Abstract

**Background:** Hydroxymethyl-glutaryl-coenzyme A reductase inhibitors (‘statins’) are prescribed to millions of people. Statins are anti-inflammatory independent of their cholesterol-reducing effects. To date, most reports on the immune effects of statins have assayed a narrow array of variables and have focused on cell lines, rodent models, or patient cohorts. We sought to define the effect of rosuvastatin on the ‘immunome’ of healthy, normcholesterolemic subjects.

**Methods:** Prospective study of rosuvastatin (20 mg/day x 28 days) in 18 statin-naïve adults with low density lipoprotein-cholesterol <130 mg/dL. A panel of >180 immune/biochemical/endocrinologic variables was measured at baseline, and days 14, 28, and 42 (14 days after drug withdrawal). Drug effect was evaluated using linear mixed effects models. Potential interactions between drug and baseline high-sensitivity C-reactive protein (hsCRP) were evaluated.

**Results:** A wide array of immune measures changed (nominal p<0.05) during rosuvastatin treatment, although the changes were modest in magnitude and few met a false discovery rate of 0.05. Among changes noted were a concordant increase in pro-inflammatory cytokines (IFNγ, IL-1β, IL-5, IL-6, TNFα) and peripheral blood neutrophil frequency, and a decline in activated T regulatory cell frequency. Several drug effects were significantly modified by baseline hsCRP, and some did not resolve after drug withdrawal. Among other unexpected rosuvastatin effects were changes in erythrocyte indices, glucose-regulatory hormones, CD8+ T cells, and haptoglobin.
**Conclusion:** Rosuvastatin induces modest changes in immunologic and metabolic measures in normocholesterolemic subjects, with several effects dependent upon baseline CRP. Future, larger studies are warranted to validate these changes and their physiological significance.

**Introduction**

Hydroxymethyl-glutaryl (HMG)-coenzyme A reductase inhibitors (‘statins’) are prescribed to more than ¼ of adults over 40 years of age in the U.S. for atherosclerotic cardiovascular disease (ASCVD) treatment or prophylaxis (1). In addition to decreasing serum cholesterol, statins have anti-inflammatory and immunomodulatory properties (2), suggesting their potential for wider disease application. Most reports on the immune effects of statins, however, have either been performed in rodent models, commonly using very high doses delivered parenterally (3, 4), or in *in vitro* cell-based studies, using supraphysiologic concentrations (5-7). Reported effects of statins on the human immune system *in vivo* have largely derived from studies of patients with hypercholesterolemia, coronary artery disease, and/or human immunodeficiency virus (HIV) infection (8-12) and are thus of uncertain generalizability. In this context, different statins have been reported to reduce serum pro-inflammatory cytokines (e.g., tumor necrosis factor alpha [TNFα], interleukin [IL]-6, IL-8), C-reactive protein (CRP), and T cell and monocyte activation (8, 11, 13), some of these effects within 6-8 weeks (8, 14) or earlier (9), and in a manner independent of serum cholesterol reduction (15). There is a great deal of heterogeneity across these clinical reports, however, including some that failed to observe any immune effects (10, 12, 16). Moreover, some cell-based reports have even indicated the potential for statins to induce pro-inflammatory cytokine production by human leukocytes (17, 18), prompting recent calls to determine whether this occurs *in vivo* (19). Given the potential public health implications, there is a critical need to better resolve the effects of this widely used class of drugs on the human immune system.
To date, few reports have examined the *in vivo* immune effects of statins in healthy, normocholesterolemic subjects, and these studies have measured a narrow array of immune markers. One group found that simvastatin and atorvastatin had opposite effects on T cell activation within 14 days of treatment but no effect on serum cytokines or high-sensitivity (hs)CRP (20), whereas another group found that simvastatin reduced serum monocyte chemoattractant protein-1 within this timeframe (21). Atorvastatin and lovastatin were reported to increase T regulatory (Treg) cells within 30 days in healthy subjects (22). Notably, the JUPITER trial showed that rosuvastatin reduced major ASCVD events and serum hsCRP in >17,000 subjects with baseline low density lipoprotein-cholesterol (LDL-C) <130 mg/dL and hsCRP ≥2 mg/L but did not report any additional immune measures (23). Smaller studies in subjects with hypercholesterolemia and HIV have found that suppressive effects of statins on hsCRP (24) and T cell activation (11) were restricted to those with baseline elevations in hsCRP or T cell activation, respectively. Whether baseline inflammatory status determines statin effects in healthy subjects is unknown.

