Abstract: This paper studies the aging mechanism of elastomeric gaskets made from silicone rubbers in simulated proton exchange membrane fuel cells (PEMFCs) in humid, acidic, and high-temperature environments. The changes in the surface morphology are observed using optical microscopy. Attenuated total reflection Fourier transform infrared spectroscopy (AFT-FTIR) and X-ray photoelectron spectroscopy (XPS) are used to investigate the changes in the chemical molecular structure. The stress relaxation test is conducted to characterize the decay process of the mechanical properties. The results indicate that cracks appear on the surface and that the aging mechanism is mainly due to decomposition in the backbone and hydrolysis of the crosslinking. The stress relaxation modulus decreases as the acid concentration increases, which suggests a decrease in elasticity and an increase in brittleness. A master curve that relates time and concentration is constructed. Based on this inference, the experimental time can be shortened by about four times.

Keywords: degradation mechanism, silicone, stress relaxation, fuel cell, lifetime

1 Introduction

Proton exchange membrane fuel cells (PEMFCs) are an alternative clean energy widely used in multiple applications, such as energy generation, transportation, and automotive industries, on account of their quick start, zero emissions, and high current density (1–3). Their long-term electrochemical performance limits widespread commercial use of PEMFCs. Therefore, most studies on PEMFCs investigate the overall performance of fuel cells, including the effect of components (4,5). In addition, gaskets between the bipolar plate and gas diffusion layers are employed to prevent leakage of reactant gases under the clamping load in the fuel cell. If the gasket materials degrade, the gasket will not only lose its sealing property, but also induce a mixture of hydrogen and air, which causes safety problems (6,7). Therefore, chemical stability and mechanical properties of gaskets are key issues in improving the performance of these fuel cells.

The gaskets in fuel cells are usually made from rubbers. These polymeric materials are subject to aging under all types of extreme environments, and their chemical and mechanical properties will change (8–10). These changes result in the failure of the entire component. Aging tests on gaskets have received significant attention because of gasket failures. Wu et al. (8) studied the effect of temperature on the mechanical properties of gaskets, including the tensile strength, elongation at failure, compression stress relaxation, and compression permanent deformation. The mechanical properties tend to decay as the temperature increases. Lou et al. (9,10) investigated the chemical structures and mechanical properties of nitrile rubber O-rings exposed to hydraulic oil and air. They found that chemical degradation is attributed to the loss of additives and oxidation reactions. The changes in mechanical properties, such as elongation at the breaking point, tensile strength, and Young’s modulus, are due to the hardened brittle outer layer, voids, and agglomerates, which result in fracture morphologies. proposed a new model of silicone rubber exposed to electrolyzed aqueous salt. This model was verified by previous experiments. The polymer network exposed to electrolyzed aqueous salt was more significantly damaged than the samples exposed to non-electrolyzed standard aqueous salt conditions. The goal was to obtain the complex degradation mechanism in some critical lines and substations.

The accelerated durability test is an effective method for studying the degradation of polymeric materials due to the reduction of test time in the lab. Dubovský et al. (12) investigated the aging process and properties of gasket seal materials made of NBR exposed to critical operating conditions in aircraft engines. Static immersion tests in B10, B50, and B100 (representing 10%, 50%, and 100% biodiesel in diesel, respectively) were performed at 100°C for 500 h and at ambient temperature for 3,000 h. The aging behavior was described by calculating the relative changes of the physical properties, such as hardness and weight, and the trend of the mechanical properties, such as tensile strength and elongation. The surface morphology in the rubber was observed using optical microscopy and a camera. It was determined that either a higher temperature or a higher concentration of biodiesel can accelerate the degradation of the seals. Cai et al. (13) studied the aged biorejuvenated asphalts at a microscale and measured aging changes using FTIR, AFM, and component analysis. More special variations are appeared in the aged biorejuvenated asphalt. The Young’s modulus changes significantly, indicating the degree of the aging. Tang et al. (14) studied the failure mechanism of NBR samples at room temperature for two years and aged mechanism using accelerated tests individually. The aging mechanism is different at 80°C due to free radical oxidation and at 90°C because of chain scission. The stress relaxation mechanisms are also different. Thus, the same aging mechanism is the foundation for accelerated durability testing in the lab. Recently, the aging process of seal materials used in PEMFCs has been attracting new focus (15–22). Pehlivan-Davis et al. (16) discussed the changes in properties and chemical structure of silicone rubber gasket seal material used in a fuel cell condition and an accelerated aging condition individually. The accelerated aging environments were made by sulfuric acid, and the test solutions had pH values of 1, 2, and 4 at elevated temperatures up to 140°C. The degradation mechanism for the samples in PEM fuel cell conditions was similar to the samples exposed to extreme conditions. Shen et al. (17) fabricated an EPDM with a multilayered structure. The hardness and the compression set increased as the layer number increased, which suggests a better sealing capacity.

