Abstract. Formal, mathematically rigorous programming language semantics are the essential prerequisite for the design of logics and calculi that permit automated reasoning about concurrent programs. We propose a novel modular semantics designed to align smoothly with program logics used in deductive verification and formal specification of concurrent programs. Our semantics separates local evaluation of expressions and statements performed in an abstract, symbolic environment from their composition into global computations, at which point they are concretised. This makes incremental addition of new language concepts possible, without the need to revise the framework. The basis is a generalisation of the notion of a program trace as a sequence of evolving states that we enrich with event descriptors and trailing continuation markers. This allows to postpone scheduling constraints from the level of local evaluation to the global composition stage, where well-formedness predicates over the event structure declaratively characterise a wide range of concurrency models. We also illustrate how a sound program logic and calculus can be defined for this semantics.

1 Introduction

We propose a trace semantics that scales flexibly to a range of concurrent, imperative programming paradigms, as found, for example, in C, JAVA, ProMELA [44], Actors [41], or Active Objects [22]. Specifically, given a program $P$, running on a collection of communicating processors or cores, we want to obtain the set of all global system traces that $P$ can produce starting from some initial state. Our overall goal is to provide a semantics that aligns well with contract-based deductive verification [35]. To this end, it is essential that the semantics cleanly separates local computations (one statement on one core) from global ones; i.e., there must be a suitable notion of composition that can generate the global traces from the local ones. It is known [16,58] that compositionality in denotational semantics shifts the flavour of the semantics in the direction of operational semantics [64], by transitioning from state transformers [42,9] to traces of execution states [39,17,15] or communication events [21,43,48,26]. We propose a hybrid notion of trace that combines states and events, and show that the ensuing semantic framework is well-suited to compositionally capture different forms of concurrency for imperative languages.

The envisaged semantics should also be modular in the following sense: it must be possible to support a new language construct without the need to revise the whole framework. Ideally, there is a single evaluation rule for each construct of the target language that can be applied independently from all other rules: the recursive call to evaluate subsequent statements is not inside the semantic evaluation of each statement. This is not only a good match with deductive verification rules of program logics [35], but also with formal specification languages for concurrent programs that have a trace semantics [63,12,76,61].

A trace semantics for a given target language, satisfying the requirements sketched above, can be defined in three phases:

1. Declare local evaluation rules for each syntax construct of the target language.
2. Declare composition rules that combine local evaluation and process creation into global traces. Scheduling is expressed declaratively as well-formedness constraints over traces.
3. Define the generation of all global traces with the help of the composition rules from a suitable initial configuration.
To achieve the desired degree of modularity, we generalise the standard notion of a program trace \cite{15}, i.e. a sequence of evolving system configurations, starting in some initial state. We make two generalisations. The first is that local states \(\sigma\) can be abstract. This means the value \(\sigma(x)\) of a memory location \(x\) is permitted to be unspecified. One can think of an abstract value \(\sigma(x)\) as a Skolem constant \(x_0\) whose interpretation is determined by an external context. Alternatively, think of symbolic execution \cite{19,54}, where the value of a memory location \(x\) may be a symbolic term \(x_0\) representing an unknown value. States containing abstract values are called symbolic, otherwise they are called concrete.

Symbolic states allow us to evaluate local code independently of its call context. For example, when evaluating the semantics of a statement \(s\) that receives a message from another process, then the value of that message cannot possibly be known independently of the call context. In this case, the local evaluation of \(s\) can be expressed in a trace with symbolic states. These symbolic states are concretised when the global context of the local computations (here, the sender) is resolved, i.e. in the composition rules during phase (2) above. Hence, the resulting global traces are concrete. Thus, the name of our semantic framework: locally abstract, globally concrete (LAGC).

The second generalisation of traces concerns scheduling: concurrency models differ in the exact locations at which a local computation can be interrupted (aka preempted) and how exactly the computation is continued afterwards, i.e. which scheduling decision is taken next. To achieve maximum modularity, we do not build scheduling into a fixed set of rules. Instead, we use continuation markers to specify when scheduling and preemption is possible.

As a result, local traces are not merely abstract, but as well contain events used in the composition rules as interaction points. With the event mechanism, various concurrency models can be defined easily in two parts: first, ensure that local evaluation rules generate suitable synchronisation events. Second, define a well-formedness predicate on concrete traces restricting the global traces that can be generated to those reflecting the targeted concurrency model. Now it is sufficient to add the well-formedness predicate as a premise to each composition rule. Events turn out to be a flexible and intuitive mechanism, which can be used to express a range of dependencies between processes beyond synchronous communication (for example, object generation).

An LAGC-style trace semantics was pioneered for the active object language ABS \cite{27}. Here we show that, due to its modularity, LAGC semantics constitutes a general semantic framework for a wide range of concurrent programming models: it is easy to add new syntactic constructs and to accommodate different concurrency paradigms. We will demonstrate this as follows: starting with a simple WHILE-language, we define LAGC semantics for an increasingly complex series of languages by successively adding new features, sequential as well as parallel ones. In the end we cover a representative set of language features and concurrency models and instantiate our semantic framework to two quite different concurrent programming languages.

The paper is organised as follows: In Section 2 we set up the formal framework that the LAGC semantics is based upon. As explained above, we need symbolic states and traces that may contain abstract values for memory locations. We also need a concretisation operator that instantiates a symbolic trace to match a concrete context. In addition, we equip traces with states and continuation markers. Section 3 introduces the LAGC framework along phases (1)–(3) for a WHILE-language. We substantiate the claim made above, that an LAGC semantics is a good match for deductive verification calculi, by defining in Section 4 a program logic for WHILE with a concise soundness proof. In Section 5 we gradually extend the semantics to local parallelism (with atomicity), local memory, and procedure calls. In Section 6 we take the step to multiple processors that send and receive messages among each other. We show that a wide range of communication patterns can be intuitively and declaratively characterised via well-formedness, including synchronous and asynchronous communication, bounded and unbounded FIFO, as well as causality. Section 7 instantiates the LAGC framework to the rather different concurrency models found in the languages PtoMELA and ABS, respectively. For the latter, we need to add objects and futures, as well as to change the interleaving semantics, which turns out to be easily possible. Related work is discussed in Section 8 while Section 9 considers future directions for work and concludes.

2 Basics

2.1 States

We assume given standard basic types, including integers, Booleans and process identifiers, with standard value domains and associated operators. In addition, we allow starred expressions, representing unknown, symbolic values.

**Definition 1 (Variables, Values, (Starred) Expressions).** Let \(\text{Var}\) be a set of program variables, \(\text{Val}\) a set of values, and \(\text{Op}\) a set of operators, with typical elements \(x, v,\) and \(o\) respectively. The sets \(\text{Val}\) and \(\text{Op}\)
include the values and operators of the basic types (see Figure \ref{fig:explicit}). The set \texttt{Exp} contains expressions, with typical element \( e \), obtained from variables, values, and by applying operators to expressions. The set \texttt{Sexp} contains starred expressions, with typical element \( se \), obtained by extending expressions with an additional symbol \( * \).

We assume that all expressions are well-typed; i.e., in expressions, operators are only applied to subexpressions which can be reduced to values of appropriate types. Let \( op \) denote an evaluation function for the operators \( op \) defined over the values of the basic types, such that \( v \ op \ v' \) is a value in the basic types. A Boolean expression is an expression that evaluates to a Boolean value when its arguments are values of the basic types, and similarly for expressions of other basic types. Overline notation is used for lists of different syntactic categories; e.g., \( \overline{v} \) and \( \overline{e} \) represent lists of values and expressions, respectively. Let \( \text{vars}(e) \) denote the set of variables in an expression \( e \), which has a straightforward inductive definition.

We now define computation states. Usually, states are mappings from variables to concrete values. To permit symbolice expressions (i.e., expressions containing variables) occurring as values in states, the starred expression \( * \) is used to represent a value for symbolic variables that cannot be further evaluated. The * symbol does not occur in programs, it is part of the semantic domain.

Definition 2 (Symbolic State, State Update). A symbolic state \( \sigma \) is a partial mapping

\[
\sigma : \text{Var} \to \text{Sexp}
\]

from variables to starred expressions. The notation \( \sigma[x \mapsto se] \) expresses the update of state \( \sigma \) at \( x \) with expression \( se \):

\[
\sigma[x \mapsto se](y) = \begin{cases} 
se & x = y \\
\sigma(y) & x \neq y
\end{cases}
\]

In a symbolic state, a symbolic variable is defined as a variable bound to an unknown value, represented by the starred expression \( * \). Symbolic variables play a different role than ordinary variables: they act as parameters, relative to which a local computation is evaluated. To distinguish them syntactically, we adopt the convention of using capital letters for symbolic variables as much as possible. Note that the set of symbolic and non-symbolic variables are not two distinct categories and a variable that is symbolic can become non-symbolic after substitution (see Example 2 below).

Definition 3 (Symbolic Variable). Symbolic variables in a state \( \sigma \) are variables mapped to \( * \):

\[
\text{symb}(\sigma) = \{ X \in \text{Var} \mid \sigma(X) = * \}.
\]

We will also need the concept of the extension of a state:

Definition 4 (State Extension). We say that a state \( \sigma' \) extends a state \( \sigma \) if (i) \( \text{dom}(\sigma) \subseteq \text{dom}(\sigma') \) and (ii) \( \sigma(x) = \sigma'(x) \) for all \( x \in \text{dom}(\sigma) \). We overload the subset symbol and write \( \sigma \subseteq \sigma' \).

Example 1. Consider a state \( \sigma_0 = [x_0 \mapsto Y_0 + w_0, Y_0 \mapsto *, w_0 \mapsto 42, x_1 \mapsto Y_1] \). Observe that (1) the expressions in the range of \( \sigma_0 \) can be simplified and (2) there are dangling references, such as \( Y_1 \), not in the domain of \( \sigma_0 \).

The example shows that symbolic states are slightly too general for our purpose, motivating the following definition, which constrains the variables that may occur in value expressions of states to symbolic variables:

Definition 5 (Well-Formed State). A state \( \sigma \) is well-formed if it fulfils the following condition:

\[
\{ x \in \text{vars}(\sigma(y)) \mid y \in \text{dom}(\sigma) \} \subseteq \text{symb}(\sigma).
\]

A well-formed state \( \sigma \) is concrete if \( \text{symb}(\sigma) = \{ \} \). For a concrete, well-formed state \( \sigma \) and all \( x \in \text{dom}(\sigma) \), there is a value \( v \) such that \( \sigma(x) = v \).
Example 2. The state $σ_0$ in Example 4 can be turned into a well-formed state $σ_1$ by simplifying the expression $Y_0 + w_0$, and binding $Y_1$ to a star, obtaining $σ_1 = [x_0 \mapsto Y_0 + 42, Y_0 \mapsto *, w_0 \mapsto 42, x_1 \mapsto Y_1, Y_1 \mapsto *]$. We have that $σ_1 = σ_0[x_0 \mapsto Y_0 + 42, Y_1 \mapsto *]$ and $\text{symb}(σ_1) = \{Y_0, Y_1\}$. Let $σ_2 = σ_1[Y_0 \mapsto 3, Y_1 \mapsto 2]$. After simplification, $σ_2$ is a concrete, well-formed state that can be written as $σ_2 = [x_0 \mapsto 45, Y_0 \mapsto 3, w_0 \mapsto 42, x_1 \mapsto 2, Y_1 \mapsto 2]$.

Henceforth, all states are assumed to be well-formed. We always assume states to be simplified by propagation of concrete values, similar to $σ_2$ in Example 2 otherwise non-symbolic variables might occur as values. Symbolic states, i.e. states with symbolic variables, are close to states in symbolic execution as used in path exploration [33], but simplified and with an additional restriction (Definition 11 below).

2.2 Evaluation

The evaluation of expressions in the context of a symbolic state reduces known variables to their values and keeps the symbolic variables inside the expression, reducing an expression as much as currently possible. The evaluation function is defined as follows:

Definition 6 (Evaluation Function). Let $σ$ be a symbolic state. The evaluation function $\text{val}_σ : \text{Exp} \to \text{Exp}$ for expressions in the context of $σ$ is defined inductively:

$$\text{val}_σ(x) = \begin{cases} x & \text{if } σ(x) = * \\ σ(x) & \text{otherwise} \end{cases}$$

$$\text{val}_σ(v) = v$$

$$\text{val}_σ(e_1 \op e_2) = \begin{cases} \text{val}_σ(e_1) \op \text{val}_σ(e_2) & \text{if } \text{val}_σ(e_1) \in \text{Val} \text{ and } \text{val}_σ(e_2) \in \text{Val} \\ \text{val}_σ(e_1) \op \text{val}_σ(e_2) & \text{otherwise} \end{cases}$$

In the following we will ensure that $\text{vars}(e) \subseteq \text{dom}(σ)$ holds, such that $\text{val}_σ$ is a total function.

Example 3. Using state $σ_1$ of Example 2 we evaluate $\text{val}_σ_1(x_0 + Y_0 + Y_1) = (Y_0 + 42) + Y_0 + Y_1$.

Let $\text{val}_σ(\tau)$ denote the element-wise application of the evaluation function to all expressions in the list $τ$, and likewise for sets.

2.3 Traces and Events

Traces are sequences over states and structured events. The presence of events makes it easy to ensure global properties of traces via well-formedness conditions over events. Since states may be symbolic, traces will be symbolic as well and it is necessary to constrain traces by symbolic path conditions. We start with a general definition of events. Their specific structure will be added later.

Definition 7 (Event Marker). Let $\text{ev}(\tau)$ be an event marker over expressions $\tau$.

Definition 8 (Path Condition). A path condition $pc$ is a finite set of Boolean expressions. If $pc$ contains no variables, then we can assume it to be fully evaluated; i.e. it is either $\emptyset, \{\text{t}\}, \{\text{f}\}$, or $\{\text{t}, \text{f}\}$. A fully evaluated path condition is consistent if and only if it does not contain $\text{f}$.

For any concrete state $σ$, $\text{val}_σ(pc)$ is a path condition with no variables that can be fully evaluated.

Definition 9 (Conditioned Symbolic Trace). A symbolic trace $τ$ is defined co-inductively by the following rules ($ε$ denotes the empty trace):

$$τ ::= ε \mid τ \concat t$$

$$t ::= σ \mid \text{ev}(\tau)$$

A conditioned symbolic trace has the form $pc ▷ τ$, where $pc$ is a path condition and $τ$ is a symbolic trace. If $pc$ is consistent, we simply write $τ$ for $pc ▷ τ$.

Traces can be finite or infinite. For simplicity, let $⟨σ⟩$ denote the singleton trace $ε \concat σ$. Concatenation of two traces $τ_1, τ_2$ is written as $τ_1 \cdot τ_2$ and only defined when $τ_1$ is finite. The final state of a non-empty, finite trace $τ$ is selected with $\text{last}(τ)$, the first state of a non-empty trace $τ$ with $\text{first}(τ)$.

