose                      | No                       | Yes                | Yes       | No/Yes                           | No       |

SREBP: Sterol regulatory element binding protein; PTEN: Phosphatase and tensin homologue deleted on chromosome 10; AOX: Acyl-coenzyme A oxidase; MATIA: Methionine adenosyltransferase-1A; PPAR: Peroxisome proliferator-activated receptor.

tumors. Furthermore, the animal should show metabolic abnormalities such as obesity, insulin resistance, fasting hyperglycemia, dyslipidemia, and altered adipokine profile. It is questionable whether the results of a study using an animal model that does not completely fulfill these conditions can be extrapolated to human disease. Animal models of NAFLD/NASH are classified into genetic models, nutritional models, and combination models of genetic and nutritional factors. Numerous animal models of NAFLD/NASH have been reported to date; however, no animal model completely reflects hepatic histopathology and pathophysiology of human NAFLD/NASH. It is, therefore, important to select the animal model that best conforms to the aim of the study. Biochemical and pathological characteristics of animal models described in this paper are summarized in Table 1. As described below, in many of the genetic models of NASH [e.g., sterol regulatory element binding protein (SREBP)-1c transgenic mice and phosphatase and tensin homologue deleted on chromosome 10 (PTEN) null mice], hepatic steatosis occurs first, and steatohepatitis develops later. Ob/ob, db/db, and KK-A’ mice do not progress to steatohepatitis spontaneously. On the other hand, in a dietary model induced by methionine and choline deficiency, steatohepatitis occurs very quickly.

GENETIC MODELS

**SREBP-1c transgenic mice**

In the fat tissue of these mice, SREBP-1c, a lipogenic transcription factor, is overexpressed. This creates a model of congenital lipodystrophy in which severe insulin resistance and diabetes develop secondary to impaired adipose differentiation. In these mice, decreased fat tissue with lipid accumulation in the liver is observed, and marked hepatic steatosis occurs by 8 d of age. When fed a standard diet, steatosis, lobular inflammation, and perivenular and pericellular fibrosis develop at 20 wk, ballooned hepatocytes and MH are also observed. These mice appear to be appropriate for the lipodystrophy-associated steatohepatitis model. However, it is questionable whether they can be used as a model for typical NAFLD/NASH, because visceral fat characteristically increases in human NAFLD/NASH.

**Ob/ob mice**

Ob/ob mice possess a spontaneous mutation in the leptin gene (leptin-deficient). Leptin is an adipokine produced by white adipose tissue and operates on the hypothalamic ventral median nucleus exerting a marked anorexic effect. Ob/ob mice are hyperphagic, inactive, and extremely obese, and show hyperglycemia, insulin resistance, and hyperinsulinemia. Ob/ob mice develop spontaneous hepatic steatosis; this does not, however, progress to steatohepatitis spontaneously. Secondary insults such as a methionine- and choline-deficient (MCD) diet, a high fat (HF) diet, or low-dose lipopolysaccharide (endotoxin) are needed to trigger steatohepatitis in ob/ob mice. Another feature of ob/ob mice is that they are protected against fibrosis, a phenomenon which led to the characterization of leptin as an essential mediator of hepatic fibrogenesis. Mutations in the ob gene are not prevalent in obese subjects or NASH patients, and leptin levels correlate poorly with the development of NASH.

**Db/db mice**

Db/db mice possess a natural mutation in the leptin receptor (Ob-Rb) gene and, therefore, show normal or elevated levels of leptin but are resistant to the effects of leptin. These mice are obese, insulin resistant, and dia-
betac, and develop macrovesicular hepatic steatosis. They develop NASH when a second hit such as an MCD diet is added [38]. When db/db mice are fed an MCD diet, significant liver fibrosis is observed as compared to that in ob/ob mice [38]. The advantage of ob/ob and db/db mice is that the phenotype of these mice simulates the human condition of metabolic syndrome in many aspects. However, these mice have the disadvantage that they do not spontaneously develop steatohepatitis or liver fibrosis.

KK-Aα mice
A heterozygous mutation of the agouti gene (KK-Ay/α) results in a loss of melanocortin and an obese phenotype due to hyperphagia from impaired hypothalamic appetite suppression [38]. Although these mice develop hepatic steatosis in conjunction with obesity and insulin resistance, significant steatohepatitis does not occur spontaneously. It was reported that KK-Aα mice exhibited increased susceptibility to MCD diet-induced steatohepatitis, where hyperadiponectinemia most likely played a key role in exacerbation of both inflammatory and profibrogenic responses [39].