The aging test was conducted, and it showed that the EPDM with a multilayered structure has better mechanical properties than did the blended EPDM. Tan et al. (7,21) and Li et al. (22) investigated the stability and durability of silicone rubbers and EPDM in PEMFC environments by detecting the chemical composition and recording the changes in the mechanical properties and conducting dynamic mechanical properties tests to analyze the aging process.

The goal of this study is to determine the chemical and mechanical degradation mechanisms of silicone rubber samples exposed to two solutions with different acid concentrations. The correlation between time and acid concentration is investigated to predict the lifetime.

First, optical microscopy is used to inspect the surface morphology of the materials. The absorbance of the chemical group is recorded using ATR-FTIR spectroscopy. The surface chemical composition and distribution of elements are investigated using X-ray photoelectron spectroscopy (XPS). Then, a stress relaxation test is performed to determine the mechanical aging process of the samples. A generalized Maxwell model is adopted to describe the stress relaxation behaviors, and the lifetime is predicted by constructing a relationship between time and acid concentration according to the principle of time-temperature superposition (TTS).

2 Experiments

2.1 Samples and experimental environments

In this study, silicone rubber, which is a commercial elastomeric material (Dongjue, Inc., China), was chosen for the tests. The material is crosslinked by polydimethylsiloxane with vinyl and polymethylsiloxyxane with a hydro-silylated functional group. It is composed of siloxane by hydrosilylation, and the fillers are mostly composed of silica, quartz, and calcium carbonate. The silicone rubbers are shaped into squares (10 mm by 10 mm; 6 mm thick) and cylinders (12.5 mm in diameter; 6 mm thick). Two test solutions with different acid concentrations are prepared. One test solution is called the regular solution (RS). It approximates the actual PEMFC operating conditions (6,7,19,21). The solution includes 12.5 ppm sulfuric acid (H₂SO₄) and 1.8 ppm hydrofluoric acid (HF). The other solution, with 1 mol L⁻¹ H₂SO₄, 30 ppm HF, is marked as ADT for the accelerated durability test in a short time. The aging temperature is controlled at 70°C.
2.2 Characterization methods

The samples were individually exposed to two different experimental conditions for a period of time. Then, the aged samples were taken out and cleaned before the tests. The modification of the surface morphology of the samples was analyzed using optical microscopy. The ATR-FTIR and XPS techniques can help qualitatively and quantitatively determine changes in the chemical structure. The ATR-FTIR was conducted to obtain the absorbance of the chemical group on the surface of specimens with the help of a Nexus Model 670 device, with a resolution of 0.1 cm\(^{-1}\). XPS using a Thermo Fisher Scientific K-Alpha spectrometer with a monochromatic Al K\(\alpha\) X-ray source was employed to analyze the chemical changes on the surface of specimens. The survey spectra ranged from 0 to 1,350 eV and were maintained at 1 eV steps for each specimen. The stress relaxation test was performed, and the compression Young's modulus was chosen to characterize the changes in the mechanical properties.

3 Results and discussion

3.1 Morphology analysis

The micro characteristic changes on the surface of the silicones are displayed in Figure 1. The magnification is 200\(\times\). Figure 1a and c show the micro topography of the unexposed samples. Figure 1b and d show the micro topography of the samples immersed into RS and ADT test solutions for 33 days at 70\(^\circ\)C individually. It can be summarized from Figure 1 that the surface morphologies of the samples taken out of the RS test environment changed, but no cracks appeared (Figure 1c). The ADT test environment accelerates the aging of the samples from outside to inside. The surface becomes rough, and many cracks appear. The samples degrade severely in the ADT test solution. This aging process exhibits both acid-dependent and time-dependent processes. This conclusion is in agreement with the results found in previous research (7).