Example 4. Continuing Example 2 we define a conditioned symbolic trace $pc_0 ▷ τ_0 = \{Y_0 > Y_1\} ▷ ⟨σ_1⟩ \concat σ_1[x_0 \mapsto 17]$.
**Sequential Composition** It is important that traces can semantically model the sequential composition of program statements. Assume that \( \tau_1 \) is a trace of a statement \( r \) and \( \tau_2 \) a trace of another statement \( s \). To obtain the trace corresponding to the sequential composition of \( r \) and \( s \), the traces corresponding to \( r \) and \( s \) should be concatenated, but the last state of the first trace and the first state of the second trace are generally identical. We generalize such a concatenation in case the states are not exactly the same: to concatenate two traces \( \tau_1 \) and \( \tau_2 \) the first state of \( \tau_2 \) should be an extension of the last state of \( \tau_1 \), but the resulting trace should only contain the largest of the two states. This motivates the *semantic chop* \( \dagger \dagger \) on traces (following [36], who in turn were inspired by interval temporal logic [35]):

**Definition 10 (Chop on Traces).** Let \( pc_1, pc_2 \) be path conditions and \( \tau_1, \tau_2 \) be symbolic traces, and assume that \( \tau_1 \) is a non-empty, finite trace. The semantic chop \( \dagger \dagger (pc_1 \triangleright \tau_1 \dagger \dagger pc_2 \triangleright \tau_2) \) is defined as follows:

\[
\dagger \dagger (pc_1 \triangleright \tau_1 \dagger \dagger pc_2 \triangleright \tau_2) = (pc_1 \cup pc_2) \triangleright \tau \cdot \tau_2 \quad \text{where} \quad \tau = \tau_1 \triangleright \sigma, \quad \tau_2 = \langle \sigma' \rangle \cdot \tau' \quad \text{and} \quad \sigma \subseteq \sigma'.
\]

For infinite and empty traces \( \tau_1 \), the chop operator is undefined. Whenever the final state of the first trace cannot be extended to the first state of the second trace, the operator is undefined.

The definition can be specialised to traces without path conditions in the obvious way: \( \tau_1 \dagger \dagger \tau_2 \) is \((\emptyset \triangleright \tau_1) \dagger \dagger (\emptyset \triangleright \tau_2)\).

**Traces with Events.** Events will be uniquely associated with the state in a trace at which they occurred. The events do not update the values in a state, but they may extend a state with fresh symbolic variables. To this aim, an event \( ev(\tau) \) is inserted into a trace after a state \( \sigma \) and the state is then augmented by a set \( V \) of symbolic variables. The notation we use for this operation is an *event trace* \( ev_\theta V(\tau) \) of length three:

\[
ev_\theta V(\tau) = \langle \sigma \rangle \cap ev(\text{val}_\sigma(\tau)) \cap \sigma' \quad \text{where} \quad \sigma' = \sigma \cup V \mapsto \star.
\]

Given a trace of the form \( \sigma \cap \sigma \) and event \( ev(\tau) \), appending the event is achieved by the trace \( \tau' = ev_\theta V(\tau) \).

The preceding definition ensures that events in traces are "choppable"; \( \tau \dagger \dagger ev_\theta V(\tau) \) is well-defined whenever last(\( \tau \)) = \( \sigma \). If \( V \) is empty then the state is unchanged, in this case we omit the set of symbolic variables:

\[
ev_\emptyset V(\tau) = ev_\emptyset(\tau)
\]

**Example 5.** Event traces can be inserted at the middle of a trace. To insert an event \( ev(\emptyset) \) that does not introduce symbolic variables at \( \sigma_1 \) to trace \( \tau_0 \) in Example 4 we use the event trace \( ev_{\emptyset}(\emptyset) = \langle \sigma_1 \rangle \cap ev(\text{val}_{\emptyset}(\emptyset)) \cap \sigma_1 = \langle \sigma_1 \rangle \cap ev(\emptyset) \cap \sigma_1 \). This results in the trace: \( \tau_2 = \{ Y_0 > Y_1 \} \triangleright \langle \sigma_1 \rangle \cap ev(Y_0) \cap \sigma_1 \cap \sigma_1[x_0 \mapsto 17] \). To insert an event \( ev(Y_2) \) that introduces the symbolic variable \( Y_2 \), we use the event trace \( ev_{\emptyset}^Y(\emptyset) = \langle \sigma_1 \rangle \cap ev(Y_2) \cap \sigma_1[Y_2 \mapsto \star] \cap \sigma_1[Y_2 \mapsto \star, x_0 \mapsto 17] \).

**Well-Formed Traces.** Similar to the values of well-formed states, the expressions in events and path conditions of a well-formed trace should only contain symbolic variables. This requires all states in a trace to agree upon which variables are symbolic. We also impose an additional well-formedness condition on events: any event occurring in a trace must be immediately preceded and followed by the same state \( \sigma \); i.e., it can be obtained by inserting an event trace at \( \sigma \). This implies that a trace always starts and ends with a state, never with an event. Well-Formed traces are formalised as follows:

**Definition 11 (Well-Formed Trace).** Let \( pc \triangleright \tau \) be a conditioned symbolic trace and let \( V = \bigcup_{\sigma \in \tau} \text{symb}(\sigma) \). The trace \( pc \triangleright \tau \) is well-formed if the following conditions hold:

\[
\forall \sigma \in \tau. \sigma \text{ is well-formed} \quad (1)
\]

\[
\forall \sigma \in \tau. (\text{dom}(\sigma) \setminus \text{symb}(\sigma)) \cap V = \emptyset \quad (2)
\]

\[
\text{vars}(pc) \subseteq V \quad (3)
\]

\[
\forall ev(\tau) \in \tau. \text{vars}(\tau) \subseteq V \quad (4)
\]

\[
\forall ev(\tau), \tau_1, \tau_2. (\tau = \tau_1 \triangleright ev(\tau) \cdot \tau_2 = \exists \sigma. \text{last}(\tau_1) = \sigma \land \text{first}(\tau_2) = \sigma) \quad (5)
\]

Equation (4) states that a variable that is symbolic in a state cannot be non-symbolic in another state of the trace. Equations (3) - (4) ensure that any variable to occur in a path condition or event is a symbolic variable from some state. Equation (5) guarantees that any event in a trace is surrounded by identical states.
Example 6. The traces \( \tau_2 \) and \( \tau'_2 \) in Example 5 have well-formed states. Only symbolic variables occur in path conditions and events, and the events were added by inserting event traces. Hence, they are well-formed.

**Definition 12 (Concrete Traces).** A concrete trace is a well-formed trace containing only concrete states and events, as well as a fully evaluated, consistent path condition. We use \( \text{sh} \) for concrete traces, where the letters stand for “shining” trace.

Example 7. Let \( \sigma_3 = [x_0 \mapsto 45, Y_0 \mapsto 3, x_0 \mapsto 42, x_1 \mapsto 2, Y_1 \mapsto 2] \), then a concrete trace of length two is \( \tau_3 = (\sigma_3) \cap \sigma_3[x_0 \mapsto 17] \). The path condition \( Y_0 > Y_1 \) is evaluated to \( 3 > 2 = \text{false} \) in \( \sigma_3 \) and thus consistent.

Observe that \( \tau_3 \) can be obtained from \( \tau_0 \) in Example 3 by a suitable instantiation of its symbolic variables. The precise definition of this operation is the purpose of the following subsection.

2.4 Concretisation

A concretisation mapping is defined relative to a state. It associates a concrete value to each symbolic variable of the state.

**Definition 13 (State Concretisation Mapping).** A mapping \( \rho : \text{Var} \to \text{Val} \) is a concretisation mapping for a state \( \sigma \) if \( \text{dom}(\rho) \cap \text{dom}(\sigma) = \text{symb}(\sigma) \).

A concretisation mapping \( \rho \) may additionally define the value of variables that are not in the domain of \( \sigma \).

Example 8. Consider \( \sigma_1 \) of Example 2 where \( \text{symb}(\sigma_1) = \{Y_0, Y_1\} \). We define the concretisation mapping \( \rho_1 = [Y_0 \mapsto 3, Y_1 \mapsto 2] \) for \( \sigma_1 \).

Let \( \sigma_4 = [X \mapsto *, z \mapsto 3] \). Then a concretisation mapping must give a value to \( X \), but not to \( z \), for example, \( \rho_2 = [X \mapsto 2, Y \mapsto 0] \) is a concretisation mapping for \( \sigma_4 \).

A symbolic state can be concretised using the values assigned to its symbolic variables in a concretisation mapping to evaluate the symbolic expressions.

**Definition 14 (State Concretisation).** Let \( \sigma \) be a state and \( \rho \) a concretisation mapping for \( \sigma \). The concretisation of \( \sigma \) with \( \rho \) is defined as follows:

\[
\rho \bullet \sigma = \rho \cup \{ x \mapsto \text{val}_\rho(\sigma(x)) \mid x \in \text{dom}(\sigma) \setminus \text{dom}(\rho) \}.
\]

**Example 9.** Continuing Examples 7 and 8 we obtain \( \rho_1 \bullet \sigma_1 = \sigma_3 \).

To concretise a symbolic trace \( pc \triangleright \tau \), we must apply a concretisation mapping \( \rho \) to all states and events of the trace. This means the domain of \( \rho \) must comprise all symbolic variables that occur in the trace. This is the case for well-formed traces, whose states must agree on which variables are symbolic (equation 2 in Definition 1).

**Definition 15 (Trace Concretisation Mapping).** A mapping \( \rho \) is a trace concretisation mapping for \( \tau \) if it is a concretisation mapping for all the states in \( \tau \). We say that \( \rho \) concretises \( \tau \).

**Definition 16 (Symbolic Trace Concretisation).** Let \( pc \triangleright \tau \) be a well-formed trace and \( \rho \) a concretisation mapping for \( \tau \). The concretisation \( \rho(pc \triangleright \tau) \) of \( pc \triangleright \tau \) is obtained as \( \rho(pc) \triangleright \rho(\tau) \), where \( \rho(pc) = \text{val}_\rho(pc) \) and \( \rho(\tau) \) is defined as follows:

\[
\rho(t_1 \cdots t_n \cdots) = \rho(t_1) \cdots \rho(t_n) \cdots
\]

\[
\rho(\sigma) = \rho \bullet \sigma
\]

\[
\rho(\text{ev}(\tau)) = \text{ev}(\text{val}_\rho(\tau))
\]

**Proposition 1.** The concretisation of a state is a concrete state. The concretisation of a well-formed trace is a concrete, well-formed trace. Any concrete state or trace is a concretisation of itself.

**Example 10.** We continue to use the symbolic trace \( pc_0 \triangleright \tau_0 \) of Example 4 and concretise it with the mapping \( \rho_1 \) of Example 8. The resulting concrete trace is \( \tau_3 \) from Example 7 with path condition \( \{\text{false}\} \).
\[ s \in Stmt ::= \text{skip} \mid x := e \mid \text{if } e \{ s \} \mid s; s \mid \text{while } e \{ s \} \]

Fig. 2: The syntax for statements in WHILE.

2.5 Continuations

To capture the local semantics of a language, below we define an evaluation function \( \text{val}_\sigma (s) \) that evaluates a single statement \( s \) in a—possibly symbolic—state \( \sigma \) to a set of conditioned, symbolic traces. \textit{Compositional} local evaluation rules can then be defined for each statement by adding a \textit{continuation marker} at the end. Continuation markers are needed, if \( s \) is a composite statement that requires separate evaluation of its constituent parts. In particular, \( s \) might not terminate, but this should not jeopardise parallel computations when computing a sequential trace for a global system. We avoid this issue by stopping the evaluation after a finite number of steps by means of a continuation marker, defined as follows:

\textbf{Definition 17 (Continuation Marker).} Let \( s \) be a program statement. The continuation marker \( K(s) \) expresses that a given trace is extended by the traces resulting from computing \( s \). The empty continuation, denoted \( K(\emptyset) \), expresses that nothing remains to be computed.\(^6\)

The argument to the continuation marker is the code on which evaluation is continued. When atomic statements are evaluated, there is no continuation code but only a return of control. In this case, we end the trace with an empty continuation (see Section 3.1). Local evaluation (corresponding to phase (1) in Section 1) is defined below such that for each statement \( s \) and symbolic state \( \sigma \) the result of \( \text{val}_\sigma (s) \) is a set of conditioned, symbolic traces. These traces are called \textit{continuation traces}; we denote by \( \text{CTr} \) the type of continuation traces.

3 LAGC Semantics of WHILE

We define a LAGC semantics for WHILE, a language with basic sequential constructs that can be seen as a kernel of imperative programming languages [9]. The statements of WHILE consist of \textit{skip}, assignment, conditional, sequential composition, and \textit{while}-loops. The syntax for statements is given in Figure 2, where we assume given standard expressions \( e \). Assignment binds the value of an expression to a variable. Conditionals and \textit{while}-loops depend on the value of a Boolean expression \( e \). We assume the standard semantics of this language to be known, and use it to illustrate our trace semantics. \textit{Local rules} (phase (1)) unfold the traces until the next possible scheduling point, marked by a continuation. \textit{Composition rules} (phase (2)) select the next trace to be unfolded at the scheduling point; for the sequential language, there is only one trace so the latter selection is deterministic. Due to its simplicity, WHILE merely needs state-based traces, the use of events is covered in Section 5.4.

3.1 Local Evaluation

Local evaluation rules a single statement in the context of a symbolic state, and return a set of finite continuation traces. Each evaluation rule represents the execution of a single statement, producing a set of continuations traces. The evaluation rules are reminiscent of small-step reduction rules, but work in a denotational setting and with a symbolic context. We overload the symbol \( \text{val}_\sigma \) and declare it with the type \( \text{val}_\sigma : Stmt \to 2\text{CTr} \).

The rule for \textit{skip} generates an empty path condition, returns the state it was called in, and continues with the empty continuation. The result is a set containing one singleton trace:

\[ \text{val}_\sigma (\text{skip}) = \{ \emptyset \succ \langle \sigma \rangle \cdot K(\emptyset) \} . \] (6)

The assignment rule generates an empty path condition and a trace from the current state \( \sigma \) to a state which updates \( \sigma \) at \( x \), and continues with an empty continuation. The result is one trace of length two:

\[ \text{val}_\sigma (x := e) = \{ \emptyset \succ \langle \sigma \rangle \cap \sigma[x \mapsto \text{val}_\sigma (e)] \cdot K(\emptyset) \} . \] (7)

The rule for the conditional statement branches on the value of the condition, resulting in two traces with different path conditions. The first trace is obtained from the current state and the continuation with the

\(^6\) The mnemonics of the symbol is that from an empty bottle nothing can be consumed.
statements in the if-branch, and the second trace has the empty continuation (corresponding to the empty else-branch):

\[
\text{val}_\sigma(\text{if } e \{ s \}) = \{ \text{val}_\sigma(e) = \top \} \triangleright \langle \cdot \rangle \cdot K(s), \quad \{ \text{val}_\sigma(e) = \bot \} \triangleright \langle \cdot \rangle \cdot K(\emptyset) \}.
\]

(8)

The semantics of while is similar to the semantics for the conditional statement. This gives us the opportunity to illustrate that the semantics of a statement can easily be expressed in terms of the semantics of another statement, without having to expose intermediate states:

\[
\text{val}_\sigma(\text{while } e \{ s \}) = \text{val}_\sigma(\text{if } e \{ s; \text{while } e \{ s \} \})).
\]

(9)

The rule for sequential composition \( r; s \) is obtained by first evaluating \( r \) to traces of the form \( pc \triangleright \tau \cdot K(r') \) with continuation \( r' \). The statement \( s \) can simply be added to this continuation:

\[
\text{val}_\sigma(r; s) = \{ pc \triangleright \tau \cdot K(r') \cdot s \mid pc \triangleright \tau \cdot K(r') \in \text{val}_\sigma(r) \}.
\]

(10)

A subtle point concerns the propagation of empty continuations: \( r' \) might be the empty continuation \( \emptyset \), which should be ignored. This behavior is captured in the following rewrite rule, which is exhaustively applied to statements occurring inside continuations:

\[ s; s' \sim s' \text{ if } s = \emptyset. \]

This rewrite rule reflects that the empty continuation is an identity element for sequential composition. Similar rewrite rules will be added to handle identity elements for other composition operators in the sequel.