PTEN 10 null mice
PTEN is a tumor suppressor gene encoding a lipid phosphatase whose major substrate is phosphatidylinositol-3,4,5-triphosphate (PIP3). PTEN is a negative regulator of several signaling pathways such as phosphatidylinositol-3 kinase and serine-threonine protein kinase B (PKB, or Akt) [38]. These pathways regulate apoptosis, cell proliferation, and tumor formation [38]. Liver-specific Pten knockout mice (AlbCrePTEN flox/flox mice) show extensive hepatomegaly and steatohepatitis, and the histopathology is similar to that in human NASH [40]. Steatosis is observed at 10 wk of age, and steatohepatitis with fibrosis is observed at 40 wk. Hepatocellular adenomas occur with an incidence of 47% by 44 wk, and by 74-78 wk, all of the livers show adenomas, whereas 66% develop HCCs [40]. Pten knockout mice are hypersensitive to insulin, and Pten null hepatocytes have high proliferative activity in vitro [40]. The advantage of this model is that the histological phenotype resembles that of human NASH. The disadvantage of this model is that it is hypersensitive to insulin.

Peroxisome proliferator-activated receptor-α knockout mice
Peroxisome proliferator-activated receptor-α (PPAR-α) is a key regulator of genes involved in peroxisomal, mitochondrial, and microsomal fatty acid oxidation systems in the liver, and a significant decrease in PPAR-α is observed in the HF diet model [41]. Fat does not accumulate in the liver of mice with a homozygous mutation of the PPAR-α gene under conditions of normal feeding, but in the starved state, hepatic steatosis occurs because fatty acid oxidation is inhibited [42].

Acyl-coenzyme A oxidase null mice
Acyl-coenzyme A oxidase (AOX) is the rate-limiting enzyme of peroxisomal β-oxidation of LCFA. AOX null (AOX -/-) mice have defective peroxisomal β-oxidation of LCFA, which accumulate in the liver and lead to steatohepatitis. AOX -/- mice begin to exhibit macrovesicular fatty change of hepatocytes in zones 2 and 3 of liver lobules at 7 d of age [43]. By 30 d of age, the AOX -/- mouse liver shows increased severity of steatosis of liver parenchymal cells and concomitant occurrence of focal inflammatory cell infiltrate [43]. At 2 mo of age, clusters of hepatocytes with peroxisome-rich eosinophilic granular cytoplasm are observed in periportal areas [43]. By 4-5 mo of age, increased expressions of PPAR-α, cytochrome P450 (Cyp) 4a10 and Cyp 4a14, and increased levels of H2O2 are observed [44]. However, compensative increase of fatty acid oxidation is observed by 6-7 mo of age, and hepatic steatosis recovers by regeneration of hepatocytes. AOX -/- mice develop hepatocellular adenomas and HCCs by 15 mo of age [44].

Methionine adenosyltransferase-1A null mice
Methionine adenosyltransferase-1A (MAT1A) is a liver-specific rate-limiting enzyme of methionine metabolism and catalyzes the formation of S-adenosylmethionine. MAT1A null mice have decreased levels of antioxidants, including glutathione, and decreased expressions of genes involved in lipid oxidation such as Cyp 4a10 and Cyp 4a14 [45]. MAT1A null mice spontaneously develop steatohepatitis after 8 mo of age, and proliferation of hepatocytes increases, resulting in tumor development [46].

The mice are susceptible to choline-deficient diet-induced fatty liver at 3 mo of age [46]. Although MAT1A null mice are hyperglycemic, their insulin levels are normal and they do not appear to develop other features of metabolic syndrome [46].

Dietary Models of NASH
Methionine and choline deficiency
The MCD diet contains high sucrose and fat (40% sucrose, 10% fat) but lacks methionine and choline, which are essential for hepatic β-oxidation and production of VLDL [22]. In addition, choline deficiency impairs hepatic VLDL secretion [37]. As a result, lipid is deposited in the liver. Furthermore, oxidative stress [48,49] and changes in cytokines and adipocytokines [50] occur, contributing to the liver injury. Antagonizing oxidative stress by increasing antioxidant capacities attenuates the degree of steatohepatitis and stresses the importance of reactive oxygen species in this model [51].