3.2 ATR-FTIR and XPS results

ATR-FTIR and XPS, advanced material analysis techniques, were chosen to investigate the chemical composition changes on the surface of the silicone rubber specimens before and after aging under the experimental conditions. Figures 2 and 3 show the spectra of specimens measured using the ATR-FTIR method. The spectra ranging from 650 to 1,500 cm\(^{-1}\) are displayed in Figures 2a and 3a, and spectra from 2,500 to 3,500 cm\(^{-1}\) are displayed in Figures 2b and 3b. The spectra A in Figures 2 and 3 belong to the specimens before exposure. The spectra B in Figures 2 and 3 belong to the specimens after being immersed into two different solutions, respectively.

For unaged specimens (Figures 2a and 3a), the peak that appears at 1,412 cm\(^{-1}\) is ascribed to the rocking vibration of the CH\(_2\) groups in the crosslinking area. The peak that appears at 1,257 cm\(^{-1}\) is caused by the Si–CH\(_3\) bending vibration. A broadened peak from 1,057 to 1,007 cm\(^{-1}\) is strong and represents the characteristic of stretching vibrations of the backbone Si–O–Si. The peak that appears at 864 cm\(^{-1}\) is caused by the rocking vibration of the Si–CH\(_3\) groups. A prominent peak near 785 cm\(^{-1}\) is ascribed to the coupling of the CH\(_3\) chemical bond rocking vibration and Si–C stretching vibration. Two peaks that appear at 692 and 2,962 cm\(^{-1}\) are due to CH\(_3\) chemical bond stretching vibrations. All these vibration modes at different spectra are analyzed based on prior references (7,23).

For specimens immersed in the RS test environment for 33 days (shown in Figure 2b), the intensity of all absorption peaks decreases compared with that of the unexposed specimens (Figure 2a). This phenomenon demonstrates that the chemical composition on the surface of the specimens changes after they are aged in the RS solution.

For specimens exposed to the ADT test solution for 33 days (Figure 3a), the intensity of the peaks weakens sharply with exposure time compared with that of the unexposed specimens (Figure 3b). The peaks at 2,962 cm\(^{-1}\) (CH\(_3\)) and 864 cm\(^{-1}\) (Si–CH\(_3\)) disappear for the specimen after 33 days of exposure. The intensities of the peaks at 1,257 cm\(^{-1}\) (Si–CH\(_3\)), 785 cm\(^{-1}\) (CH\(_3\)), Si–C, and 692 cm\(^{-1}\) (CH\(_3\)) decrease dramatically. This may be due to the breakage of the side chain Si–CH\(_3\). The peak at 1,412 cm\(^{-1}\) (CH\(_3\)) disappears after 33 days of exposure. This may be due to the hydrolysis of the crosslink point –CH\(_2\)–CH\(_2\)– in the crosslink area. The intensity of the peak from 1,057 to 1,007 cm\(^{-1}\) decreases sharply, which suggests decomposition of the silicone rubber backbone Si–O–Si. Based on the comparison of the changes of peaks for specimens immersed in two different test solutions, the conclusion is that the degradation process of specimens is highly dependent on the concentration of the acid in the exposure environments. The solution with a higher acid concentration

Figure 2: IR spectra for (A) unexposed specimens and (B) aged specimens in RS for 33 days at 70°C. (a) Wavenumbers from 650 to 1,500 cm\(^{-1}\), and (b) wavenumbers from 2,500 to 3,500 cm\(^{-1}\).

Figure 3: IR spectra for (A) unexposed specimens and (B) aged specimens in ADT solution for 33 days at 70°C. (a) Wavenumbers from 650 to 1,500 cm\(^{-1}\), and (b) wavenumbers from 2,500 to 3,500 cm\(^{-1}\).
could make the Si–O–Si, –CH₂–CH₂–, and CH₃ structures decompose more seriously and accelerate the aging of silicone rubber materials.