Example 11. Consider the sequential statement \( s_{seq} = (x := 1; y := x + 1) \). To explain how its evaluation is performed, we start from an arbitrary symbolic state \( \sigma \) (to be instantiated later by a composition rule). The equation for sequential composition yields

\[
\text{val}_\sigma(s_{seq}) = \{ \emptyset \triangleright \langle \cdot \rangle \land \sigma[x \mapsto 1] \cdot K(y := x + 1) \}.
\]

(11)

To perform this evaluation, we need the result of evaluating the first assignment in the context of \( \sigma \):

\[
\text{val}_\sigma(x := 1) = \{ \emptyset \triangleright \langle \cdot \rangle \land \sigma[x \mapsto 1] \cdot K(\emptyset) \}.
\]

In the composition rules it might be necessary to evaluate the empty continuation, so we must define it. It is simply the empty set of traces:

\[
\text{val}_\sigma(\emptyset) = \{ \}.
\]

(12)

Proposition 2. Given a concrete state \( \sigma \) and a program \( s \) such that \( \text{vars}(s) \subseteq \text{dom}(\sigma) \), then \( \text{val}_\sigma(s) \) is a set of concrete continuation traces of the form \( pc \triangleright \tau \cdot K(s') \). There is exactly one continuation trace with a consistent path condition.

3.2 Trace Composition

Local traces are composed into concrete global ones. As WHILE is sequential and deterministic, we expect to obtain exactly one trace, provided that the execution starts in a concrete state that assigns values to all the variables of a program. Proposition 2 ensures that all local evaluation rules produce concrete traces in this case.

The task of the composition rule for WHILE-programs is to repeatedly evaluate one statement at a time in a concrete state until the next continuation, then stitch the resulting concrete traces together. Given a concrete trace \( sh \) with final state \( \sigma \) and a continuation \( K(s) \), we evaluate \( s \) starting in \( \sigma \). The result is a set of conditioned traces from which one trace with a consistent path condition and a trailing continuation \( K(s') \) is chosen. The chosen trace \( \tau \) is clipped with the given trace \( sh \). Afterwards, the composition rule can be applied again to the extended concrete trace and \( K(s') \).

\[
\frac{\sigma = \text{last}(sh) \quad pc \triangleright \tau \cdot K(s') \in \text{val}_\sigma(s) \quad pc \text{ consistent}}{sh, K(s) \rightarrow sh \ast \tau, K(s')}.
\]

(13)

The rule assumes that \( s \) is evaluated to a concrete trace so that \( sh \ast \tau \) stays concrete. At this stage, symbolic traces do not yet figure. This works as long as Proposition 2 ensures that \( pc \triangleright \tau \) is a concrete trace, however, in general the proviso \( \text{vars}(s) \subseteq \text{dom}(\sigma) \) does not hold. There are several approaches to address this. For example, it is sufficient to consider the non-initialised variables of \( s \), instead of all of them. We avoid a lengthy definition to address this technicality by simply assuming that last \( (sh) \) defines all variables of \( s \). This can be easily achieved by initialising all variables to default values at program start, as done below.

\footnote{For a deterministic language like WHILE, there is exactly one trace, but the rule is designed to work for the non-deterministic extension below as well.}
3.3 Global Trace Semantics

Let \(sh, K(s) \xrightarrow{*} sh', K(s')\) denote the transitive closure of applying rule (13), expressing that \(sh', K(s')\) can be reached from \(sh, K(s)\) in zero or more steps.

**Definition 18 (Program Semantics).** Given a program \(s\) and a state \(\sigma\), let

\[
sh_0, K(s_0) \rightarrow sh_1, K(s_1) \rightarrow \cdots
\]

be a maximal sequence obtained by the repeated application of rule (13), starting from \(\langle \sigma \rangle, K(s)\). If the sequence is finite, then it must have the form\(^8\)

\[
\langle \sigma \rangle, K(s) \rightarrow sh, K(\emptyset).
\]

If the sequence is infinite, let \(sh = \lim_{i \to \infty} sh_i\). The set of all such traces \(sh\) for a program \(s\) starting from a state \(\sigma\) is denoted \(Tr(s, \sigma)\).

For any statement \(s\), let \(I_s\) be the state, where \(\{x \mapsto 0\}\) for all \(x \in vars(s)\) (for simplicity, assume all variables are of integer type—the generalisation is obvious). To help readability, we sometimes omit such default values from the states in the following examples.

**Example 12.** We apply rule (13) to \(\langle I_{seq}\rangle, K(s_{seq})\), the program from Example 11. To obtain the premise, we instantiate equation (11) with \(\sigma = I_{seq}\).

\[
\begin{align*}
I_{seq} &= \text{last}(\langle I_{seq}\rangle) & \emptyset \text{ consistent} \\
\emptyset \triangleright \langle I_{seq}\rangle \land I_{seq}[x \mapsto 1] & \cdot K(y := x + 1) \in \text{val}_{I_{seq}}(x := 1; y := x + 1) \\
\langle I_{seq}\rangle, K(x := 1; y := x + 1) & \rightarrow \langle I_{seq}\rangle \land I_{seq}[x \mapsto 1], K(y := x + 1)
\end{align*}
\]

(14)

For the subsequent rule application, it is necessary to evaluate the program \(y := x + 1\) in the continuation. Again, we do this for a general state, while in the rule we use \(\sigma = I_{seq}[x \mapsto 1]\) (from now on we omit \(I_{seq}\)):

\[
\text{val}_{\sigma}(y := x + 1) = \{\emptyset \triangleright \langle \sigma \rangle \land \sigma[y \mapsto \text{val}_{\sigma}(x + 1)] \cdot K(\emptyset)\}
\]

\[
\begin{align*}
\emptyset \triangleright \langle x \mapsto 1 \rangle \land [x \mapsto 1][y \mapsto \text{val}_{\langle x \mapsto 1 \rangle}(x + 1)] & \cdot K(\emptyset) \in \text{val}_{\langle x \mapsto 1 \rangle}(y := x + 1) \\
\langle I_{seq}\rangle \land [x \mapsto 1], K(y := x + 1) & \rightarrow \langle I_{seq}\rangle \land [x \mapsto 1] \land [x \mapsto 1, y \mapsto 2], K(\emptyset)
\end{align*}
\]

(15)

Hence, \(Tr(x=1; y=x+1, I_{seq}) = \{\langle I_{seq}\rangle \land [x \mapsto 1] \land [x \mapsto 1, y \mapsto 2]\}\).

3.4 Discussion

As mentioned, as long as we start semantic evaluation in a sufficiently initialised concrete state, Proposition 2 ensures that only concrete traces will be generated by local rules. Consequently, we have a semantics that can be aptly called modular and compositional (exactly one independent rule per language construct and a uniform composition rule), but the overhead introduced with symbolic traces is not yet justified.

The advantages offered by symbolic traces and states are realised in the following two sections. In Section 4 we define a program logic for WHILE that employs symbolic traces at the level of the calculus. This close correspondence between semantics and deduction system is the basis for an intuitive soundness proof for the deductive system.

In Sections 5–7 we extend WHILE with a number of complex instructions, in particular, for parallel programming. It will be seen that a wide range of concurrency paradigms fit naturally into the LAGC semantic framework.

\(^8\) Observe that \(sh, K(\emptyset)\) is the end of the execution because the evaluation of \(K(\emptyset)\) returns \(\{}\) such that the composition rule (13) is no longer applicable. The empty continuation is obtained once the whole program has been evaluated.
4 A Program Logic and Sound Calculus for WHILE

We provide a dynamic logic (DL) \[37\] as well as a calculus for reasoning about the correctness of WHILE-programs that is sound relative to our semantics. In deductive verification dynamic logic \[114\] offers technical advantages over Hoare logic \[42\]: it is syntactically closed with respect to first-order logic, more expressive, and cleanly separates first-order (“logical”) from program variables \[4\] p. 50]. Below we define program formulas of the form \(ψ \rightarrow τ[s]φ\), where \(τ\) is a finite symbolic trace, \(s\) any WHILE-statement, \(ψ\) a first-order formula, and \(φ\) a formula that in turn may contain programs. The intuitive meaning is that any terminating execution of \(s\) continuing a trace that concretises \(τ\) and started in a state that satisfies \(ψ\), must end in a state that satisfies \(φ\). The modality \([s]φ\) corresponds to a continuation in the semantics of WHILE, represented symbolically.

The unusual aspect of this setup is the presence of a symbolic trace \(τ\) inside a formula. It aligns with our locally abstract semantics, but it is also justified, because—unlike a semantics—rule schemata in calculus rules necessarily deal with symbolic values: a verification calculus aims at proving a property that holds for all inputs of a program, not merely for a single run. Nevertheless, the presence of symbolic traces inside formulas may appear as insufficiently syntactic or as an inappropriate intrusion of the semantics into the calculus. However, efficient syntactic representations of symbolic assignments are fairly common and well understood: for example, the deductive verification system KeY uses symbolic update\[2\] and in the B-method explicit generalised substitutions play a comparable role \[1\]. To keep the calculus as general as possible, we do not commit to a particular implementation of symbolic traces.

The calculus rules given below will symbolically execute a program \(s\) in a sequent of the form \(ψ \rightarrow τ[s]φ\) and produce verification conditions of the form \(I' \Rightarrow τ φ\), where \(φ\) is a first-order formula and \(τ\) a symbolic trace.

4.1 Dynamic Logic

Given a signature \(Σ\) with typed function and predicate symbols and a set \(V\) of logical variables which is disjoint from the symbols in \(Σ\), let \(\text{Terms}(Σ, V)\) denote the well-formed terms over \(Σ\) and \(V\) (respecting type compatibility). Note that the logical variables in \(V\) are disjoint from program variables \(\text{Var}\). Unlike the latter, the logical variables can be bound by quantifiers and do not change their value during program execution.

Definition 19 (DL Formula). Let \(Σ\) be a signature and \(V\) a set of logical variables disjoint from \(Σ\). The language \(\text{DL}(Σ, V)\) of formulas in dynamic logic is defined inductively as follows:

1. \(B \in \text{DL}(Σ, V)\) if \(B \in \text{Terms}(Σ, V)\) and the type of \(B\) is Boolean
2. \(¬ψ_1, ψ_1 \land ψ_2, ψ_1 \lor ψ_2, ψ_1 \rightarrow ψ_2, φ_1 \leftrightarrow φ_2 \in \text{DL}(Σ, V)\) if \(φ_1, φ_2 \in \text{DL}(Σ, V)\)
3. \(∃x·φ, ∀x·φ \in \text{DL}(Σ, V)\) if \(x \in V\) and \(φ \in \text{DL}(Σ, V)\)
4. \([s]φ \in \text{DL}(Σ, V)\) if \(s\) is a, possibly empty, WHILE-program and \(φ \in \text{DL}(Σ, V)\)

We often omit the signature and variable set of \(φ \in \text{DL}(Σ, V)\) and simply write \(φ \in \text{DL}\).

There is a subtle point about empty programs. As explained above, the program \(s\) in the modality can be viewed as the continuation of the current trace. The rules of the calculus defined below will symbolically execute \(s\) from left to right, until the program remaining to be executed is empty. For this reason, we allow empty programs, denoted \(\circ\), in clause \(4\). The empty program is the identity element for the composition operators (i.e., \(c; s = s; c = s\)). However, the continuation with the empty program is not the same as the empty continuation; it requires a semantics that amounts to an empty trace, which is reflected in Definition \(21\) below.

Definition 20 (Substitution). Given a language \(\text{DL}(Σ, V)\) and a set of logical variables \(V' = \{x_1, \ldots, x_n\}\) such that \(V' \subseteq V\), a substitution \([x_1/t_1, \ldots, x_n/t_n]\) is a function \(V' \rightarrow \text{Terms}(Σ, V)\) which associates with every \(x_i \in V'\) a type-compatible term \(t_i \in \text{Terms}(Σ, V)\).

Denote by \(φ[x_1/t_1, \ldots, x_n/t_n]\) the application of a substitution \([x_1/t_1, \ldots, x_n/t_n]\) to a logical formula \(φ \in \text{DL}(Σ, V)\). Observe that applying a substitution removes occurrences of logical variables in a formula and does not affect programs. The application of the substitution has a straightforward inductive definition over \(φ\) (omitted here).

We write \(τ ≡ φ\) and \(σ \models φ\) to denote\[14\] that a formula \(φ\) is valid for a concrete trace \(τ\) and in a concrete state \(σ\), respectively (equivalently, \(τ\) and \(σ\) satisfy \(φ\)). Formally, satisfiability can be defined as follows:

\[\text{Updates can be viewed as a syntactic, efficient, lazy representation of symbolic traces: concrete values are not eagerly substituted and assignments are kept in single static (SSA) shape.\]

\[\text{To simplify presentation, we assume a fixed standard interpretation of the symbols in } Σ. \text{ It is straightforward to accommodate undefined symbols and relativise satisfiability to first-order models.}\]
then free”) formulas; i.e., if ⊢ \sigma \vdash s \phi

Proof. The proof is by induction over the structure of \phi. We assume the soundness of first-order (or “program-free”) formulas; i.e., if ⊢ B then \models B for B ∈ Terms(\Sigma, V).

Case \textbf{Empty}. Assume ⊢ ψ ⇒ τ [\epsilon] \phi. By rule (Empty), we get ⊢ ψ ⇒ τ \phi.
For the base case, we may assume that \( \phi \) is a first-order formula. Then, by assumption, \( \models \psi \Rightarrow \tau \phi \), which means that for any concretisation mapping \( \rho \), if \( \text{first}(\rho(\tau)) \models \psi \), then \( \text{last}(\rho(\tau)) \models \phi \). The latter is, by Definition 21, equivalent to \( \text{last}(\rho(\tau)) \models [\sigma] \phi \). Since \( \rho \) was arbitrary, this yields \( \models \psi \Rightarrow \tau [\sigma] \phi \).

For the inductive case, we may assume that \( \phi \) is any DL formula. Then, \( \models \psi \Rightarrow \tau \phi \) follows from the induction hypothesis (hereafter, IH), and the rest of the proof is analogous to the base case.

**Case SKIP.** Assume \( \models \psi \Rightarrow \tau [\text{skip}; s] \phi \). By rule (SKIP), we get \( \models \psi \Rightarrow \tau [s] \phi \), and by IH we have \( \models \psi \Rightarrow \tau [s] \phi \).

Hence, for any concretisation mapping \( \rho \), if \( \text{first}(\rho(\tau)) \models \psi \), then \( \text{last}(\rho(\tau)) \models [s] \phi \). Then \( \tau' \models [\sigma] \phi \) for all \( \tau' \in \text{Tr}(s, \text{last}(\rho(\tau))) \). By equations (13), (10) and (9), we have \( \text{Tr}(s, \sigma) = \text{Tr}(\text{skip}; s, \sigma) \) for any \( \sigma \). Therefore, for all \( \tau'' \in \text{Tr}(\text{skip}; s, \text{last}(\rho(\tau))) \) we have \( \tau'' \models [\sigma] \phi \), and it follows that \( \models \psi \Rightarrow \tau [\text{skip}; s] \phi \).

**Case ASSIGN.** Assume \( \models \psi \Rightarrow \tau [x:=e; s] \phi \). By rule (ASSIGN), we get \( \models \psi \Rightarrow \tau \cap \sigma'[s] \phi \) where \( \text{last}(\tau) = \sigma \) and \( \sigma' = \sigma[x \mapsto \text{val}_s(e)] \). By IH we have \( \models \psi \Rightarrow \tau \cap \sigma'[s] \phi \).

Hence, for any concretisation mapping \( \rho \), if first(\( \rho(\tau \cap \sigma') \)) \models \psi, then last(\( \rho(\tau \cap \sigma') \)) \models [s] \phi \), i.e. \( \rho(\sigma') \models [s] \phi \). By equations (13), (10) and (7), we have
\[
\text{Tr}(x:=e; s, \sigma) = \{ \langle \sigma \cap \sigma' \models \tau' \models \text{Tr}(s, \sigma') \} \}
\]

Therefore, last(\( \rho(\tau) \)) \models [x:=e; s] \phi \) and, since \( \rho \) was arbitrary and first(\( \rho(\tau \cap \sigma') \)) \models first(\( \rho(\tau) \)), we have \( \models \psi \Rightarrow \tau [x:=e; s] \phi \).