Here, we report the results of a prospective 4-week study of rosuvastatin 20 mg daily in 18 subjects with baseline LDL-C<130 mg/dL, followed by 2 weeks of drug washout. A comprehensive panel of >180 immune, hematologic, and biochemical measures was evaluated at baseline, during treatment, and after drug discontinuation. Rosuvastatin induced wide-ranging effects. Of interest, we identified several pro-inflammatory cytokines that appeared to increase during statin treatment and then decreased after statin discontinuation. A subset of drug effects differed significantly between subjects with baseline hsCRP ≥2 mg/L vs. <2 mg/L, suggesting interaction with inflammatory status. Taken together, this is the first report, to our knowledge, of
the *in vivo* impact of a statin on the immunome of normocholesterolemic, healthy subjects, identifying several potential drug effects that warrant further investigation.
Results

In order to define the effect of statins on the immunome of healthy, normocholesterolemic subjects, we recruited 18 statin-naïve (within 6 months prior to enrollment) adults with LDL-C <130 mg/dL. Although the original objective was to recruit 20 subjects, 10 with normal (<2 mg/L) and 10 with elevated (≥2 mg/L) hsCRP, only 7 high-hsCRP subjects could be identified despite extending the screening period. Baseline characteristics of the study participants are shown in Table I. Following an initial 7-day washout period during which participants were asked to refrain from non-steroidal anti-inflammatory drugs, antihistamines, steroids (including topical), and niacin formulations, a baseline panel of immune, hematological, and endocrine measurements was collected (Table S1) (25). Subjects were then commenced immediately on a 28-day course of rosuvastatin 20 mg daily. As shown in Figure 1, the panel of measurements was repeated on days 14, 28, and 42 (i.e., 14 days after drug washout).

Baseline immune profile of subjects with normal vs. elevated hsCRP

CRP has been proposed as a clinically robust biomarker for identifying subjects with increased systemic inflammation, and a hsCRP cutpoint of 2 mg/L has been proposed (26). As shown in Table S2, 51 measures were found to differ significantly (p<0.05) at baseline between subjects with normal and elevated hsCRP (47 of 51, higher in subjects with CRP ≥2 mg/L). Of these, 19 met a false discovery rate (FDR) threshold of 0.05. Consistent with previous reports of the utility of CRP as a pro-inflammatory biomarker, several pro-inflammatory cytokines (interferon [IFN]γ, TNFα, IL-6, IL-12p70, IL-17, IL-18) and chemokines (IL-8, GROα, MIP-1α, MIP-1β, RANTES) were elevated in high hsCRP subjects. Type-2 (IL-4, IL-5, IL-9, IL-13) inflammatory mediators and the anti-inflammatory cytokine IL-10 were also elevated in high hsCRP subjects,
suggesting a complex, mixed inflammatory milieu with compensatory signals. Consistent with their higher serum granulocyte-colony stimulating factor and neutrophilic chemokines, high hsCRP subjects tended to have relatively increased neutrophils and decreased lymphocytes in their leukocyte differential. High hsCRP subjects also had higher insulin, C-peptide, glucagon, and leptin than normal hsCRP counterparts, consistent with metabolic stress. Random forest analysis identified IL-6 and IL-4 as the measures of highest importance for discriminating between CRP-high and CRP-low subjects (Figure S1). Taken together, a hsCRP cutpoint of 2 mg/L distinguished subjects displaying an associated cluster of low vs. high pro-inflammatory measures.

**Measures altered during rosuvastatin treatment**

As expected, and confirming rosuvastatin effect, total cholesterol and LDL-C were significantly reduced in all subjects while on rosuvastatin, with rebound to baseline after drug discontinuation (Figure 2, Table II). Triglycerides were also reduced, whereas HDL cholesterol was unchanged. The effect on serum lipids was seen at day 14 and occurred equivalently in low and high hsCRP subjects.

Although several measures from the immunophenotypic panel met nominal statistical significance (p<0.05), the only other measure to meet an FDR<0.05 threshold was a reduction in mean corpuscular hemoglobin concentration (MCHC) (Table II) (i.e., the concentration of hemoglobin within erythrocytes). Concordant with this, rosuvastatin treatment was also associated with a reduction in hemoglobin mass and mean corpuscular hemoglobin mass, and with an increase in mean corpuscular volume (MCV), collectively suggesting independent
effects on hemoglobin and erythrocyte size. Erythrocyte count was also depressed by rosuvastatin, whereas hematocrit, while reduced, was not significant (p=0.09). Arguing against induction of hemolysis (27), haptoglobin was significantly increased during rosuvastatin administration, followed by normalization after rosuvastatin discontinuation (Table II, Figure S2A).