For further analysis, the surface elemental compositions of specimens were determined using XPS. As shown in Figure 4a, survey XPS shows the presence of elements of silicon (Si), oxygen (O), and carbon (C) in the unexposed specimens. In addition, there is little fluorine (F). The high-resolution spectra for Si₂p, O₁s, and C₁s (24–26), as shown in Figure 4b–d, respectively, in specimens before and after immersion into two different test solutions for 83 days are chosen to further study the chemical compositions. The high-resolution spectra for elements Si, O, and C are saved at each 0.1 eV step by deconvolution using curve-fitting. From Figure 4b–d, it can be seen that the binding energies of Si₂p, O₁s, and C₁s for a specimen immersed in the RS test solution do not obviously change. For the specimens immersed in the ADT test solution, the binding energy (approximately 101.3 eV) of Si₂p shifts 2 eV (Figure 4b) toward a higher binding energy level (approximately 103.2 eV). The binding energy of O₁s (approximately 531.5 eV) shifts 0.9 eV (Figure 4c) toward a higher binding energy level (approximately 532.4 eV). The binding energy of C₁s (approximately 283.75 eV) has no obvious shift.

Atomic concentrations of four types of elements are calculated by integrating the relevant peak intensities and are listed in Table 1. The proportion of C and Si atomic concentration (C/Si) and the proportion of O and Si atomic concentration (O/Si) for specimens over time are calculated and listed in Table 1. The atomic concentration ratio of C/Si decreases dramatically (1.663 → 1.556 → 0.657), while the atomic concentration ratio of O/Si increases (0.919 → 0.958 → 1.416) as the acid content increases in the solutions over time. The decrease in the C/Si atomic concentration ratio may be due to the hydrolysis of the crosslink bond –CH₂–CH₂–, which transforms it into Si–O under the action of the acid and temperature, and then it forms a different crystal structure SiO₂ from the original –Si–O–Si– backbone structure. An increase in the O/Si atomic concentration ratio may occur because the side chain Si–CH₃ is transformed to Si–O under the action of oxidation and H⁺. First, the

3.3 Compression mechanical properties

Compression stress relaxation tests were performed on the silicone rubbers at 25% strain levels. The variations of the time-dependent Young’s modulus are shown in Figure 5. The Young’s modulus $E(t)$ increases more for the samples aged in the ADT test solution than the samples in the RS test solution and the unexposed samples, which represents a decrease in the elasticity. In general, the stress relaxation curves show a nearly exponential decay of stress with time. A higher acid concentration contributes to a greater increase in modulus and a faster decay of stress in the first, which indicates a poorer sealing property.

To better understand the viscoelastic behavior of the silicone rubbers, a generalized Maxwell model shown in the Eq. 1 is adopted to describe the stress relaxation behavior of elastomeric materials. This model has multiple springs and dashpots. Because the components of the generalized Maxwell model are connected in parallel, all branches have the same strain at all times, and the overall stress of the system is the sum of the stresses in each branch (27,28):

$$\sigma(t) = \sigma_0 + \sum_{i=1}^{n} g_i e^{-t/\tau_i}$$  \hspace{1cm} (1)

where $\sigma_0$ – stress after a long time, Pa; $\sigma_i$ – stress, Pa; $t$ – time, s; $\tau_i$ – a material constant, s.

The equation can also be rewritten as follows (Eq. 2):

$$E(t) = \frac{\sigma(t)}{E_0} = \frac{1}{E_0} \left[ \sigma_0 + \sum_{i=1}^{n} g_i e^{-t/\tau_i} \right] = E_0 \sigma_0 + \sum_{i=1}^{n} E_i e^{-t/\tau_i}$$  \hspace{1cm} (2)

where $E_0$ – the strain.

When the Young’s modulus is normalized, it becomes Eq. 3, which is called the Prony series:

$$g(t) = 1 - \sum_{i=1}^{n} g_i (1 - e^{-t/\tau_i})$$  \hspace{1cm} (3)

where $g(t) = \frac{E(t)}{E_0}$ and $g_i = \frac{E_i}{E_0}$.