**Case COND.** Assume \( \models \psi \Rightarrow \tau [\text{if } e \{ s' \}; \sigma; s] \phi \). By rule (COND), we get \( \models \psi \Rightarrow \tau \cap \sigma'[s] \phi \) and \( \models \psi \Rightarrow \text{val}_s(e) = \text{ff} \Rightarrow \tau[s; \sigma] \phi \). Correspondingly, we have two induction hypotheses: \( \models \psi \Rightarrow \text{val}_s(e) = \text{ff} \Rightarrow \tau[s; \sigma] \phi \) (hereafter, IH1) and \( \models \psi \Rightarrow \text{val}_s(e) = \text{tt} \Rightarrow \tau[s; \sigma] \phi \) (hereafter, IH2). Let \( \rho \) be any concretisation mapping and assume first(\( \rho(\tau) \)) \models \psi \). Depending on the value of \text{val}_s(e), exactly one of the subcases applies.

**Subcase IH1.** We can assume \text{val}_s(e) = \text{ff} and, by IH1, \( \models \psi \Rightarrow \text{val}_s(e) = \text{ff} \Rightarrow \tau[s; \sigma] \phi \), which together gives last(\( \rho(\tau) \)) \models [s] \phi \). By definition, \( \tau' \models [s] \phi \) for all \( \tau' \in \text{Tr}(s, \text{last}(\rho(\tau))) \). By Equations (13), (10) and (9), we have
\[
\text{Tr}(s, \sigma) = \text{Tr}(\text{if } e \{ s' \}; s, \sigma), \text{ observing that the path condition is consistent. Therefore, } \tau' \models [\text{if } e \{ s' \}; s] \phi \text{ for all } \tau' \in \text{Tr}(\text{if } e \{ s' \}; s, \text{last}(\rho(\tau))) \text{ and so } \models \psi \Rightarrow \tau [\text{if } e \{ s' \}; s] \phi \).

**Subcase IH2.** We can assume \text{val}_s(e) = \text{tt} and proceed by a completely analogous argument as in the other subcase.

**Case WHILE.** Follows directly from the case for COND.

### 5 Semantics for a Shared-Variable Parallel Programming Language

In this and the following section we show that the LAGC semantics naturally extends to cover advanced language constructs. We gradually extend WHILE with parallel programming constructs: parallel execution, procedure calls, distributed memory, dynamic process creation, and communication between procedures. To cater for interleaved execution of parallel instructions, and to allow for the compositional definition of semantics, the traces of the sequential language are gradually unfolded by means of continuations.

#### 5.1 Local Parallelism

We extend WHILE with a statement for parallel execution, such that the syntax for statements from Figure 2 becomes:

\[
s \in \text{Stmt} ::= \text{co } s \mid s \ \text{oc} \quad . . .
\]

The semantics of this statement consists in interleaving the evaluation of the two parallel branches at the granularity of atomic statements, as exemplified below.

**Example 13.** The program of the program \( s_{\text{co}} = \text{co } x := 1; y := x + 1 \mid x := 2 \text{ oc} \) produces one of three possible traces that correspond to the traces of the following sequential programs: \( x := 1; y := x + 1 \); \( x := 2; \) or \( x := 1; x := 2; y := x + 1, \) or \( x := 2; x := 1; y := x + 1 \).

**Local Evaluation** The evaluation rule for the parallel execution statement \( \text{co } r \mid s \text{ oc} \) branches on the statement which first gets to execute, resulting in two sets of traces where the first set contains traces with the path condition of \( r \) and the continuation of \( r \) in parallel with \( s \) and the second set contains traces with the path condition of \( s \) and the continuation of \( s \) in parallel with \( r \). The valuation rule is formalised as follows:

\[
\text{val}_s(\text{co } r \mid s \text{ oc}) = \{ \text{pc}_r \triangleright \tau_r \cdot K(\text{co } r \mid s \text{ oc}) | \text{pc}_s \triangleright \tau_s \cdot K(r') \in \text{val}_s(r) \} \\
\cup \{ \text{pc}_s \triangleright \tau_s \cdot K(\text{co } r \mid s' \text{ oc}) | \text{pc}_s \triangleright \tau_s \cdot K(s') \in \text{val}_s(s) \}.
\]

(16)
As with sequential composition in rule (10), we need to ensure that empty continuations are not propagated. To this end we define the following rewrite rule for parallel composition inside continuations (observe that the case \( s \neq s' \neq \emptyset \) cannot occur):

\[
\text{co } s \ | \ s' \text{ co } \rightarrow \begin{cases} 
  s' & \text{if } s = \emptyset, \ s' \neq \emptyset \\
  s & \text{if } s \neq \emptyset, \ s' = \emptyset 
\end{cases}.
\tag{17}
\]

**Trace Composition** The composition rule (13) can be kept unchanged (although the abstract variant in rule (23) below can be used as well). Its effect is that all combinations of execution sequences of atomic statements in the parallel branches can be generated. This behaviour corresponds to the classical interleaving semantics (e.g., [5]), as demonstrated below.

**Example 14.** Consider program \( s_{\text{co}} \) from Example (13) its evaluation is

\[
\text{val}_{s}(s_{\text{co}}) = \{ 0 \triangleright \langle \sigma \rangle \cap \sigma[x \mapsto 1] \cdot K(\text{co } y := x + 1 \mid x := 2 \text{ co}) \} \cup \\
\{ 0 \triangleright \langle \sigma \rangle \cap \sigma[x \mapsto 2] \cdot K(\text{co } x := 1; y := x + 1 \mid \emptyset \text{ co}) \} \\
= \{ 0 \triangleright \langle \sigma \rangle \cap \sigma[x \mapsto 1] \cdot K(\text{co } y := x + 1 \mid x := 2 \text{ co}) \} \cup \\
\{ 0 \triangleright \langle \sigma \rangle \cap \sigma[x \mapsto 2] \cdot K(\text{co } x := 1; y := x + 1) \},
\]

using the following sub-evaluations: \( \text{val}_{s}(x := 1; y := x + 1) = \{ 0 \triangleright \langle \sigma \rangle \cap \sigma[x \mapsto 1] \cdot K(y := x + 1) \} \) and \( \text{val}_{s}(x := 2) = \{ 0 \triangleright \langle \sigma \rangle \cap \sigma[x \mapsto 2] \cdot K(\emptyset) \} \). For trace composition, we first need to evaluate the continuation \( \text{co } y := x + 1 \mid x := 2 \text{ co} \):

\[
\text{val}_{s}(\text{co } y := x + 1 \mid x := 2 \text{ co}) = \{ 0 \triangleright \langle \sigma \rangle \cap \sigma[y \mapsto \text{val}_{s}(x + 1)] \cdot K(\text{co } \emptyset \mid x := 2 \text{ co}) \} \cup \\
\{ 0 \triangleright \langle \sigma \rangle \cap \sigma[x \mapsto 2] \cdot K(\text{co } y := x + 1 \mid \emptyset \text{ co}) \}
\]

\[
= \{ 0 \triangleright \langle \sigma \rangle \cap \sigma[y \mapsto \text{val}_{s}(x + 1)] \cdot K(x := 2) \} \cup \\
\{ 0 \triangleright \langle \sigma \rangle \cap \sigma[x \mapsto 2] \cdot K(y := x + 1) \},
\]

using the following sub-evaluations: \( \text{val}_{s}(y := x + 1) = \{ 0 \triangleright \langle \sigma \rangle \cap \sigma[y \mapsto \text{val}_{s}(x + 1)] \cdot K(\emptyset) \} \) and \( \text{val}_{s}(x := 2) = \{ 0 \triangleright \langle \sigma \rangle \cap \sigma[x \mapsto 2] \cdot K(\emptyset) \} \).

To illustrate trace composition, let us consider the trace where statement \( x := 1 \) is executed first and explore the remaining possible traces. We start from the state \( I_{\text{co}} \). The first application of rule (23) results in the following concrete trace and continuation:

\[
(I_{\text{co}}) \cap [x \mapsto 1], K(\text{co } y := x + 1 \mid x := 2 \text{ co}).
\]

At this point, two different instances of the composition rule are applicable, corresponding to the two possible interleavings; i.e., there is a choice between the two continuations in \( \text{val}_{[x \mapsto 1]}(\text{co } y := x + 1 \mid x := 2 \text{ co}) \) as shown above. The first possible instance of the composition rule is:

\[
\begin{align*}
[x \mapsto 1] &= \text{last}((I_{\text{co}}) \cap [x \mapsto 1]) \quad \emptyset \text{ consistent} \\
0 \triangleright [x \mapsto 1] &\cap [y \mapsto \text{val}_{[x \mapsto 1]}(x + 1)] \cdot K(x := 2) \\
\in \text{val}_{[x \mapsto 1]}(\text{co } y := x + 1 \mid x := 2 \text{ co}) \\
(I_{\text{co}}) &\cap [x \mapsto 1], K(\text{co } y := x + 1 \mid x := 2 \text{ co}) \\
&\rightarrow \\
(I_{\text{co}}) &\cap [x \mapsto 1] \cap [x \mapsto 1, y := 2], K(x := 2)
\end{align*}
\tag{18}
\]

One further rule application is possible, which results in the final step:

\[
(I_{\text{co}}) \cap [x \mapsto 1] \cap [x \mapsto 1, y := 2], K(x := 2) \rightarrow \\
(I_{\text{co}}) \cap [x \mapsto 1] \cap [x \mapsto 1, y := 2] \cap [x \mapsto 2, y := 2], K(\emptyset).
\]

The second possible instance of the composition rule is similar and yields:

\[
(I_{\text{co}}) \cap [x \mapsto 1] \cap [x \mapsto 2], K(y := x + 1) \rightarrow \\
(I_{\text{co}}) \cap [x \mapsto 1] \cap [x \mapsto 2] \cap [x \mapsto 2, y := 3], K(\emptyset)
\]

The third possible trace is obtained analogously by starting with the second branch. After this, only one continuation is possible. Altogether, the following traces are obtained:

\[
\text{Tr}(s_{\text{co}}, I_{\text{co}}) = \{ (I_{\text{co}}) \cap [x \mapsto 1] \cap [x \mapsto 1, y := 2] \cap [x \mapsto 2, y := 2], \\
(I_{\text{co}}) \cap [x \mapsto 1] \cap [x \mapsto 2] \cap [x \mapsto 2, y := 3], \\
(I_{\text{co}}) \cap [x \mapsto 2] \cap [x \mapsto 1] \cap [x \mapsto 1, y := 2] \}
\]
**Calculus** Let $ar$ and $as$ range over the atomic statements of WHILE (i.e., assignment and skip). It is straightforward to realise a set of DL rules directly inspired by rule (16). Local parallelism introduces a new composition operator, and the rules need to cover the different cases of nested statements.

\[
\begin{align*}
\text{(PAR)} & \quad \Gamma, pc \Rightarrow \tau [ar; co r'; | as; s' oc] \phi \\
\text{(PAR-EMPTY1)} & \quad \Gamma, pc \Rightarrow \tau [as; co ar; r'; | s' oc] \phi \\
\text{(PAR-EMPTY2)} & \quad \Gamma, pc \Rightarrow \tau [r] \phi \\
\end{align*}
\]

The base cases are covered by rules (PAR), (PAR-EMPTY1) and (PAR-EMPTY2). Rule (PAR), where $ar$ and $as$ match atomic statements, splits the proof into two cases, depending on the first executed atomic statement in the interleaved execution. The two rules (PAR-EMPTY1) and (PAR-EMPTY2) correspond to rewriting with empty continuations in rule (17). The remaining rules deal with the case when the statement inside the parallel statement is not atomic. We illustrate these rules with (PAR-IF1) and (PAR-IF2), which resolve a conditional inside the parallel statement. Similar rules are required for inner loops, which unfold a while-statement in either branch into a conditional, and for nested parallel statements, which split the proof by recursively unfolding different branches. While the soundness of these rules, relative to the LAGC semantics, is evident, they are impractical because they quickly lead to path explosion. Numerous approaches to mitigate this effect have been proposed in the literature (e.g., [3][1][2][2]), but here is not the place to dwell on them.

### 5.2 Atomic

We extend WHILE with atomic blocks to control interleaving in the execution of parallel statements, such that the syntax for statements from Figure 2 becomes

\[ s \in Stmt ::= co s | s oc | \text{atomic}(st) \ldots , \]

where $st$ is a statement without while loops.

**Local Evaluation** The atomic statement protects its argument against interleaving computations from other branches of a parallel execution operator. A (loop-free) statement $st$ can be made to execute atomically, i.e., without preemption, written $\text{atomic}(st)$. Atomic execution requires interleaving points to be removed during trace composition.

\[
\text{val}_s(\text{atomic}(st)) = \{ pc_1 \cup pc_2 \triangleright t_1 \ast \ast t_2 \cdot K(\emptyset) \mid pc_1 \triangleright t_1 \cdot K(st') \in \text{val}_s(st) \land st' \neq \emptyset \land \text{pc}\triangleright t_2 \cdot K(\emptyset) \in \text{val}_s(\text{atomic}(st')) \land st' = \text{last}(t_1) \cup \{ pc\triangleright t \cdot K(\emptyset) \mid pc\triangleright t \cdot K(\emptyset) \in \text{val}_s(st) \} \}
\]

The main idea behind rule (19) is to recursively unfold the execution of its atomic argument $st$, while removing continuation markers. During trace composition, this will prevent the atomic code from being interleaved. The rule has two cases, depending on whether the evaluation of $st$ contains a non-empty continuation or not: if the continuation is not empty, we need to evaluate it immediately, as the execution cannot be interrupted before the end of the atomic statement. Note the structural similarity in the definition of the first trace set above and the composition rule (13). The difference is that the consistency check and concretisation are deferred until the actual trace composition.

**Discussion.** In this execution model, the semantics $\text{val}_s$ of non-terminating atomic statements is undefined, which is the reason for excluding loops. This is a design choice and not a principal limitation: It is possible to define the semantics of non-terminating atomic programs with suitable scheduling events that allow to process non-terminating code piece-wise [27]. However, that approach is more complex than the adopted solution and breaks with the modularity we aim at with only one rule per syntactic construct. A different solution is to equip
**atomic** with a path condition argument (using pc\(_1\) in the recursive call) and only keep consistent traces. When \(\sigma\) is concrete, this would suffice for terminating loops.

Another solution, presented in Section 5.3 below, is to define a trace composition rule with run-to-completion semantics: atomic execution of *any* statement is the default, which can be interrupted only at explicit suspension points.

Observe that the semantics of non-terminating *non-atomic* programs is well-defined: infinite traces are produced by an infinite number of applications of the composition rule.

**Trace Composition** The trace composition rule (13) is unchanged, but it is worthwhile to observe how it works in the presence of **atomic**. When rule (13) processes a continuation of the form \(\text{atomic}(st)\), it needs to evaluate \(\text{val}_\sigma(\text{atomic}(st))\) for the concrete state \(\sigma = \text{last}(sh)\). Rule (19) evaluates \(s\) until it reaches a continuation \(s'\), then recursively evaluates \(s'\), until \(s\) is completely executed. No interleaving can occur during the evaluation, which reflects the intended semantics of atomic statements.

**Example 15.** To illustrate the evaluation of interleaved execution with **atomic**, we modify Example 14 as follows: let \(s_{at} = \text{co atomic}(x := 1; y := x + 1) \parallel x := 2 \text{ cc}\). The evaluation branches into either \(\text{atomic}(x := 1; y := x + 1)\) and then \(x := 2\), or \(x := 2\) and then \(\text{atomic}(x := 1; y := x + 1)\). In either case, the final value of \(y\) is 2, as shown in the following evaluation:

\[
\text{val}_\sigma(s_{at}) = \{\emptyset \triangleright (\sigma) \land \sigma[x \mapsto 1] \mid [y \mapsto \text{val}_\sigma(x + 1)] \cdot K(x := 2)\} \cup \\
\{\emptyset \triangleright (\sigma) \land \sigma[x \mapsto 2] \cdot K(\text{atomic}(x := 1; y := x + 1))\}.
\]

Now the trace in which \(y\) has the final value 3, is no longer produced; starting from state \(I_{at} = I_{co}\) we have \(\text{Tr}(s_{at}, I_{at}) = \{(I_{at}) \triangleright [x \mapsto 1] \triangleright [x := 2, y := 2], (I_{at}) \triangleright [x \mapsto 2] \triangleright [x := 1, y := 2]\}\).