Of interest, several pro-inflammatory cytokines (IFNγ, IL-1β, IL-5, IL-6) increased, albeit modestly, in subjects while on rosuvastatin (nominal p<0.05) (Table II, Figure 3A-E). Both IL-18, like IL-1β, a product of the inflammasome (17, 18), and TNF, an inflammasome-independent cytokine, also increased while in response to rosuvastatin treatment, but these marginally missed statistical significance (Figure S2B-C). Formal correlation analysis revealed that all of the aforementioned cytokines, along with several others (IL-2, IL-4, IL-7, IL-8, IL-12p70) were strongly correlated in their response over time to rosuvastatin (Figure S3). By contrast, serum total cholesterol and LDL-C showed no correlation with this cytokine module. Although in most cases the increase in cytokine levels was more marked in CRP-high subjects, formal testing did not reveal a significant interaction between rosuvastatin and baseline hsCRP (Table S3). In parallel with the increases in these pro-inflammatory mediators, rosuvastatin induced an increase in the anti-inflammatory cytokine IL-10 in CRP-high subjects (p=0.05) (Figure S2D) and in the anti-protease and anticoagulant protein, α2-macroglobulin (A2M) (Table II). Although modeling indicated that rosuvastatin was associated with a reducing effect on CRP, this did not achieve statistical significance (p=0.08).
With regard to leukocyte subpopulations, rosuvastatin treatment was associated with an increase in neutrophil frequency in both CRP groups (Table II, Figure 3F). By contrast, a decline in the frequency of activated T regs (CD4+CD127loCD25hiCCR4+HLA-DR+ cells) that was transient in CRP-high subjects but sustained in CRP-low subjects was observed (Figure 3G). In addition, a decline was seen in CD127hiCD27hiCD39+HLA-DR+ T regs during rosuvastatin administration. Rosuvastatin was also associated with a decline in some naïve CD4+ T cell populations, such as CD28−CCR7+CD45RA+.

Complex effects were observed among CD8+ T cell subpopulations and B cells. Rosuvastatin treatment was associated with a reduction in CD28+CCR7−CD45RA+ CD8+ T cells irrespective of CRP status (Table II), whereas reductions in DR+CD8+ T cells and in CD38+ CD8+ T cells were seen only in CRP-high subjects (Figure 3H-I), as confirmed by formal interaction testing (Table S3). This CRP-selective effect on CD8+ T cells interestingly occurred despite the two CD8+ T cell subsets displaying reciprocal relationships to CRP (CD38+ cells elevated in high-CRP subjects, DR+ cells reduced in CRP-high subjects [Table II, Figure 3]). By contrast, the CD28+CCR7−CD45RA− subset of CD8+ T cells was increased on rosuvastatin irrespective of CRP status (p=0.05). Finally, CD19+CD20−CD38−CD24− B cells were noted to increase significantly in response to rosuvastatin treatment only in CRP-high subjects (Figure 3J), as confirmed by formal interaction testing (Table S3). Taken together, rosuvastatin administration was associated with complex changes in circulating myeloid and lymphoid populations.

Among metabolic measures, glucagon and glucagon-like peptide (GLP)-1 exhibited a similar pattern of response to rosuvastatin, modestly increasing by day 28 and then declining after drug
discontinuation (Tables II and III, Figure 4A-B). Of interest, these two measures were highly correlated in their response pattern to the cytokine module noted above (Figure S3). Insulin and C-peptide both progressively increased on rosuvastatin (p=0.05) especially in CRP-high subjects, and their levels did not normalize after drug discontinuation (Figure 4C-D).

**Measures altered after rosuvastatin withdrawal**

By mixed linear effects modeling, 31 measures were nominally statistically significant (p<0.05) for an effect of rosuvastatin discontinuation; of these, 5 met an FDR 0.05 threshold (Table III). Several measures, including glucagon, GLP-1, and haptoglobin exhibited a reciprocal response to rosuvastatin initiation (increase) vs. discontinuation (decrease), suggesting a temporal and reversible effect of the drug. Of the pro-inflammatory measures that increased while on rosuvastatin, several were noted to decline after statin discontinuation (IFN$\gamma$, TNF$\alpha$, IL-1$\beta$, IL-5, IL-6, IL-15) (Figure 3), also temporally consistent with a causal effect of the drug; however, of these, only the decline in IL-1$\beta$ achieved statistical significance, and this effect was restricted to the high-CRP group (Table S4, Figure 3B). A total of 11 measures exhibited a statistically significant interaction of the drug discontinuation effect with baseline hsCRP status (Table S4).