Serum alanine aminotransferase (ALT) level is consistently increased after MCD-diet feeding in mice [52]. Steatohepatitis occurs at day 10 [53], and perisinusoidal fibrosis is observed by 8-10 wk in mice [48,53]. After 10 wk of MCD feeding, extensive macrovesicular steatosis is observed in...
all areas except for the periportal region, and many necro-inflammatory foci containing lymphocytes and neutrophils are observed in mice. Although the MCD model causes more severe inflammation, oxidative stress, mitochondrial damage, apoptosis, and fibrogenesis than other animal nutritional models of NAFLD/NASH, the severity of NASH in rodents fed the MCD diet may depend on the species, gender, and strain of the animal. Kirsch et al. compared the effects of MCD diet using male and female Wistar, Long-Evans, and Sprague-Dawley rats, and C57BL/6 mice. As a result, the Wistar strain and the male sex were associated with the greatest degree of steatosis in rats. Of the groups studied, male C57BL/6 mice developed the most inflammation and necrosis, and best approximated the histological features of NASH.

The main disadvantage of the MCD model is that the metabolic profile of the model is opposite to that of typical human NASH. Namely, mice fed the MCD diet show significant weight loss (often, more than 20% weight loss after 3 wk), low fasting blood sugar, peripheral insulin sensitivity, low serum insulin and leptin levels, and unchanged or increased serum adiponectin levels. To improve these problems, genetically obese mice, such as ob/ob and db/db mice, are occasionally used as a MCD-fed animal. The main advantages of the MCD diet are that it is easy to obtain and use.

**HF diet**

Lieber et al. reported a diet of NASH by using an HF diet (71% of energy from fat, 11% from carbohydrates, and 18% from proteins). Rats fed this diet ad libitum for 3 wk showed elevated plasma insulin levels reflecting insulin resistance. Rats fed the HF diet developed marked panlobular steatosis, and the hepatic lipid concentrations of these rats were approximately twice those of control rats fed the standard Lieber-DeCarli diet (35% fat, 47% carbohydrates, and 18% protein). Like human NASH, the rats fed the HF diet developed oxidative damage in the liver. When dietary consumption was restricted, steatosis and inflammation in the liver, oxidative stress, and plasma insulin levels were decreased. Feeding of an HF emulsion to Sprague-Dawley rats also induced changes closely resembling human NASH. In the longitudinal study by Ito et al., chronic administration of an HF diet (60% of calories from fat) caused steatohepatitis in male C57BL/6J mice.

Intragastric overfeeding of mice with an HF diet up to 85% in excess of standard intake for 9 wk has been reported to replicate the histopathological and pathogenetic features of NASH. Overfed C57BL/6 mice became obese (71% higher body weight), had increased visceral fat (white adipose tissue: WAT), and showed hyperglycemia, hyperinsulinemia, hyperleptinemia, glucose intolerance, and insulin resistance. Almost half (46%) of the animals developed NASH, and their plasma ALT levels showed 9- to 10-fold increases. Neutrophilic infiltration and perisinusoidal fibrosis reminiscent of human NASH were observed. The WAT exhibited increased TNF-α and leptin expressions and reduced adiponectin expression.

An HF diet is widely used to cause hepatic steatosis and NASH in experimental animals. However, it seems that the HF diet model produces variable results with regard to the degree of steatosis, inflammation, and fibrosis, and the results depend on rodent species and strain, the fat content in the diet, the composition of dietary fat, and the duration of treatment. For example, Sprague-Dawley rats appear susceptible to steatohepatitis development when fed an HF diet, and this is likely associated with their susceptibility to diet-induced obesity. On the other hand, it was reported that long term high saturated fat feeding did not induce hepatic steatosis and NASH in Wistar rats. In mice, it was reported that BALB/c male mice accumulated more hepatic lipid than C57BL/6J male mice when fed an HF diet. In general, compared with the MCD model, the degree of liver injury in the HF model is less severe. Among the HF models, the histopathology and pathophysiology of the intragastric overfeeding method most resemble those of human NASH. However, this method is difficult to implement, because it requires specific equipment and expertise. The optimization of the composition of the HF diet to reliably cause NASH in animals by ad libitum administration warrants future investigation. Recently, Ogasawara et al. reported a combined model of HF diet and gold thioglucose (GTG) administration. GTG is known to induce lesions in the ventromedial hypothalamus, leading to hyperphagia and obesity. They administered GTG intraperitoneally to C57BL/6 mice, and thereafter, fed an HF diet to the mice for 12 wk. As a result, obesity with increased abdominal adiposity, glucose intolerance, insulin resistance, and steatohepatitis with hepatocyte ballooning, MH, and pericellular fibrosis were induced.