**Calculus** Rules for **atomic** are remarkably simple, because non-interleaved execution is the default in the calculus while interleaving is modeled with a case distinction. We let \(\text{atomic}(st)\) be an atomic statement which matches *ar* and *as* in Section 5.1 such that rule (PAR) applies, and introduce a rule which captures that an atomic statement is equivalent to the statement itself in a sequential setting:

\[
\frac{}{\Gamma, pc \Rightarrow \tau [\text{atomic}(st); s] \phi}
\]

**5.3 Local Memory**

We extend WHILE with local variable declarations by introducing a syntactic category of variable declarations *VarDecl* and add blocks to the syntax for statements from Figure 2:

\[
s \in \text{Stmt} ::= \{d \ s\} \ldots
\]

\[
d \in \text{VarDecl} ::= \varepsilon \mid x; \ d
\]

For simplicity, we omit an empty list of variable declarations in a scope \(\{\varepsilon \ s\}\) and just write \(\{s\}\).

**Local Evaluation** A block \(\{d \ s\}\) introduces a local variable scope such that the program variables \(d\) should only be accessible for the statement \(s\). To avoid interference among variable declarations in different scopes, possibly introducing the same variable name, the evaluation rule renames the variables in \(d\) to unused names and adds the renamed program variables to the state. The local program variables are correspondingly renamed in \(s\). The local evaluation rules cover a non-empty and empty list of local variable declarations, respectively:

\[
\text{val}_\sigma(\{\ x; d \ s\ \}) = \{\emptyset \triangleright (\sigma) \land \sigma[x' \mapsto 0] \cdot K(\{d \ s[x \leftarrow x']\}) \mid x' \notin \text{dom}(\sigma)\} \quad (20)
\]

\[
\text{val}_\sigma(\{s\}) = \text{val}_\sigma(s) \quad (21)
\]

Here, \(s[x \leftarrow x']\) denotes the textual substitution of program variable \(x\) by \(x'\) in the statement \(s\).
Trace Composition Trace composition in rule (13) is unchanged. It will gradually extend the state with fresh variables, bound to the default value 0, until the local variable declarations of the scope have been reduced to an empty list, at which point the scope is removed and execution can continue as normal.

Calculus The rules are straightforward. We model initialisation by an assignment to the default value, for which a rule already exists. Actually, this requires a slight generalisation of the language syntax, such that variable declarations can occur anywhere in a block, not just at the beginning.

\[
\begin{align*}
(\text{LOCAL}_1) & \quad \Gamma, pc \Rightarrow \tau [x' := 0; \{s\}] \phi \quad x' \text{ fresh} \quad s' = s[x \leftarrow x'] \\
(\text{LOCAL}_2) & \quad \Gamma, pc \Rightarrow \tau [\{s\}] \phi
\end{align*}
\]

5.4 Introducing Events and Symbolic Traces

Symbolic traces can contain states in which variables may be bound to unknown values. A simple case where this become necessary is when WHILE is extended with a statement to express user input, such that the syntax for statements from Figure 2 becomes

\[ s \in \text{Stmt} ::= \text{input}(x) \mid \ldots \]

For the input-statement, Proposition 2 does not hold, because we do not know the value of the user input \( x \) when locally evaluating the statement. To represent these unknown values in the local semantics, we use symbolic variables introduced in Definition 3. Events can be used to introduce a point of interaction; we define an event type \( \text{ inpEv}(Y) \) that captures the introduction of a symbolic variable \( Y \) by an input-statement. The local evaluation rule for \( \text{input}(r) \) can be formalised as follows:

\[ \text{val}_s(\text{input}(x)) = \{0 \triangleright \text{inpEv}(Y)(Y) \land \sigma[Y \mapsto \ast][x \mapsto Y] \cdot K(\emptyset) \mid Y \not\in \text{dom}(\sigma)\} . \quad (22) \]

The trace is well-formed, because the variable \( Y \) inside the event is symbolic.

The composition rule accommodates Proposition 2 by using a concretisation mapping to concretise the emitted trace. Concretisation captures the actual user input when the statement is executed in a concrete trace.

\[ \sigma = \text{last}(sh) \quad pc \triangleright \tau \cdot K(s') \in \text{val}_s(s) \quad \rho \text{ concretises } \tau \quad \rho(pc) \text{ consistent} \]

\[ sh, K(s) \rightarrow sh ** \rho(\tau), K(s') \quad (23) \]

The concretisation mapping \( \rho \) ensures that the resulting trace \( sh ** \rho(\tau) \) is concrete.

The previous composition rule (13) is a special case of this one, when all the states are concrete (this follows from Proposition 1).

Example 16. \( \text{Tr}([\text{input}(x), I_{\text{seq}}]) = \{[I_{\text{seq}}] ** \text{inpEv}(Y)(Y) \land \sigma[Y \mapsto v][x \mapsto v] \mid v \in \text{Val}\} = \{[I_{\text{seq}}] \triangleright \text{inpEv}(v) \land I_{\text{seq}}[Y \mapsto v] \land I_{\text{seq}}[Y \mapsto v, x \mapsto v] \mid v \in \text{Val}\} \). All possible values \( v \) may occur as an input. Variable \( Y \) has a concrete value now; \( x, Y \) are needed to propagate the input value correctly, for example, in subsequent code of the form “if \((x > 0)\) then ...”.

Calculus The calculus rule directly follows the local evaluation rule (22) by introducing a fresh variable \( Y \) to model the unknown user input. By definition we have \( \sigma_v(Y) = \ast \), so we do not need this assignment.

\[ \begin{align*}
(\text{INPUT}) & \quad \text{last}(\tau) = \sigma \quad \Gamma, pc \Rightarrow \tau ** \text{inpEv}(Y)(Y)[x := Y; s] \phi \quad Y \text{ fresh} \\
& \quad \Gamma, pc \Rightarrow \tau [\text{input}(x); s] \phi
\end{align*} \]

Interestingly, the abstract composition rule (23) has no effect on the calculus, which is already symbolic, but the soundness proof needs to be adapted.
Historically, it is more common to use the term "procedure" whereas in object-oriented programming the term "method" is usual, which is where the LAGC concept originated from. We use both terms interchangeably.

5.5 Procedure Calls

Figure 4 introduces procedure calls with the statement \texttt{call}(m, e): A program is a set of method declarations \( \mathcal{M} \) with main block \( \{ s \} \). We consider \( \mathcal{M} \) to be a \textit{method table} that is implicitly provided with a program. Each method declaration associates a unique name \( m \) with the statement in its body. To reduce technicalities, we assume without loss of generality that a method call has one argument and no return value on which the caller needs to synchronise.\(^{11}\)

In contrast to parallel \( \texttt{co s || s oc} \) statements, where parallelism is explicit in the program syntax, procedure calls introduce implicit parallel execution: there is a context switch between the syntactic call site and the processor, whereupon the call is executed in parallel. This decoupling has an important consequence: according to the local evaluation principle, method bodies are evaluated independently of the call context. This necessitates a new composition rule that starts the execution of a called method. We also need to ensure that a method is not executed before it is called, requiring the introduction of suitable \textit{events}.

\textbf{Local Evaluation} The new events are \( \text{invEv}(m, \text{val}_\sigma(e)) \) and \( \text{invREv}(m, \text{val}_\sigma(e)) \) for a given state \( \sigma \). These events denote the \textit{invocation} and the \textit{activation} (also called the \textit{invocation reaction}) of a method \( m \) with argument \( e \), respectively. Recall from Section 2.3 that events inserted into a trace at a state \( \sigma \) are preceded and succeeded by that state. The local evaluation rule (24) for a call to \( m \) with argument \( e \) has an empty path condition, inserts an \textit{invocation} event \( \text{invEv}(m, \text{val}_\sigma(e)) \) into the trace, and continues with the empty continuation. This means that the call is \textit{non-blocking}: the code following the call could be executed immediately, if scheduled. The rule is formalised as follows:

\footnotesize
\[ \text{val}_\sigma(\text{call}(m, e)) = \{ \emptyset \vdash \text{invEv}_\sigma(m, \text{val}_\sigma(e)) \cdot \text{K}(\emptyset) \}. \] (24)

\textbf{Trace Composition: Concrete Variant} The concurrency model so far is still very simple: method invocations and processors are anonymous, there is no way to distinguish between two calls to the same method: these execute identical code and all executions can be interleaved. For this reason, it is sufficient to represent continuation candidates for the next execution step as a multiset \( q \). We denote with "+" the \textit{disjoint} multiset union. We add a rewrite rule to simplify empty continuations in the multisets of tasks; this rule is applied exhaustively when adding tasks in multisets.

\[ q + \{ \text{K}(\emptyset) \} \sim q. \]

The judgment representing trace extension by one step has the form: \( sh, q \rightarrow sh', q' \) where \( q, q' \) are multisets of continuations of the form \( \text{K}(s) \).

\[ \sigma = \text{last}(sh) \quad \text{pc} \triangleright \tau \cdot \text{K}(s') \in \text{val}_\sigma(s) \quad \text{pc consistent} \]

\[ sh, q + \{ \text{K}(s) \} \rightarrow sh \ast \ast \tau, q + \{ \text{K}(s') \} \] (25)

The difference between rule (13) and rule (25) is that we no longer commit to one possible continuation, because the continuation code is now located in a method. Therefore, the rule selects and removes one matching continuation from the pool \( q \), executes it to the next continuation marker, exactly like rule (13), and then puts the code remaining to be executed back into \( q \). We also need a new composition rule that adds method bodies to the pool \( q \).

\[ m(x)\{ s \} \in \mathcal{M} \quad \sigma = \text{last}(sh) \quad \text{uf}(sh \ast \ast \text{invREv}_\sigma(m, v)) \quad y \notin \text{dom}(\sigma) \]

\[ sh, q \rightarrow sh \ast \ast \text{invREv}_\sigma(m, v) \land \sigma[y \mapsto v], q + \{ \text{K}(s[x \leftarrow y]) \} \] (26)

\(^{11}\) Historically, it is more common to use the term "procedure", whereas in object-oriented programming the term "method" is usual, which is where the LAGC concept originated from. We use both terms interchangeably.

\(^{12}\) Synchronisation on return values is discussed in Section 2.3.
The rule handles the creation of a new execution thread. We select a method with body $s$ from table $\mathcal{M}$ and create a new continuation $K(s[x \leftarrow y])$, where the call parameter $x$ is substituted with a fresh variable $y$ for disambiguation. The new continuation is added to the pool $q$. Next, we need to record that a new method with argument $v$ has started to execute, as a consequence of a previous method call. The existence of this call is ensured by the premise expressing the well-formedness of the extended trace, which requires an invocation event of the form $\text{invEv}(m, v)$ to be present in $sh$. We extend the current trace with the invocation reaction event $\text{invREv}(m, v)$ to mark the start of method execution and record the extension of the current state in which the parameter $y$ has the value $v$. It remains to formalise well-formedness.

**Well-Formedness** A trace is well-formed if its events obey certain ordering restrictions. Whenever a trace $sh$ is extended with an invocation reaction event of the form $\text{invREv}(m, v)$, there must be a corresponding invocation event $\text{invEv}(m, v)$ in $sh$. This ordering restriction can be captured by counting the number of occurrences of both event forms in $sh$ using the comprehension expression $\#_{sh}(\text{ev}(\tau))$. In all other cases, the trace stays well-formed when it is extended with a new event. We formalise well-formedness as a predicate on traces.

**Definition 23 (Well-Formedness).** The well-formedness of a concrete trace $sh$ is formalised by a predicate $\text{wf}(sh)$, defined inductively over the length of $sh$:

- $\text{wf}(\varepsilon) = \text{true}$
- $\text{wf}(sh \cdot \sigma) = \text{wf}(sh) \wedge \text{invEv}(m, v) \in sh$ \hspace{1cm} \text{for each } m, v \in \mathcal{M}$
- $\text{wf}(sh \cdot \text{invREv}(m, v)) = \text{wf}(sh) \wedge \#_{sh}(\text{invEv}(m, v)) > \#_{sh}(\text{invREv}(m, v))$

The well-formedness predicate is used in the global composition rules to ensure that only a valid concrete trace for a given program can be generated during the trace composition. Any trace emitted by the trace composition rules is well-formed, because it is an invariant established each time a trace is extended. It is sufficient to define well-formedness on concrete traces, because in the end it has to hold for them. It follows that well-formedness is always a simple, decidable property.

**Global Trace Semantics**

**Definition 24 (Program Semantics with Procedure Calls).** Given a finite program $P$ with a method table $\mathcal{M}$ and a main block $s_{\text{main}}$. Let $sh_0, q_0 \rightarrow sh_1, q_1 \rightarrow \cdots$ be a maximal sequence obtained by the repeated application of the composition rules (25)–(26), starting with $\langle I_P \rangle, \{K(s_{\text{main}})\}$. If the sequence is finite, then it must have the form

$$\langle I_P \rangle, \{K(s_{\text{main}})\} \rightarrow \cdots \rightarrow sh, \emptyset .$$

If the sequence is infinite, let $sh = \lim_{i \to \infty} sh_i$. In either case, $sh$ is a trace of $P$. The set of all such traces is denoted by $\text{Tr}(P, I_P)$.