Additional patterns of drug discontinuation effect were noted. Some immune measures were noted to increase significantly after statin discontinuation, despite not having changed significantly from baseline during statin therapy. Among these were TNF-related apoptosis-inducing ligand [TRAIL] and IL-17A2 (Table III, Figure 3K-L), the latter of which was noted to interact with CRP (i.e., only to increase in CRP-high subjects; Table S4, Figure 3L). Of interest, IL-25 (i.e., IL-17E) was also noted to increase after statin discontinuation in interaction
with CRP (Table S4). Other measures increased from baseline during statin administration and then further increased after statin administration (IL-18, stem cell growth factor [SCGF] beta) (Table III, Figure S2B, S2E).
Discussion

Statins modulate the function of multiple immune cell types (2). Many of these effects have been shown to arise from reduced prenylation of signaling proteins (due to statin-mediated depletion of cellular isoprenoids) or reduced cell cholesterol (2-4), but anti-inflammatory effects that are independent of HMG CoA reductase have also been identified (e.g., inhibition of LFA-1 and HDAC-2 (28, 29)). Additional anti-inflammatory or pro-resolving actions that have been identified for statins include induction of 15-epi-lipoxin A4 (30) and PPAR-γ (21). The majority of the reports on immune effects of statins were derived from studies using cell lines, rodents, or human cells studied ex vivo. Studies of statin-treated humans have largely arisen from patient cohorts with hypercholesterolemia, HIV infection, or ASCVD and have generally focused on select immune readouts (8-12). Defining the immune effects of statins in broader populations is important as statins are increasingly being considered in normocholesterolemic subjects at risk of ASCVD (23) as well as in a growing list of immunologic human disorders, including asthma, ARDS, pneumonia, sepsis, chronic obstructive pulmonary disease, rheumatoid arthritis, lupus, multiple sclerosis, graft vs. host disease, and organ transplantation rejection (31). Moreover, there is increasing interest in the effects of statins on infection risk and vaccination efficacy at a population level (2).

Here, we report the first prospective comprehensive immunologic and biochemical profiling of statin-treated normocholesterolemic subjects. Taken together, we have succeeded in cataloguing a large number of putative statin effects, many of them, previously unreported, to our knowledge. Given that few of these changes met a FDR threshold of 0.05, the results should be considered as hypothesis-generating in nature. Contrary to some (24), but not all (20) prior reports, we did not
detect a decrease in hsCRP with rosuvastatin. Rosuvastatin discontinuation was, however, associated with an increase in hsCRP (Table III).

Of interest, we found that rosuvastatin treatment was associated with concordant, albeit modest upregulation of several pro-inflammatory indicators, including cytokines (IFNγ, IL-1β, IL-5, IL-6) and peripheral blood neutrophil frequency. Most reports of ex vivo-treated human leukocytes and of ex vivo assays on in vivo-treated leukocytes have found that statins reduce pro-inflammatory cytokines (32-34). Simvastatin was also found to reduce serum cytokines within 2 weeks in normocholesterolemic subjects (21). By contrast, ex vivo treatment of human monocytes with lipophilic statins (simvastatin, atorvastatin, lovastatin) but not pravastatin induced upregulation of multiple cytokines in a manner blocked by co-treatment with mevalonic acid (35). Simvastatin has also been reported to induce IL-18, TNFα, and IFNγ in human peripheral blood mononuclear cells (36), to augment LPS induction of multiple cytokines in human peripheral blood mononuclear cells (18), and to promote caspase-1-dependent processing of IL-1β in THP-1 cells through a mechanism involving prenylation inhibition (37). Similarly, fluvastatin reportedly induces caspase-1-dependent release of mature IL-1β through a mechanism involving ATP release (38), and pravastatin induces IL-1β and IL-18 in macrophages through induction of mitochondrial reactive oxygen species (39). A recent report also found that ARDS patients treated with rosuvastatin tended to have higher plasma levels of IL-18 (40).

Taken together, our finding that rosuvastatin treatment is associated with increases in both caspase-1 (inflammasome)-dependent (IL-1β, IL-18) and -independent (IFNγ, TNFα, IL-5, IL-6, IL-15) cytokines is thus consistent with prior reports of rosuvastatin and other statins. The reason for divergent findings for statins in inflammation is unclear but may possibly relate to
technical/biological differences across reports, including the specific statin formulation studied as well as the basal inflammatory state of the cells/subjects studied. Our finding that the upregulation of several mediators by rosuvastatin was more pronounced in subjects with high hsCRP status is consistent with the latter possibility. A recent reanalysis of the HARP-2 trial found that only those ARDS subjects with a ‘hyperinflammatory’ subphenotype benefitted clinically from treatment with simvastatin (41). Somewhat similar to this, we found that several immune effects of rosuvastatin were dependent upon baseline hsCRP (Tables S3-S4), with several of these effects more pronounced in CRP-high subjects.

Our findings of reduced hemoglobin, MCHC, and erythrocyte number, and increased erythrocyte volume (MCV) during rosuvastatin treatment suggest complex effects of rosuvastatin on red blood cells. In an analysis of U.S. national survey data, we previously reported that non-high density lipoprotein (HDL)-cholesterol is directly related to serum hemoglobin and erythrocyte number, whereas HDL-cholesterol is directly related to MCV, suggesting communication between cholesterol and erythrocyte biology (42). Rosuvastatin has been reported to reduce the cholesterol content of erythrocyte membranes and to increase their fluidity/deformability (43-46). Moreover, statins alter erythrocyte Na+/K+-ATPase activity and ATP release (45, 46). A post-hoc analysis of the JUPITER trial did not find any effect of rosuvastatin on hemoglobin mass (47), nor did a study of a 24-week course of atorvastatin in 81 hypercholesterolemic subjects (48); however, neither study reported MCHC or MCV.