The normalized stress relaxation modulus, called $g(t)$, versus time is shown in Figure 6. The curves displayed in Figure 6 show a similar trend. At the beginning, the modulus decreases sharply, indicating a quick relaxation of the stress. Afterwards, the modulus declines gradually over time. This test was stopped after 6 h due to the low relaxation rate. By comparing the two curves in Figure 6, it can be seen that the stress relaxes faster for samples from the ADT test solution than the samples from the RS test solution. Figure 6 shows the exponential decay nature of the stress with time similar to that described by

the Maxwell model. It also shows that a higher temperature contributes to a faster stress relaxation. Here, a method similar to the TTS principle, which represents the equivalence between time and temperature, is applied to study the viscoelasticity of the materials and predict the lifetime. The equivalence of time and acidic concentration are discussed and this method is named Time-Acid Superposition (TAS) principle. The mathematical expression is shown in Eq. 1. A master curve is constructed by shifting the curves a certain amount, $\alpha_T$, horizontally to a particular reference test solution with acid concentration $A_0$. Using the RS as the reference test solution, the curves of the samples in ADT solution with the acid concentration $A$ are shifted to the reference test solution of RS in the logarithmic scale, as shown in Figure 7. The two curves overlap well. It can be seen that the time is longer than the actual experimental time. The stress relaxation master curve can be constructed using this principle of shifting to any reference test condition. The stress relaxation behavior for a long time period can be predicted in a short test time under a severe test condition by this method. The coefficients of the three-term Prony series have been fitted and listed in Table 2. In this experiment, the curve of samples exposed to the ADT test solution has been shifted by 0.898, fitted by the least square method, horizontally to the right on a logarithmic scale. The lifetime of the specimens is estimated to be about 27 h, while the test time under the ADT environment is only 6 h. The result points out that via the time-concentration superposition theory, the life extrapolating time is about 4 times of the experimental time at a harsh test environment. Cui et al. (26) studied the stress relaxation behavior of silicone rubbers aged in simulated PEM fuel cell environments and predicted a service life of approximately 6,000 h using the TTS principle. However, they only also studied the equivalence between time $t$ and temperature $T$, without referring to the acid concentration. This work studied the equivalence between time and the acid concentration. The two curves overlap well via the time-concentration superposition principle. If the lifetime of seals compressed in a PEM fuel cell must be predicted, one can use the test data of the seals exposed to a severer test environment than its operating condition in a laboratory for a short time to construct the master curve. This is the advantage of equivalence between time and acid concentration. This work will provide a foundation for future studies, and this method will be investigated further.

$$E(A, t) = E(A_0, t/\alpha_T)$$ (4)

where $E(A, t)$ – stress relaxation modulus at time $t$ and temperature $T$; $A_0, A$ – two different acid concentrations; $t$ – time; $\alpha_T$ – shift factor.

### 4 Conclusion

In this work, silicone rubber, which is a potential gasket material, is aged in two test conditions prepared according to real PEMFC operational conditions. The degradation process is observed, and the degradation mechanisms are analyzed. The surface morphology of the samples

![Figure 6: Normalized stress relaxation modulus for 2-week exposure samples at 70°C.](image)

![Figure 7: Master curve of stress relaxation for 2-week exposure samples at a reference solution of RS at 70°C.](image)

**Table 2: Fitted coefficients of the Prony series**

| $g_1$  | $g_2$  | $g_3$  | $\tau_1$ (s) | $\tau_2$ (s) | $\tau_3$ (s) |
|--------|--------|--------|---------------|---------------|---------------|
| 0.0421 | 0.0461 | 0.0243 | 18,492        | 37.8322       | 961.3681      |
could range from smooth to rough, and cracks appeared during the aging process. The significant changes in the chemical structure of the specimens are mainly due to the decomposition of the backbone Si–O–Si, hydrolysis of the crosslinks –CH₂–CH₂–, and fracture of side chain –CH₃–. The chemical bonds are transformed into crystal structure SiO₂. The stress relaxation modulus increases with the increase of acid concentration over time. This result indicates that the elastomeric material is losing its elasticity and the sealing force will decrease when the strain is held constant. The relation between time and concentration can be constructed to predict the lifetime of the material according to the TTS principle. The life extrapolating time is about 4 times of the experimental time at the environment.