**Example 17.** Consider the following program $P$:

$$m(x) \{ y := x; \; x := x + 1 \}$$
$$\{ \text{call}(m, 1); \; z := 2 \}$$

The method table for this program is $\mathcal{M} = \{ m(x) \{ y := x; \; x := x + 1 \} \}$. The evaluation of the main method is as follows:

$$\text{val}_\sigma(\text{call}(m, 1)) = \{ \emptyset \cdot \sigma \} \cdot \text{invEv}(m, 1) \cdot \text{K}(z := 2) \cdot \\text{K}(0)$$

To prepare the evaluation of the method body of $m(x)$ (where $x$ is any integer):

$$\text{val}_\sigma(y := x) = \{ \emptyset \cdot \sigma \} \cdot \text{K}(x := y) \cdot \text{K}(0)$$
$$\text{val}_\sigma(x := x + 1) = \{ \emptyset \cdot \sigma \} \cdot \text{K}(x := \text{val}_\sigma(x) + 1) \cdot \text{K}(0)$$

(27)

$$\text{val}_\sigma(y := x; \; x := x + 1) = \{ \emptyset \cdot \sigma \} \cdot \text{K}(x := y \rightarrow \text{val}_\sigma(x) + 1) \cdot \text{K}(x := x + 1)$$

13 Recall that $\text{invREv}(m, v)$ is a triple with two copies of $\sigma$ around $\text{invEv}(m, v)$.
Let $I_P$ be the initial state of $P$. We consider the state where the statement call$(m, 1)$ in main has already been executed, and explore the possible traces. The concrete trace and the continuation pool at this point are $sh = \langle I_P \rangle \cap \text{invEv}(m, 1) \cap I_P$ and $q = \{K(z := 2)\}$, respectively. Let $s_m$ be the method body of $m$. Both composition rules (24) and (20) are applicable and yield different interleavings: the execution continues either with the main method or with the creation of a new execution thread. In the following, we assume that the execution continues with thread creation, i.e. we apply rule (20):

$$m(x)\{s_m\} \in \mathcal{M} \quad I_P = \text{last}(sh) \quad \text{wf}(sh \cap \text{invEv}_m(m, 1)) \quad w \notin \text{dom}(I_P)$$

$$\langle sh, q \rangle \rightarrow sh \cap \text{invEv}_m(m, 1) \cap [w \mapsto 1], q + \{K(s_m[x \leftarrow w])\}$$

At this point, both composition rules are again applicable, but only rule (24) is useful: since only one invocation event is present in $sh$, well-formedness will not allow more than one instance of $m$ to execute. We use some abbreviations:

$$sh' = sh \cap \text{invEv}_m(m, 1) \cap [w \mapsto 1]$$

$$sh'' = sh \cap \text{invEv}_m(m, 1) \cap I_P \cap \text{invEv}_m(m, 1) \cap [w \mapsto 1]$$

$$s_m = \{s_m[x \leftarrow w]\} = \{y := w; w := w + 1\}$$

$$q' = q + \{K(s_m[x \leftarrow w])\} = \{K(z := 2), K(y := w; w := w + 1)\}$$

The two continuations in $q'$ indicate two possible interleavings. We assume execution continues with the body of $m$:

$$\emptyset \triangleright \langle [w \mapsto 1] \cap \text{val}_{[w \mapsto 1]}(w) \cap K(w := w + 1) \cap \text{val}_{[w \mapsto 1]}(s_m') \cap \{K(z := 2)\} + \{K(w := w + 1)\} \triangleright$$

We introduce the abbreviations:

$$sh'' = \langle I_P \rangle \cap \text{invEv}(m, 1) \cap I_P \cap \text{invEv}(m, 1) \cap [w \mapsto 1] \cap [w \mapsto 1, y \mapsto 1]$$

$$q'' = \{K(z := 2)\} + \{K(w := w + 1)\}$$

At this point, rule (25) is again applicable and the two continuations in $q''$ indicate two possible interleavings. We assume the execution continues with the main method body.

$$\emptyset \triangleright \langle [w \mapsto 1, y \mapsto 1] \cap \text{val}_{[w \mapsto 1, y \mapsto 1]}(w) \cap K(w := w + 1) \cap \text{val}_{[w \mapsto 1, y \mapsto 1]}(s_m') \cap \{K(z := 2)\} + \{K(w := w + 1)\} \triangleright$$

At this point only one continuation is possible, which results in the concrete trace:

$$\langle I_P \rangle \cap \text{invEv}(m, 1) \cap I_P \cap \text{invEv}(m, 1) \cap I_P \cap [w \mapsto 1] \cap [w \mapsto 1, y \mapsto 1, z \mapsto 2], \{K(w := w + 1)\} \cap [w \mapsto 2, y \mapsto 1, z \mapsto 2] \cap$$

There are two other possible interleavings that all result in the same final state. If, for example, the assignment in the main method of $P$ were changed to $y := 2$, then traces with different final states would be generated. \hfill $\square$

**Trace Composition: Symbolic Variant** The trace composition in rule (26) works “eagerly” or “on demand” in the sense that a concrete trace extending $\sigma$ and a continuation containing the local parameter $y$, whose value is fixed in $\sigma[y \mapsto v]$, are generated on the spot. In the presence of multiple calls to the same method, this leads to multiple evaluation of the same code, i.e. the method body. A deductive verification calculus would avoid this and evaluate each method only once, but symbolically. We demonstrate that abstract traces allow semantic evaluation that works similarly by defining a local evaluation function for methods which combines the use of symbolic variables from the input-statement in Section 5.3 with the variable renaming used for local memory in Section 5.3. We first introduce a symbolic variable $Y$ to act as a placeholder for the value of the substituted call parameter $y$ and then substitute the call parameter $x$ with a fresh variable $y$ for disambiguation, as done in rule (26):

$$\text{val}_\sigma(m(x)(s)) = \{\emptyset \triangleright \text{invEv}_m(Y)(m, Y) \cap \text{val}_{[y \mapsto *]}(w) \cap \text{val}_{[y \mapsto Y]}(s) \cap K(s[x \leftarrow y]) \cap y, Y \notin \text{dom}(\sigma)\}$$
We conventionally write \( y, Y \not\in \text{dom}(\sigma) \) to express that no element in a list of variables is in the domain of \( \sigma \).

The concrete composition rule (32) needs to be adapted to a composition rule which takes the evaluation of a method declaration and concretises the resulting symbolic trace in a well-formed and consistent way:

\[
\begin{align*}
\exists x \in \mathcal{M} & \quad \rho \text{ concretises } \tau \\
\rho(\text{pc}) & \text{ consistent} \\
\sigma = \text{last}(\text{sh}) & \\
\text{pc} \triangleright \tau \cdot K(s') \in \text{val}_\mathcal{A}(\rho(\text{pc})) & \quad \text{wf}(\text{sh} \triangleright \rho(\tau))
\end{align*}
\]

(32)

The definition of well-formedness stays the same. Definition (24) of trace semantics of \( P \) stays the same, except that rule (32) is used instead of rule (26). It is interesting to note that, while we need one more local rule (to evaluate method declarations), the composition rule becomes simpler, more uniform with rule (26), and more modular (not referring to events) as a consequence.

**Example 18.** Consider the program \( P \) from Example 17. Let \( s_m \) be the method body of \( m \). The evaluation of the method declaration with rule (31) is as follows:

\[
\text{val}_\mathcal{A}(\rho(\text{pc})) \quad \begin{cases}
\{\emptyset \triangleright \text{InvRev}_\mathcal{G}(\rho(\text{pc}))(m, W) \wedge \sigma[W \mapsto \ast, w \mapsto W] \cdot K(s_m[w \leftarrow w]) \mid w, W \not\in \text{dom}(\sigma) \} \\
\{\emptyset \triangleright \text{InvRev}_\mathcal{G}(\rho(\text{pc}))(m, W) \wedge \sigma[W \mapsto \ast, w \mapsto W] \cdot K(y := w; \; w := w + 1) \mid w, W \not\in \text{dom}(\sigma) \}
\end{cases}
\]

**Calculus** There are several ways to model procedure calls in a calculus. The expressiveness of DL permits a modular (not referring to events) as a consequence.

We need a way to model multi-process execution like in rule (25). Since the computations of the \( s_i \) might interfere with each other, there may in the general case be many interleavings of the \( s_i \) that need to be considered. The meta rule schema (INTERLEAVE) branches into different premises, depending on which of the \( s_i \) is scheduled, thus unfolding all possible different interleavings:

\[
\begin{align*}
\text{(INTERLEAVE)} \\
\text{For all } 1 \leq i \leq n : \\
\text{wf}(\tau_j) & \\
\bigwedge_{j \in Z} \text{wf}(\tau_j) & \quad \Gamma, \text{pc} \cdot \bigwedge_{j \in Z} (\text{pc} \cup \text{pc}_j \Rightarrow \text{tau}_{j} [s_{j}]_{\phi_{i}}) \Rightarrow \tau [s_{i}]_{\phi_{i}} \\
\{ \Gamma, \text{pc} \cup \text{pc}_j \Rightarrow \text{tau}_{j} [s_{j}]_{\phi_{i}} \} & \quad \{ \bigwedge_{j \in Z} \text{wf}(\tau_j) \} \\
\Gamma, \text{pc} \Rightarrow \tau & \quad \{ \bigwedge_{j \in Z} \text{wf}(\tau_j) \}
\end{align*}
\]

Such that there is a rule

\[
\text{wf}(\tau_j) & \\
\bigwedge_{j \in Z} \text{wf}(\tau_j) & \\
\{ \bigwedge_{j \in Z} \text{wf}(\tau_j) \} & \quad \{ \Gamma, \text{pc} \cup \text{pc}_j \Rightarrow \text{tau}_{j} [s_{j}]_{\phi_{i}} \}
\]

The rule schema (INTERLEAVE) takes the form of a context rule, replacing a conjunct in the conclusion with a formula from which that conjunct can be derived with an appropriate path condition (thus generalising the rules for local parallelism in Section [5.1]). The schema unfolds the premises for each conjunct \([s_{j}]_{\phi_{i}}\) in the conclusion, such that there is a rule in the calculus which is applicable to \( \Gamma, \text{pc} \Rightarrow \tau [s_{i}]_{\phi_{i}} \) with premise(s) \( \Gamma, \text{pc} \cup \text{pc}_j \Rightarrow \text{tau}_{j} [s_{j}]_{\phi_{i}} \) for \( j \in Z \) and constraint \( \text{wf}(\tau_j) \). We use the notation \( \{ \phi_{i} \}_{j \in Z} \) to denote a set of formulas indexed by \( j \) from the index set \( Z \). Thus in the rule schema shown on the right, the bracketed sequent denotes the set of sequent premises to the rule for \( \Gamma, \text{pc} \Rightarrow \tau [s_{i}]_{\phi_{i}} \) (for example, rule (COND) has a set containing two premises).

The second premise of (INTERLEAVE) is discharged by the rule corresponding to the schema on the right. Well-formedness becomes a separate proof obligation for every trace \( \tau_j \), that can be dealt with by a fairly straightforward translation into first-order logic (see [52] for the details).

This approach rests on two assumptions about the rule displayed above on the right: first, it must follow the required syntactic form, second, it must be sound. For the composition of more general calculi, it is necessary to define syntactic restrictions and soundness constraints [52].

It remains to design calculus rules modeling rule (24) and rules (31)–(32). The first is straightforward, resulting in rule (MtdCall). We can combine rules (31)–(32) into a single rule (MtdRun) by wrapping the body of \( m \) into a block and declaring its formal parameter \( x \) as a local variable. This allows us to re-use the

---

\[ \text{The discussion of the efficiency of the rules for local parallelism in Section 5.1 also applies to rule (INTERLEAVE).} \]
Previously declared rules. We assume given method specifications in the form of a formula $\phi$ associated with each method. In the new conjunct, the modality must have a fresh index. The call argument $e$ must be supplied at the time the rule is applied. One heuristics is to look for matching invocation events in $\tau$.

\[(\text{MtdCall})\]
\[
\frac{\Gamma, pc \Rightarrow \tau \triangleright \text{invEv}_\phi(m, e)[s]}{\Gamma, pc \Rightarrow \tau [\text{call}(m, e); s], \phi} \quad \text{(MtdRun)}
\]

\[
\begin{align*}
\text{last}(\tau) &= \sigma \\
\Gamma, pc &\Rightarrow \tau \triangleright \text{invEv}_\phi(m, e)[s] \phi = \sigma \\
\Gamma, pc &\Rightarrow \tau \triangleright \text{call}(m, e; s) \phi
\end{align*}
\]

5.6 Guarded Statements

Guarded statements are a common synchronisation mechanism in concurrent languages [24][44][49]. A statement is preceded by a Boolean guard expression that blocks execution of the current process, until the guard is evaluated to true. This can be used, for example, to ensure that the result of a computation is ready before it is used, a message has arrived, etc. Our syntax for guarded commands is inspired by ProMELA; the syntax for statements from Figure 2 becomes (where $g$ is a Boolean expression):

\[
s \in \text{Stmt} ::= :: g; s \mid \ldots .
\]

Local Evaluation A local evaluation rule for a guarded statement is straightforward to design. If the Boolean guard $g$ evaluates to true, the execution continues normally. If the guard $g$ evaluates to false, the execution is blocked until $g$ evaluates to true. Blocking is modeled by re-scheduling the entire guarded statement in the continuation.

\[
\text{val}_\phi (g; s) = \{\{\text{val}_\phi(g) = \#t \} \triangleright \langle \sigma \rangle \cdot K(s), \{\text{val}_\phi(g) = \#f \} \triangleright \langle \sigma \rangle \cdot K(:, g; s)\}
\]

Trace Composition The trace composition rule (13) is unchanged, but it is interesting to observe how it works in the presence of :: $g; s$. When rule (13) processes a continuation with a guarded statement, it may result in a deadlocked trace due to the second alternative, where from some point onward no progress is made on some non-empty continuations in the process pool. How to detect and, possibly, to avoid deadlocks is a question outside the scope of this paper.

Calculus Structurally, the local rule (33) for guarded statements is very similar to the rule (8) for the conditional (in fact, the case when the guard is true, is actually identical). Indeed, we can design a calculus rule modeled after (COND):

\[
\begin{align*}
\text{last}(\tau) &= \sigma \\
\Gamma, pc &\cup \{\text{val}_\phi(g) = \#t\} \Rightarrow \tau [s] \phi \\
\Gamma, pc &\cup \{\text{val}_\phi(g) = \#f\} \Rightarrow \tau [:: g; s] \phi
\end{align*}
\]

While this rule is certainly sound, it is clearly incomplete, because it admits infinitely many possible interleavings. To achieve completeness, one would need to establish a suitable invariant that holds whenever the guard is evaluated and that is strong enough to render the proof finite (for example, by excluding a branch when the guard is false). For details on such techniques, we refer the reader to the literature [30][53].

6 Semantics For A Shared-Memory Multiprocessor Language

We consider a multiprocessor extension to the programming language of Section 5. This goes some way to realize a concurrent, object-oriented setting: We will now spawn processes, each with its own identity and its own task queue to execute, but memory is still shared among the processes. In addition, processes may exchange values by sending and receiving messages, which have their own identity and thus provide the capability to impose ordering constraints among them. Tasks are method invocations similar to the ones defined in the previous section. In particular, we use the second variant of the semantics, defined in Section 5.5 with the rules (31)–(32).

Expressions on the right-hand side of assignments are extended with $\text{spawn}(m, e)$, which creates a new (virtual) process where task $m$ is called with an actual value $e$. It returns the identifier of the newly created process. Furthermore, two statements $\text{send}(e_1, e_2)$, to send a value $e_1$ to a process with identifier $e_2$, and $\text{receive}(x, e)$, to bind a value received from $e$ to the variable $x$, are introduced such that processes may exchange values. The syntax is shown in Figure 6.
It would be possible to introduce symbolic values for message identifiers as well in the rule for $sh$, $\Omega$
the in last($h$), $\Omega$
in a trace with the identifier of the process that produced it. 

Definition 25 (Tagged Trace, Projection). Let $ev(\pi)$ be an event, $\tau$, $\tau_1$, $\tau_2$ traces, and $p \in PId$ a process identifier. A tagged trace $\tau^p$ is defined inductively as follows:

$$(ev(\pi))^p = ev^p(\pi)$$
$$\sigma^p = \sigma$$
$$(\tau_1 \cdot \tau_2)^p = \tau_1^p \cdot \tau_2^p$$

Local Evaluation In the following, let $PId$ be a set of process identifiers with typical element $p$ and $MId$ a set of message identifiers with typical element $i$. We start with the evaluation rule for $send$. The rule evaluates the arguments to $send$ and creates a trace from the current state $\sigma$ with an event $sendEv(v, p, i)$ expressing that a value $v$ is sent to the process $p$ by a message with the identifier $i$. The message can have any possible identifier, so the rule provides traces for all of them:

$$val_\sigma(send(e, e')) = \{0 \triangleright sendEv_\sigma(val_\sigma(e), val_\sigma(e'), i) \cdot K(\emptyset) \mid i \in MId\}.$$  

(34)

The local semantics of $receive$ and $spawn$ is more complex, because the values received in these statements are not known in the local evaluation. We employ the technique using symbolic variables introduced in Section 5.4. In contrast to the case for method calls (Section 5.5), we do not have the option to compose concrete continuations “on demand”, because the return values for $receive$ and $spawn$ are going to be resolved later.

The rules evaluate to a trace with the event $receiveEv(v, p, i)$, expressing that the value $v$ is received from a process $p$ by a message with identifier $i$, and a trace with the event $spawnEv(m, v, p)$, expressing that a new process with identifier $p$ is created to execute the task $m$ with the parameter value $v$. In each rule, the symbolic variable $Y$ represents the (as yet) unknown received value.

$$val_\sigma(receive(x, e)) = \{0 \triangleright receiveEv_\sigma^Y(Y, val_\sigma(e), i) \triangleright \sigma[x \mapsto Y, Y \mapsto s] \cdot K(\emptyset) \mid Y \not\in dom(\sigma), i \in MId\}$$

(35)

$$val_\sigma(x := spawn(m, e)) = \{0 \triangleright spawnEv_\sigma^Y(m, val_\sigma(e), Y) \triangleright \sigma[x \mapsto Y, Y \mapsto s] \cdot K(\emptyset) \mid Y \not\in dom(\sigma)\}$$

(36)

All previous local rules are unchanged.