Some prior reports have suggested that statins may increase glucose intolerance or even increase the incidence of diabetes mellitus (49, 50). The magnitude of this risk and its underlying
mechanism are both poorly defined. Of interest, glucagon significantly increased during rosuvastatin therapy. In parallel, and possibly in compensation, insulin, C-peptide, and the insulinotropic hormone GLP-1 (51) all also increased during rosuvastatin administration. Of the four, only glucagon and GLP-1 normalized after drug discontinuation. Future studies are warranted to investigate the possibility that statins impact glucose tolerance through altering glucagon and/or GLP-1 levels.

Limitations of our report should be noted. Our study is limited by its small size, its 28-day treatment duration, and its focus on a single statin, and thus will require independent validation. The changes we report with rosuvastatin treatment and withdrawal are also modest in magnitude and of uncertain physiologic significance, and most did not persist after multiple testing correction. We also cannot discount the possibility that some of the effects we report could be secondary to drug toxicity (e.g., muscle or hepatic inflammation). In addition, particularly in a small study such as this, interindividual environmental differences such as physical or psychological stress could have influenced the results. It is also possible that the 1-week washout period was insufficient. Although renal impairment and diabetes mellitus were exclusion criteria, these conditions are not routinely avoided in selecting patients for statin therapy in the clinical arena. Finally, the soluble mediators analyzed by Luminex were run in two batches, of which the second was comprised of 12 measurements made on 3 CRP-high subjects. In order to address the possibility of batch effects, we ran a sensitivity analysis adjusting for batch number, but found that this did not materially change the findings for rosuvastatin effect, rosuvastatin discontinuation, or rosuvastatin x CRP interactions.

Specifically, there was no change in the measures found to have p<0.05 in Table III, Table S3, or
Table S4, whereas two measures in Table II (effect of rosuvastatin treatment) rose marginally above the significance threshold (IL-5 \([p=0.054]\), IL-6 \([p=0.053]\)). In a separate analysis, we found that omission of data for the 3 CRP-high subjects in batch 2 did substantially reduce the number of significant baseline differences detected between CRP-low and -high subjects (Table S5).

Remarkably, subjects receiving the same dose of rosuvastatin or atorvastatin may have as much as a 45-fold variability in plasma concentration of the drug (52). This variation is almost certainly genetic as >40 genes have been identified to date that affect statin efficacy and safety (53). Although we did not measure serum rosuvastatin levels in study participants, the prompt and sustained reduction in LDL-C observed in all subjects (Figure 2B) indicates with a high degree of confidence that all had therapeutic rosuvastatin levels. As different statins with varying physicochemical properties (e.g, hydrophobicity vs. hydrophilicity) may potentially have distinct biological properties, future studies may be warranted to compare the immune effects of different statin formulations. The complexity of statin pharmacogenomics suggests that the effect of statins on the immune system will be found to be genetically regulated and perhaps that statin immune response phenotypes may be more granular than is achieved by dichotomizing patients by hsCRP level. Although our study was not designed to identify novel inflammatory biomarkers that aid in prediction of statin immune effects, we propose that some of the biomarkers that we found to segregate best between CRP-low and -high subjects, such as IL-6, IL-1R\(\alpha\), IFN\(\gamma\), and resistin (Table S2, Figure S1) may be interesting candidates. Detection of robust effects of statins on the human immunome may also require immune challenge (e.g., vaccination, infection) as suggested by the greater response magnitude of rosuvastatin in CR\(\Phi\)}
compared to CRP\textsuperscript{lo} groups (\textbf{Figure 3, Table S3}). Indeed, given that several of the changes seen with rosuvastatin were more prominent in, or restricted to, CRP\textsuperscript{hi} subjects and most were modest in magnitude, one conclusion that could reasonably be drawn from our findings is that rosuvastatin induces minimal changes in the steady state immunome in normocholesterolemic CRP\textsuperscript{lo} subjects.