**Cholesterol and cholate**

Matsuzawa et al. fed mice an atherogenic diet containing 1.25% cholesterol and 0.5% cholate and observed the progressive formation of steatosis, inflammation, and fibrosis in a time-dependent manner over 6-24 wk. In the model, hepatocellular ballooning, characteristic of human NAFLD/NASH, was observed at 24 wk. When 60% fat (cocoa butter) was added to the diet, development of these histopathological features was accelerated, and hepatocellular ballooning was observed at 12 wk. Furthermore, the atherogenic diet induced oxidative stress. Thus, it is conceivable that a combination diet of HF, cholesterol, and cholate in animals would cause histological features reminiscent of human NASH. However, the mice fed this diet were systematically insulin sensitive, albeit they showed hepatic insulin resistance. In fact, the mice lost 9% body weight during the experiment and had small epididymal fat pads and low plasma triglyceride levels compared with those in control mice. Therefore, this model appears to differ from human NASH in metabolic status.

**Fructose**

NAFLD/NASH is regarded as a hepatic manifestation of...
metabolic syndrome. Experimental animals fed a fructose-enriched diet are recognized as good models of metabolic syndrome. We examined livers of Wistar rats fed a high-fructose (70%) diet for 5 wk and found significantly higher macrovesicular steatosis (Figure 1A) and intralobular inflammation (Figure 1B) grades, liver:body weight ratios, and hepatic triglyceride concentrations than those in control rats [70]. In this study, the distribution of steatosis in the rats fed a high-fructose diet was characteristically predominant in zone 1. This pattern differs from that of human adult NAFLD, in which steatosis is usually predominant in zone 3. Rats fed a high-fructose diet showed significantly higher expressions of interleukin (IL)-6 protein and TNF-α protein in the liver compared with those in control rats (unpublished data). By adding plant leaf extract to the high-fructose diet, hepatic fatty change (Figure 2) and expression of IL-6 protein in the liver were completely suppressed (unpublished data).

Other groups also reported induction of NAFLD/NASH by fructose in experimental animals. Ackerman et al [71] found that male Sprague-Dawley rats fed a fructose-enriched (60%) diet developed macrovesicular and microvesicular steatosis in the liver. Armutcu et al [72] reported that male Wistar albino rats provided with drinking water containing 10% fructose for 10 d developed macrovesicular and microvesicular steatosis but did not develop inflammation in the liver. In mice, by adding 30% fructose to the drinking water, 3- to 4-fold increases in hepatic triglyceride levels and marked increases in hepatic steatosis and weight were observed at 8 wk [73]. Recently, it was reported that C57BL/6 mice fed a high-fat high-carbohydrate diet and provided with drinking water containing 55% fructose for 16 wk developed a NASH-like phenotype with significant fibrosis as well as obesity [74]. Inflammation caused by endogenous toxins of fructose metabolites is suggested as one of the mechanisms of the second hit in the pathogenesis of NASH [75].

COMBINED MODEL OF GENETIC MODIFICATION AND NUTRITIONAL/DIETARY CHALLENGES

Many animal models combine naturally occurring genetic mutations or targeted gene modifications with dietary or chemical challenges so that the histopathology and pathophysiology of the models more closely resemble those of human NAFLD. Sahai et al [36] fed an MCD diet to ob/ob and db/db mice and observed that db/db mice had significantly higher serum ALT levels and more severe hepatic inflammation and fibrosis than those in ob/ob and wild-type mice. PPAR-α null mice fed an MCD diet show more severe steatohepatitis than that in wild-type mice fed the same diet [76,77]. Many other models combining genetic abnormalities with nutritional challenges have been reported [78-80].

CONCLUSION

As reviewed in this paper, many animal models of NASH have been developed to date. These animal models do not replicate the full spectrum of the disease in humans; however, they can be used in verifying hypotheses on the pathogenesis of NASH and in performing interventional studies. We hope that animal models which more closely reflect the histopathology and pathophysiology of human NASH will be developed in the future, and information on pathogenesis and treatment of NASH will increase by using these models.