Trace Composition The trace composition rules generalize rules (25) and (32). There are three main differences: First, both composition rules now work on symbolic traces, simply because rules (35) - (36) are symbolic. Second, to account for having several processes, we introduce a mapping $\Omega$ from process identifiers $p$ to multisets of continuations $q$, i.e. $\Omega(p)$ gives the current task list for a given process. As before, we denote with $+$ the disjoint multiset union on task lists. The judgment representing trace extension by one step has the form: $sh, \Omega \rightarrow sh', \Omega'$. Third, we tag the generated concrete trace with the process identifier that created it.

The following rule selects a processor $p$ with non-empty task list and from there a continuation $s$, evaluated in last($sh$). The resulting symbolic trace $\tau$ must be concretizable such that, after tagging, it extends $sh$ in a

\footnote{It would be possible to introduce symbolic values for message identifiers as well in the rule for $send$ and $receive$. However, since programs do not manipulate message identifiers, there is no reason to do so.}
well-formed manner. Observe that $sh$ is tagged already. The remaining continuation $K(s')$ is added back to $p$’s task list.

$$
\sigma = \text{last}(sh) \quad p \in \text{dom}(\Omega) \quad \Omega(p) = q + \{K(s)\} \quad \rho \text{ concretizes } \tau \quad \rho(pc) \text{ consistent} \quad \text{wf}(sh \bowtie \rho(\tau)^p) \quad sh, \Omega \rightarrow sh \bowtie \rho(\tau)^p, \Omega[p \mapsto q + \{K(s')\}] \quad (37)
$$

The following rule is similar and follows the pattern established in rule (32). It starts to evaluate a method body on a processor $p$ and adds the remaining continuation $K(s')$ to its task list. If $p \notin \text{dom}(\Omega)$, we use the notational convention $\Omega(p) = \emptyset$ and avoid a special operation to create a process. The following rule thus either creates a task inside an existing process or spawns a new process if necessary, similar to rule (32). Well-formedness ensures that the correct number of tasks is created, relying on the fact that $val_{\lambda}(m(x)\{s\})$ starts with an invocation reaction event.

$$
m(x)\{s\} \in \overline{M} \quad \sigma = \text{last}(sh) \quad pc \bowtie \tau \cdot K(s') \in \text{val}_{\lambda}(m(x)\{s\}) \quad \rho \text{ concretizes } \tau \quad \rho(pc) \text{ consistent} \quad \text{wf}(sh \bowtie \rho(\tau)^p) \quad sh, \Omega \rightarrow sh \bowtie \rho(\tau)^p, \Omega[p \mapsto \Omega(p) + \{K(s')\}] \quad (38)
$$

**Well-formedness** We need to establish the basic properties of sending and receiving as well as to ensure that each process has the right number of tasks.

**Definition 26 (Well-formedness).** The following rules are added to the rules in Definition [25] except the final one, which replaces the final rule in Definition [25] The first rule ensures no two messages will be sent with the same message identifier, the second one states that each message is received only once. Similarly, the third rule guarantees that each spawn allocates a new process identifier. The final rule reflects the fact that the code executed on a processor $p$ can be the reaction to either a call or a spawn event, i.e. $\text{spawnEv}^p$ acts as a particular invocation event.

$$
\begin{align*}
\text{wf}(sh \bowtie \text{sendEv}^p(e, p', i)) &= \text{wf}(sh) \land \exists \text{p''}, e', p''' . \text{sendEv}^{p''}(e', p''', i) \in sh \\
\text{wf}(sh \bowtie \text{receiveEv}^p(e, p', i)) &= \text{wf}(sh) \land \exists \text{p''}, e', p''' . \text{receiveEv}^{p''}(e', p''', i) \in sh \\
\text{wf}(sh \bowtie \text{spawnEv}^p(m, v, p')) &= \text{wf}(sh) \land \exists \text{p''}, m', v' . \text{spawnEv}^{p''}(m', v', p') \in sh \\
\text{wf}(sh \bowtie \text{invREv}^p(m, v)) &= \text{wf}(sh) \land \\
\#_{sh}(\text{invEv}^p(m, v)) + \sum_{p' \in Ptd} \#_{sh}(\text{spawnEv}^{p'}(m, v, p)) &> \#_{sh}(\text{invREv}^p(m, v))
\end{align*}
$$

Message identifiers are used to avoid sending or receiving the same message (i.e. two messages with the same identifier) twice. This rule set is incomplete as it does not specify when a message is received. This aspect is discussed in Section [6.2] and will also use message identifiers. For example, the basic correctness criterion that states that “all received messages have been sent” is captured by the well-formedness condition in Definition [25] this criterion should be used in addition to the $\text{wf}$ predicate defined above.

**Global Trace Semantics**

**Definition 27 (Program Semantics with Multiprocessors).** Given a program $P$ with a method table $\overline{M}$ and a main block $s_{main}$, let $sh_0, \Omega_1 \rightarrow sh_1, \Omega_1 \rightarrow \cdots$ be a maximal sequence obtained by the repeated application of the composition rules [37]–[38], starting with

$$
(I_P) \bowtie \text{spawnEv}^0(\text{main}, 0, 0), \Omega[0 \mapsto \{K(s_{main})\}] \quad .
$$

If the sequence is finite, then it must have the form

$$
(I_P) \bowtie \text{spawnEv}^0(\text{main}, 0, 0), \Omega[0 \mapsto \{K(s_{main})\}] \rightarrow \cdots \rightarrow sh, \Omega^0 \quad ,
$$

where $\Omega^0(p) = \emptyset$ for all $p \in \text{dom}(\Omega)$. If the sequence is infinite, let $sh = \lim_{i \rightarrow \infty} sh_i$. In either case, $sh$ is a trace of $P$. The set of all such traces is denoted with $\text{Tr}(P, I_P)$.

The spawn event at the start of a trace represents the creation of an initial process that runs the main method. The well-formedness of traces ensures that subsequently spawned processes will not erroneously be assigned index 0, which is reserved for the code executed in the main method.
6.2 Communication Patterns

We now unleash the power of traces with events and show that several well-known communication patterns can be defined simply by adding well-formedness constraints to Definition [29]. Imposing such patterns in the LAGC semantics is modular in the sense that all other rules are unaffected by the enforced patterns. The well-formedness constraints defined in this section are to be added conjunctively to the well-formedness predicate \( wf \) over concrete traces \( sh \) (Definition [29]) to achieve the desired semantic properties. We recall for the definitions below that \( e \) is an expression, \( p, p' \in \Pi_{Id} \) process identifiers, and \( i \in \Pi_{Id} \) a message identifier.

We first consider the basic tenet of asynchronous communication, stipulating that received messages must have been sent.

**Definition 28 (Asynchronous Communication Constraint).** Well-formed asynchronous communication is captured by the constraint \( wf_{ac} \), defined as follows:

\[
wf_{ac}(sh \land \text{receiveEv}^p(e, p', i)) = wf(sh) \land \text{sendEv}^p(e, p, i) \in sh
\]

Next, we consider the FIFO (first-in, first-out) ordering principle, which stipulates that messages between the same processors must be received in the same order as they were sent; i.e. messages may not overtake each other. Let the notation \( ev^p(\bar{v}) <_sh ev'^p(\bar{v}') \) express that \( ev^p(\bar{v}) \) appears before \( ev'^p(\bar{v}') \) in a trace \( sh \).

**Definition 29 (FIFO Communication Constraint).** Well-formed FIFO communication is captured by the constraint \( wf_{fifo} \), defined as follows:

\[
wf_{fifo}(sh \land \text{receiveEv}^p(e, p', i)) = wf_{ac}(sh \land \text{receiveEv}^p(e, p', i)) \land
\]

\[
(\forall e,p,i) \in sh. \text{sendEv}^p(e', p', i) <_sh \text{sendEv}^p(e, p, i) \implies \text{receiveEv}^p(e', p', i) \in sh .
\]

A channel is an ordered pair \((p, p')\) of processor identifiers (not necessarily distinct) such that \( p \) sends messages to \( p' \) and \( p' \) receives messages sent by \( p \). The messages in a channel after a trace \( sh \) can be given as a set of message identifiers, defined by the following function:

**Definition 30 (Channel).** Given a concrete trace \( sh \) and a channel \( ch = (p, p') \), we define by \( \text{inChannel}(sh, ch) \) the messages in \( ch \) that have been sent, but not yet received within \( sh \):

\[
\text{inChannel}(sh, (p, p')) = \{ i \mid \exists e. \text{sendEv}^p(e, p', i) \in sh \land \text{receiveEv}^p(e, p, i) \notin sh \} .
\]

We can detect that a fixed bound \( N > 0 \), the capacity of a FIFO channel, has been reached by the following condition, which blocks a send event if the channel is full, i.e. the channel already contains \( N-1 \) messages.

**Definition 31 (Bounded FIFO Communication Constraint).** Let \( N \) be an integer. Well-formed \( N \)-bound FIFO, ensured by the predicate \( wf_{bd(N)} \), is captured by extending the constraint \( wf_{fifo} \) for standard (unbound) FIFO by a check on the bound of the channel as follows. Well-formedness of a trace ending by a reception event is given by \( wf_{fifo} \), and an additional rule checks well-formedness of message sending:

\[
wf_{bd(N)}(sh \land \text{sendEv}^p(e, p', i)) = wf(sh) \land |\text{inChannel}(sh, (p, p'))| < N .
\]

Causally ordered (CO) messages are harder to characterize than the previous communication patterns, because in the most simple definition of CO found in [20], the receiving events must occur in the right order provided that sending events are causally ordered. Our event structure does not record causal ordering. This could certainly be realized, but it would add considerable complexity to the evaluation rules. Instead, we use the information that is already provided by the events in a given trace, based on an alternative characterization of CO [20]: “a computation is CO if and only if no message is bypassed by a chain of other messages”. We first define a chain predicate such that \( Chain(e, e', sh) \) is true if there is a chain of messages inside \( sh \) that asserts the causal ordering of \( e \) and \( e' \) induced by messages.

**Definition 32 (Communication Chain).** The predicate \( Chain \) holds for two events \( e \) and \( e' \) in a given trace \( sh \), if there is a chain of messages asserting the causal ordering between \( e \) and \( e' \):

\[
Chain(e, e', sh) = \exists n, e_1, \ldots, e_n, i_1, \ldots, i_n, p_1, \ldots, p_{n+1}.
\]

\[
(\forall 1 \leq k \leq n. \text{sendEv}^p(e_k, p_{k+1}, i_k) \in sh \land \text{receiveEv}^{p_{k+1}}(e_k, p_k, i_k) \in sh) \land
\]

\[
(\forall 1 < k \leq n. \text{receiveEv}^p(e_{k-1}, p_k, i_{k-1}) <_sh \text{sendEv}^p(e_k, p_{k+1}, i_k))
\]

such that \( e <_sh \text{sendEv}^p(e_1, p_2, i_1) \land \text{receiveEv}^{p_{n+1}}(e_n, p_n, i_n) <_sh e' .
\]
We now define a well-formedness constraint that checks the absence of a message sent in the past (according to the definition of \textit{Chain}) but not yet received. The following definition generalises Definition 29 to messages causally ordered (according to the \textit{Chain} predicate) instead of messages originating from the same process:

\textbf{Definition 33 (CO Communication Constraint).} Well-formed CO communication is captured by the constraint $wf_{co}$, defined as follows:

$$wf_{co}(sh \xrightarrow{\text{receiveEv}} p(e, p', i)) = \underbrace{wf_{co}(sh)}_{\text{sendEv}} \land \underbrace{sendEv_{\sigma}(e, p, i)}_{\text{receiveEv}} \in sh \land \forall e'', p'', i''. \text{Chain}(sendEv_{\sigma}(e'', p, i''), sendEv_{\sigma}(e, p, i), sh) \implies receiveEv_{\sigma}(e'', p'', i'') \in sh.$$ 

Finally, we have a look at \textit{synchronous call} patterns. Several definitions can be found in [20]. We adopt a definition that constrains well-formed traces rather strongly: any send event is immediately followed by the corresponding receive event.

\textbf{Definition 34 (Strict Synchronous Communication Constraint).} Well-formed strict synchronous communication is captured by the constraint $wf_{sync}$, defined as follows:

$$wf_{sync}(sh \xrightarrow{\text{receiveEv}} p(e, p', i)) = \underbrace{wf_{sync}(sh)}_{\text{sendEv}} \land sh = sh'' \star sendEv_{\sigma}(e, p, i)$$

The above constraint is realized, for example, by rendez-vous channels in \textsc{ProMeLa} [44], see Section 7.1.

One can define more liberal notions of synchronous communication that accept the presence of independent events between the sending and the reception of the message. The crown criterion [20], for example, can be used for this purpose. Its definition is global over traces and requires to define \textit{wf} in a non-inductive manner (as an \textit{invariant} holding for the trace at any time). We omit a detailed elaboration, because this would distract from the main point of this paper.

7 Case Studies

7.1 \textsc{ProMeLa}

\begin{verbatim}
1 chan request = [0] of {byte};
2
3 active proctype Client0() {
4   request ! 0;
5 }
6
7 active proctype Client1() {
8   request ! 1;
9 }
10 active proctype Server() {
11   byte n;
12   do
13     :: request?n;
14     printf("client %d\n", n)
15   od
16 }
\end{verbatim}

Fig. 6: A simple \textsc{ProMeLa} program.

\textsc{ProMeLa} [44] is a concurrent modeling language that has been used to model and analyse numerous industrial systems. It comes with an industry-strength model checker [13]. We do not give a full LAGC-style semantics of \textsc{ProMeLa}, but we discuss its main features and illustrate that they can be formalised using minor variations of the concepts discussed above. We also do not give the DL calculus for \textsc{ProMeLa}, which mostly follows the calculus developed in Sections 4–5, since \textsc{ProMeLa} is designed for model checking. We assume the reader is familiar with \textsc{ProMeLa}. A simple example of a \textsc{ProMeLa} program is shown in Figure 6.

Types, Variables, Expressions All \textsc{ProMeLa} datatypes are mapped into finite integer types, including Booleans, process and channel identifiers, enumerations, arrays, etc. Strings occur only as literals in print statements. Variables declared outside a process are global and can be accessed by any process, such as the \textit{request} channel in Figure 6, line 1. Like in \textit{WHILE}, \textsc{ProMeLa} expressions are side effect-free and their evaluation is standard.
Processes Methods and method calls do not exist in ProMeLa, so call is not present. All ProMeLa processes are declared and started in the beginning by a—possibly implicit—initial process, so spawn does not occur in the ProMeLa syntax either. In Figure 6 three processes are declared and started upfront. It is easy to create an initial judgment similar to rule (59) from the process declarations of a ProMeLa program $P$:

$$\langle I_P, \Omega_P \rangle,$$

where $\Omega_P(p) = \{K(\{s_p\})\}$ for each process $p \in P$ with program code $s_p$. The code is wrapped in a scope to handle local variable declarations as in Section 5.3.

There is no need for a method table, because there are no method calls. For the same reason, the range of $\Omega$ is a singleton. ProMeLa processes execute in parallel and interleave on global variables. The granularity of interleaving in ProMeLa is the same as in Section 5.1, so the continuations in the local rules are unchanged. Composition rule (57) is adequate for the ProMeLa semantics, while rule (58) is not needed, because there are no method calls and the program code of all processes is part of the initial judgment. In consequence, neither spawn, nor invocation, nor invocation reaction events occur in ProMeLa traces.