In summary, we have performed a comprehensive interrogation of the human immunome in healthy, normocholesterolemic subjects treated for 28-days with rosuvastatin. We report that rosuvastatin induces a variety of immunologic, biochemical, and endocrinologic changes. Several new lipid-lowering agents that work through distinct mechanisms have either been approved or are currently under regulatory review for use in human subjects (54). Some of these drugs, such as bempedoic acid, have been shown in preliminary studies to reduce hsCRP (54), whereas others, such as anti-PCSK9 antibodies, appear not to do so (55). Given that some of the immunomodulatory and cardioprotective effects of statins in hypercholesterolemic subjects have been shown to be independent of cholesterol-lowering (15), it will now be critical to compare the immune effects of statins with these newly emerging drug classes.
Methods

Clinical Protocol. The study was designed to recruit up to 30 healthy subjects with normal serum cholesterol (LDL-C <130 mg/dL), with the intent of enrolling 20 evaluable healthy subjects, 10 of them with hsCRP ≥2mg/L, and 10 with hsCRP <2mg/L, as per the JUPITER trial (23). Inclusion criteria were healthy status (confirmed by history, physical examination, and routine blood work), age ≥18 years, and LDL-C <130 mg/dL. Exclusion criteria were pregnancy or active lactation, abnormal liver function tests (AST >34 U/L; ALT >41 U/L; total bilirubin >1.0 mg/dL; alkaline phosphatase >116 U/L), elevated serum creatine kinase, other contraindications to statins (e.g., renal impairment, diabetes mellitus, statin hypersensitivity), and statin usage within 6 months prior to enrollment. Subjects were advised not to initiate any new medications, including over-the-counter drugs, during study participation. After study enrollment, subjects underwent a 1-week washout period, during which they were requested to refrain from non-steroidal anti-inflammatory drugs, antihistamines, corticosteroids (including topical agents), and niacin preparations. Medication and supplement use reported by participants at enrollment is shown in Table S6. Blood was collected at the end of the 1-week washout immediately prior to the first dose of a 4-week course of rosuvastatin (20 mg daily), and again 2 weeks (±2 days), 4 weeks (±2 days; time of rosuvastatin discontinuation), and 6 weeks (±2 days) later. Participants were questioned about rosuvastatin adherence and pill counts also performed during study visits. Study flow is depicted in Figure 1.

Flow cytometry for comprehensive immunophenotyping. Methods are as previously reported (25). In brief, peripheral blood mononuclear cells were isolated by Ficoll separation and cryopreserved at -20°C according to NIH CHI protocols (https://chi.niaid.nih.gov/web/new/our-
Thawed cells were washed and resuspended in PBS. Viability was assessed using LIVE/DEAD Aqua fixable viability dye (Life Sciences, Carlsbad, CA) followed by a wash in FACS staining buffer (PBS supplemented with 1% normal mouse serum, 1% goat serum, 0.02% sodium azide) (Gemini Bioproducts, West Sacramento, CA). Cells were stained according to our protocols (25) for five tubes of the CLIP panel (Treg, TH17, TH1/TH2, B naive/memory and NK cells) (Table S1, Figure S4). Acquisition was performed using a Becton Dickinson LSR Fortessa (BD, San Jose, CA) equipped with five lasers (355 nm, 407 nm, 488 nm, 532 nm, 633 nm wavelengths) with 22 PMT detectors. Data were acquired using DIVA 6.1.2 software (BD) and we ensured a minimum of 50,000 CD4+ T cells was recorded to be able to accurately assess minor cell populations. Further details are as described in Olnes et al (25).

**Luminex assay.** Plasma was collected and stored at −20°C per NIH Center for Human Immunology protocols (http://www.nhlbi.nih.gov/resources/chi/documents/SOP-Isolation.pdf). Luminex assays were performed according to previously published methods (25) and per manufacturer’s instructions using kits from Bio-Rad (Hercules, CA, USA): 27-plex cytokine group I, 21-plex cytokine group II, 10-plex diabetes, four-plex and five-plex acute phases. Median fluorescence intensities were collected on a Luminex-100 instrument (Luminex, Bio-Rad), using Bio-Plex Manager software version 6. Standard curves were generated for each cytokine using lyophilized standards. Cytokine concentrations were determined from standard curves using five point 5-parameter logistic regression. Samples were run in duplicate and the averages used for analysis.
Clinical laboratory analyses. Complete blood cell count and differentials, CRP (CRP.bitris), and serum lipid levels were quantified using standard clinical laboratory instruments in the NIH Clinical Center (Table S1).

Statistical analysis. For study sample size calculation, it was considered that for the change of HLA DR-expressing CD4⁺ T cell percentage from baseline to the end of the study (a measurement of interest), a sample size of 20 evaluable participants would provide 82% power for a 0.05 level two-sided t-test for the null hypothesis that the mean change is 0 versus the alternative that the mean change is -0.73, assuming that the standard deviation of the change is of HLA-DR CD4⁺ T cell percentage is 0.778 (20). Outcome measures with either >10 missing observations or <14 nonzero observations were excluded from analysis; the excluded variables are indicated in Table S1. Given the small sample size and skewed distribution for many measures, Wilcoxon rank sum test was used to determine measurement differences between normal and high hsCRP subjects at baseline. For testing the effect of rosuvastatin treatment and discontinuation, linear mixed models with random intercepts for each subject were used. Treatment effect was assessed by comparing observations after rosuvastatin treatment (days 14, 28, and 42) versus day 0 and discontinuation effect was assessed by comparing observations after treatment discontinuation (day 42) versus observations when treatment was still ongoing (days 14 and 28). We first determined whether log-transformation was needed for each variable based on Shapiro-Wilk test of normality. The log-transformed data were used in the regression analysis if distribution of the residues was closer to normal after the transformation. Variables that were log-transformed are indicated in Table S1. All models were run with adjustment for age, gender, and race. Luminex assays were run in two batches; for
each, a standard curve was applied for quantitation. In separate analyses, we also evaluated whether statin effects differed between normal and high hsCRP subjects (i.e., interactions between rosvastatin and baseline hsCRP). Spearman correlation analysis using data from all individuals and all timepoints was performed using the “rcorr” function of the “Hmisc” package in R. All analyses were performed using R version 3.5.3.

**Study approval.** After completing informed consent, volunteers were enrolled in #10-H-0165, a NIH protocol approved and monitored by the NHLBI/NIH Institutional Review Board in accordance with the Declaration of Helsinki and registered under clinicaltrials.gov (NCT01200836).
Author Contributions

PWFK, MS, and MBF analyzed and graphed data and contributed to the writing of the manuscript. SP, AB, JC, FC, YK, and NY designed the study, performed the analyses, analyzed data, and contributed to the writing of the manuscript.

Acknowledgments

This research was supported by the Intramural Research Program of the NIH, National Institute of Environmental Health Sciences (Z01 ES102005) and the trans-NIH Center for Human Immunology. See Supplemental Acknowledgments for Consortium details.

Table I. Baseline characteristics of study subjects

| Study subgroup | CRP-high (N=7) | CRP-low (N=11<sup>^A</sup>) |
|----------------|----------------|-----------------------------|
| Age (years)    | Mean 38.64     | Mean 42.86                  |
|                | SD 10.38       | SD 10.54                    |
| Sex            |                |                             |
| Female, n      | 4              | 6                           |
| Male, n        | 3              | 5                           |
| Race           |                |                             |
| Asian, n       | 0              | 2                           |
| Black, n       | 3              | 1                           |
| White, n       | 4              | 8                           |
| hsCRP (mg/L)   | Mean 6.53      | Mean 0.65                   |
|                | SD 5.37        | SD 0.66                     |
| Total cholesterol (mg/dL) | Mean 176.14 | Mean 186.50                  |
|                | SD 21.14       | SD 32.79                    |
| LDL cholesterol (mg/dL) | Mean 98.71 | Mean 106.00                  |
|                | SD 19.73       | SD 29.19                    |
| HDL cholesterol (mg/dL) | Mean 56.86 | Mean 61.90                   |
|                | SD 10.40       | SD 16.42                    |
| Triglycerides (mg/dL) | Mean 102.00 | Mean 93.00                   |
|                | SD 57.50       | SD 63.35                    |

<sup>^A</sup> N=10 for biochemical measures (CRP, cholesterol, triglycerides) in CRP-low group.

hsCRP = high sensitivity C-reactive protein (as measured by NIH Clinical Center assay); HDL = high density lipoprotein; LDL = low density lipoprotein.
### Table II: Variables changed by rosuvastatin treatment in overall study group

|                | Day 0                  | Day 14                 | Day 28                 | Estimate | S. E. | Pr(≥|t|)  | FDR      |

Variables that were significantly changed in overall study group (nominal p-value $[Pr(\geq|t|)] \leq 0.05$) after commencing rosuvastatin, as assessed by linear regression. False discovery rate (FDR)-adjusted p-values are also shown. Median values for analytes at specific study days are shown for all subjects, for CRP-low subjects, and for CRP-high subjects and may be adjusted as indicated (e.g. $\times 10^4$). Where not otherwise indicated, median values are in relative units.

A $\text{CD3}^+\text{CD4}^+\text{CD8}^-\text{CD127}^\text{lo}/\text{CD27}^\text{hi}/\text{CD39}^+\text{HLA-DR}^+$ cells (% by FACS)

B $\text{CD3}^+\text{CD4}^+\text{CD8}^-\text{CD127}^\text{lo}/\text{CD27}^\text{hi}/\text{CD39}^+/\text{HLA-DR}^+$ cells (% by FACS)

C $\text{CD8}^+\text{CD28}^-\text{CCR7}^-\text{CD45RA}^+\text{HLA-DR}^+$ cells (% by FACS)

D $\text{CCR4}^-\text{HLA-DR}^+\text{Tregs} (% \text{by FACS})$

E $\text{CD4}^-\text{CD28}^-\text{CCR7}^-\text{CD45RA}^-\text{Tregs} (% \text{by FACS})$

A2M = alpha-2-macroglobulin; CBC = complete blood cell count; IFN = interferon; IL = interleukin; IL-1RA = IL-1 receptor antagonist; LDL = low density lipoprotein; MCH = mean corpuscular hemoglobin; MCHC = mean corpuscular hemoglobin concentration; MCV = mean corpuscular volume; MPV = mean platelet volume; NK = natural killer; RBC = red blood cell; SCGF = stem cell growth factor; S.E. = standard error; Treg = T regulatory cell.
Table III: Variables changed by rosuvastatin discontinuation in overall study group

| Day 28                  | Day 42                  | Estimate | S. E. | Pr(≥|t|)   | FDR     |
|-------------------------|-------------------------|----------|-------|-----------|---------|
| **Variables**           | **Variables**           | **Median** | **Median** | **S. E.** | **Pr(≥|t|)** | **FDR** |
| **LDL-C**               | **LDL-C**               | 45 (44, 50) | 104 (107, 97) | 0.84 | 0.06 | 7.14×10⁻¹⁷ | 1.38×10⁻¹⁴ |

^ Variables that were significantly changed in overall study group (nominal p-value [Pr(≥|t|)] ≤0.05) after commencing rosuvastatin, as assessed by linear regression. False discovery rate (FDR)-adjusted p-values are also shown. Median values for analytes at specific study days are shown for all subjects, for CRP-low subjects, and for CRP-high subjects and may be adjusted as indicated (e.g. ×10⁶). Where not otherwise indicated, median values are in relative units.

CD = cluster of differentiation; CRP_btris = high sensitivity C-reactive protein (as measured by NIH Clinical Center assay); GLP = glucagon-like peptide; IL = interleukin; LIF = leukemia inhibitory factor; LDL-C = low density lipoprotein-cholesterol; MCP = macrophage chemotactic protein; MIF = Macrophage migration inhibitory factor; NGF = nerve growth factor; NK = natural killer; PAI = plasminogen activator inhibitor; PCT = procalcitonin; PDGF-BB = platelet-derived growth factor-BB; SCGF = stem cell growth factor; S.E. = standard error; TRAIL = TNF-related apoptosis-inducing ligand.
Figure Legends

Figure 1. Study design for evaluating the effect of rosuvastatin initiation and discontinuation on the human immunome.

Figure 2. Effect of rosuvastatin on serum lipids. Serum total cholesterol (A), LDL cholesterol (B), HDL cholesterol (C), and triglycerides (D) were measured in study subjects at the indicated trial timepoints (baseline [day 0], rosuvastatin treatment [days 14, 28], and 14 days after rosuvastatin discontinuation [day 42]). Subjects with low vs. high CRP at baseline are plotted separately. Boxes depict the interquartile range (IQR) around the median. The upper whisker extends from the hinge to the largest value no further than 1.5 * IQR from the hinge; the lower whisker extends from the hinge to the smallest value at most 1.5 * IQR of the hinge. Outlying points are plotted individually. Nominal P values for rosuvastatin treatment and discontinuation, which were determined for the overall study group by linear regression, are shown in the figure panels (also listed in Tables II and III).

Figure 3. Effect of rosuvastatin on immune measures. Immune measures were plotted in study subjects at the indicated trial timepoints (baseline [day 0], rosuvastatin treatment [days 14, 28], and 14 days after rosuvastatin discontinuation [day 42]). Subjects with low vs. high CRP at baseline are plotted separately. Boxes depict interquartile range (IQR) around the median. Upper whisker extends from the hinge to the largest value no further than 1.5 * IQR from the hinge; lower whisker extends from the hinge to smallest value at most 1.5 * IQR of the hinge. Outlying points are plotted individually. Nominal P values for the overall study group were determined by linear regression and are shown in figure panels. P values in panels A-G are for rosuvastatin treatment compared to day 0 (Table II); in H-J, are for rosuvastatin treatment in interaction with CRP (Table S3); and in K-L, are for rosuvastatin discontinuation (Table III).
**Figure 4. Effect of rosuvastatin on endocrine measures.** Levels of glucagon (A), glucagon-like peptide-1 (GLP-1) (B), insulin (C), and C-peptide (D) were plotted in study subjects during the rosuvastatin time course. Subjects with low vs. high CRP at baseline are plotted separately. The upper whisker extends from the hinge to the largest value no further than 1.5 * IQR from the hinge; the lower whisker extends from the hinge to the smallest value at most 1.5 * IQR of the hinge. Outlying points are plotted individually. Nominal P values for rosuvastatin treatment and discontinuation, which were determined for the overall study group by linear regression, are shown in the figure panels (also listed in Tables II and III).