Statements There is a print statement with no effect on states, we decide not to observe the effect on the trace, we can thus give it the semantics of skip in rule (6). Assignments are exactly as in WHILE, discussed in Section 5. Instead of if- and while-statements, ProMeLa has selection and repetition statements over guarded commands, which may only occur there. The semantics of guarded statements is as in Section 5.6. Statements of a selection if :: $g_1$; $s_1$ $\cdots$ :: $g_n$; $s_n$ fi is a straightforward generalisation of rules (5) and (53) with $n+1$ premisses; one for each guarded statement and one premiss if no guard is true. The path condition of the $i$-th guarded statement is $g_i$. When more than one guard is true, any one of them can be taken.

More generally, in ProMeLa, any statement $s$ can serve as a guard, so a guard can have a side effect. This can be modeled simply by putting $s$ into the continuation of its premise. All statements except send and receive (see below) are executable, their path condition simply becomes it. This can be assumed even for send and receive, because their execution is modeled by well-formedness constraints (see below), not by guards.

A repetition loops infinitely over its body and executes any of the statements whose guard is true; in the loop on the lines 12–15 of Figure 6, line 13 has an empty guard, which defaults to true. A repetition can only be exited by break or goto statements (see below). The local evaluation of repetitions can be reduced to selection in a similar manner as while in rule (6).

Jumps ProMeLa features a goto statement, whose argument is a label within the same process. Such unconditional jumps without a (process) context switch are easy to characterise semantically via continuations:

$$\text{val}_r(\text{goto } l) = \{\emptyset \triangleright (\sigma) \cdot K(s)\} \quad \text{where } s \text{ is the code following } l. \quad (40)$$

The break statement is equivalent to a goto with an implicit label that points to the code after the repetition it is contained in.

Atomic ProMeLa has an atomic statement\footnote{Although ProMeLa permits loops to occur inside atomic, these are actually discouraged; if loops occur, they must always terminate.}, which works as in Section 5.2 except it may contain a guard that can cause blocking. In this case, interleaving is possible. In case the guard $g$ evaluates to true, statement $s$ is simply atomically executed according to rule (13)\footnote{Rule (13) for unguarded atomic blocks ensures that the derived trace always ends with an empty continuation.}. Otherwise, it puts the whole guarded atomic block into a continuation, so that the guard can be re-evaluated later.

$$\text{val}_{g,F}^{O,F}(\text{atomic}[:: g; s]) = \{\text{val}_r(g) = \emptyset\} \triangleright (\sigma) \cdot K(\text{atomic}[:: g; s]) \bigcup \{\text{val}_r(g) = \emptyset\} \cup \text{pc} \triangleright \tau \cdot K(\emptyset) \mid \text{pc} \triangleright \tau \cdot K(\emptyset) \in \text{val}_{g,F}^{O,F}(\text{atomic}(s)) \} \quad (41)$$

Channels In ProMeLa, the send and receive commands have the syntax seen in Figure 6 if $c$ is a channel identifier and $\tau$ a list of expressions, then the current process uses $c!\tau$ to send the value of $\tau$ to $c$. Dually, with $c?\tau$ it receives $\tau$ from $c$. In contrast to Definition (30) (Section 6), ProMeLa channels are explicitly declared, and the address of a send (the origin of a receive) statement is not the recipient (sender) process, but a channel. A message can be read by anyone who has access to the channel identifier it was sent to. In the case of globally
declared channels (line [4]), this is any process. For locally declared channels the receiving process must have received or declared the channel identifier.

The semantics of ProMeLa's send and receive can be modeled in analogy to Section 6.1, but one uses send and receive events of the form sendEvP(τ, c, i) and receiveEvP(τ, c, i), respectively, where the address is a channel.

**Well-formedness** Only the first two rules of Definition 26 (with obvious adaptations) are needed, because there are no method calls or dynamically created processes. On the other hand, the option of local channels requires to model the visibility of channels. This can be done by well-formedness constraints of the following form:

\[
  \text{wf}_{c:a}(\text{sh} \ni \text{receiveEv}^P(e, c, i)) = \text{wf}(\text{sh}) \land (\text{isLocal}(p, c) \lor \text{isGlobal}(c) \lor \text{receiveEv}^P(c, e', i) \in \text{sh})
\]

The predicate isLocal(p, c) holds if the process p declares a local channel named c, isGlobal(c) holds if channel c is declared globally. These predicates can be easily checked by inspecting the code of a ProMeLa program. The constraint expresses that each channel used in a receive statement in process p must be visible at that point. This is the case if it is either local, or globally declared in p, or it was received earlier. There is a similar constraint for send statements.

There are two channel variants in ProMeLa: rendez-vous channels impose strictly synchronous communication. For those channels the well-formedness constraint in Definition 31 is used. The other channel type are buffer channels with a capacity \( N > 0 \). These are characterised by the bound FIFO pattern in Definition 31.

The standard ProMeLa semantics stipulates that received messages are consumed, i.e. they can be read only once, which is ensured by the following constraint:

\[
  \text{wf}(\text{sh} \ni \text{receiveEv}^P(e, c, i)) = \text{wf}(\text{sh}) \land \beta(e', p'). \text{receiveEv}^F(e', c, i) \in \text{sh}
\]

It is possible to change certain features of ProMeLa channels, for example, reception can be made non-consumptive, out-of-order reception can be permitted, send and receive can be made non-blocking. All of these can be characterised by suitable well-formedness constraints, but we refrain from spelling out details.

**Synchronisation** Channels, like guarded commands, are often used for synchronisation purposes in ProMeLa. The receive statement on a buffered channel is only executable if it contains a message; one can only send to a channel that is not full. Non-executable statements block a process until they become executable. In contrast to guarded commands, no specific evaluation rule is required to model blocking senders and receivers, because the correct communication order is already guaranteed by the well-formedness constraints.

This consideration suggests that blocking guards might as well be modeled by suitable "waiting" events. Indeed, this is possible, but less natural in that case.

### 7.2 Actors

We define a pure, object-based actor language based on the language in Section 6. Figure 7 shows the syntax. There is a one-to-one mapping between objects and actors. Each actor has its own process with local memory and executes calls to its methods with run-to-completion semantics (in consequence, non-terminating method calls render an actor unresponsive). Each actor can only access its own local memory. The state of another actor can only be modified via a method call.

---

\[ P \in \text{Prog} ::= \text{CD} \text{ sc} \]

\[ \text{CD} \in \text{ClassDecl} ::= \text{class} C \{ \text{M} \} \]

\[ M \in \text{MethDecl} ::= m(\overrightarrow{d}) \text{ sc} \]

\[ d \in \text{VarDecl} ::= e \mid x; d \]

\[ \text{sc} \in \text{Scope} ::= \{ \text{d atomic}(s) \} \]

\[ s \in \text{Stmt} ::= \text{skip} \mid x := \text{rhs} \mid \text{if} e \{ s \} \mid x!m(\overrightarrow{d}) \mid s; s \]

\[ \text{rhs} \in \text{Rhs} ::= e \mid \text{new} C(\overrightarrow{d}) \]

---

**Fig. 7: Syntax of the Actor Language in Section 7.2**

---

\[ ^{19} \text{In case one of the } e \text{ is not a variable, but a match expression, the assignment in the local evaluation rule } (31) \text{ has the variables occurring in } e \text{ in its domain.} \]
In this actor language, a program $P$ consists of a set of class declarations $CD$ with a main block $sc$. Each class has a name $C$, which also becomes the type of the class, with a sequence of field declarations $fd$ and method declarations $M$. Field declarations have the same syntax as local variable declarations $d$. For simplicity, we let each method declaration associate a unique name $m$ to a list of arguments $\bar{\pi}$ and a method body $se$.

A method body starts with local variable declarations followed by an atomic statement wrapping a sequence of statements $s$. Recall from Section 5.2 that we excluded loops inside atomic, and thus exclude the while statement from the syntax. This is no fundamental restriction, because actors may call each other and permit unbounded recursion.

The effect of atomic is to enforce a run-to-completion semantics. Rather than changing the semantics of the programs discussed in Sections 3–6, we here make atomicity explicit. In most actor languages [22], the atomic keyword is not used because actors are single threaded, and thus “locally atomic” by default.

We extend the statements of WHILE, given in Figure 2 with asynchronous method calls $x!m(\bar{\pi})$ on a caller object $x$. The semantics of asynchronous calls combines the semantics of sending a message and a method call. These calls are not blocking, so in the absence of futures or promises, there is no direct way to return a value to the caller (return values via futures are modeled in Section 7.3 below) 28. The right-hand side of assignments includes expressions and new $C(\bar{\pi})$. The latter creates a new actor object of class $C$ with constructor arguments $\bar{\pi}$.

In the following, let $Old$ be a set of object identifiers with typical element $o$. We represent a program $P$ in terms of a global lookup table $\mathcal{G}$: A set of triples each consisting of a class name with its field and method declarations:

$$\mathcal{G} = \{(C, fd, m(\bar{\pi})) | fd \in \text{fields}(C), m \in \text{methods}(C), C \in P\}.$$ 

In the above expression we use selector functions with obvious definitions: fields($C$) returns the field names of a class $C$, methods($C$) returns the methods declared in a class $C$. We also define class($X$), where $X$ is either an object identifier or a variable of type $Old$, that returns the class of $X$, as well as lookup($m, \mathcal{G}$) that returns the declaration of a method with name $m$ in $\mathcal{G}$.

Local Evaluation When following the principle of local evaluation, we face the problem that a statement $se$, which is locally evaluated, cannot possibly know the object it is running on. We address this issue in the same manner as we dealt with unknown values before, i.e. by introducing a parameter $O$ that is instantiated during trace composition. Since this parameter must be instantiated consistently for all statements an object $O$ executes, it becomes a parameter of the semantic evaluation function, denoted $\text{val}_O^O(s)$, where $O$ is a symbolic variable. The evaluation function $\text{val}_O^O(s)$ produces the traces when $s$ is running on object $O$; in particular, we let $\text{val}_O^O(\text{this}) = O$.

The evaluation rule for new below introduces an event $\text{newEv}_o(o, \bar{\pi})$ to capture that a new object $o$ with arguments $\bar{\pi}$ is created. Similar to Rule (40) that spawns a task, the local evaluation Rule (42) for object creation creates a fresh symbolic variable $X$ to represent the unknown object identity that is returned. Hence, Rule (42) has an empty path condition, extends the trace by the new object creation event followed by an updated state, where $x$ is mapped to symbolic variable $X$ and object fields are mapped to the constructor arguments. We suppose that $\mathcal{G}$ is pre-populated with enough variables of each class. Consequently, Rule (42) can pick a symbolic variable $X$ that is fresh in $\sigma$ and such that class($X$) = $C$.

$$\text{val}_O^O(x := \text{new } C(\bar{\pi})) =$$

$$(\emptyset \triangleright \text{newEv}_o^X(o, \bar{\pi}), \text{val}_O^O(\bar{\pi})) \triangleright \sigma[x \mapsto X, X \mapsto *, X, fd \mapsto \text{val}_O^O(e)] \cdot \text{K}(\emptyset) \quad (42)$$

Rule (43) for non-blocking asynchronous method calls is similar to Rule (24), but the invocation event $\text{invEv}_o(\bar{\pi}, x, m, i)$ also includes the callee object $x$ and a message identifier $i \in \text{MId}$. Thus, asynchronous method calls can be viewed as a combination of procedure calls and message sending.

$$\text{val}_O^O(x!m(\bar{\pi})) = \{\emptyset \triangleright \text{invEv}_o(\text{val}_O^O(\bar{\pi}), \text{val}_O^O(x), m, i) \cdot \text{K}(\emptyset)| i \in \text{MId}\} \quad (43)$$

The following rule evaluates the body of a method and corresponds to Rule (31) but adapted to a list of arguments instead of a single one. The invocation reaction event inserted by the rule includes symbolic variables

---

28 It is possible to pass the caller’s identity as a call argument, which the callee could then use to return a value to the caller’s side via a separate callback. But this does not give the caller a handle to access the result.
which represent the method’s actual parameters, which are unknown in the local context. Since there are no return values, it does not need to know the caller.

\[
\text{val}_O^\Omega(m(\overline{x})) = \{ \emptyset \triangleright \text{invREv}_O^\Omega(\overline{Z}, m, i) \land \sigma[\overline{x} \mapsto \overline{Z}, \overline{Z} \mapsto \ast] \cdot K(sc[\overline{x} \leftarrow \overline{Z}]) \mid \overline{x}, \overline{Z} \notin \text{dom}(\sigma), i \in \text{Mld} \}
\]  

(44)

**Trace Composition** As explained above, the local evaluation is parameterised with the executing object \( O \). During trace composition, this parameter is instantiated by a concrete object identifier \( o \). To associate events with the object they originate from, traces are tagged with that object. This works exactly like the process identifier tags in Definition 23 of Section 4.

We use a mapping \( \Omega \) into multisets of possible continuations like in Section 6, with the difference that its domain is object identifiers instead of process identifiers. We use the same notation for multiset operations as before.

Trace composition in Rule (45) follows Rule (37) closely, with two small modifications: instead of process identifiers, objects identifiers are used and the evaluation of the continuation \( s \) is performed on the object \( o \), where it is scheduled. The first two premises of the rule capture the scheduling decision to continue the trace by executing task \( s \) on object \( o \).

\[
\sigma = \text{last}(sh) \quad pc \triangleright \tau \cdot K(s') \in \text{val}_O^\Omega(s) \quad \rho \text{ concretizes } \tau \quad \rho(pc) \text{ consistent} \quad \text{wf}(sh \ast \rho(\tau)_o)
\]

\( sh, \Omega \rightarrow sh \ast \rho(\tau)_o, O[o \rightarrow q + \{K(s')\}] \)

(45)

Likewise, Rule (46) exactly follows the pattern established with Rule 38. The rule picks a method \( m \) and an object \( o \), on which it is supposed to be executed. If that object is not yet in the domain of \( \Omega \), then we use the notational convention \( \Omega(o) = \emptyset \). This corresponds to object creation. Either way, the method declaration is evaluated on \( o \). Observe that Rule (44) issues an invocation reaction event. Well-formedness ensures that an invocation event of the form \( \text{invEv}(\overline{x}, o, m, i) \) is present in \( sh \) that matches the message identifier, method parameters, and callee.

\[
\text{lookup}(m, \overline{G}) = m(\overline{x}) \quad sc \quad \sigma = \text{last}(sh) \quad pc \triangleright \tau \cdot K(s') \in \text{val}_O^\Omega(s) \quad \rho \text{ concretizes } \tau \quad \rho(pc) \text{ consistent} \quad \text{wf}(sh \ast \rho(\tau)_o)
\]

\( sh, \Omega \rightarrow sh \ast \rho(\tau)_o, O[o \rightarrow \Omega[o] + \{K(s')\}] \)

(46)

**Well-formedness** Well-formedness must essentially ensure two aspects:

1. the uniqueness of events, for example, there is at most one \( \text{newEv}(o, \underline{v}, \underline{w}, o, m, i) \) per object, i.e. an object cannot be created twice; 2. the event sequence related to a call to a method \( m \) on object \( o \) with parameters \( \overline{x} \) has the following form:

\[
\cdots \ \text{newEv}''(o, \overline{v}, o, m, i) \ \cdots \ \text{invEv}''(\overline{v}', o, m, i) \ \cdots \ \text{invREv}''(\overline{v}''', o, m, i) \ \cdots
\]

where \( o' \) and \( o'' \) can be the same object. This is achieved with the equations in Figure 8 (we do not repeat the first two lines of Definition 23, which are always assumed to be part of well-formedness).

\[
\text{wf}(sh \ast \text{newEv}''(o, \overline{v})) = \text{wf}(sh) \land \exists o'', \overline{v}''. \text{newEv}'''(o, \overline{v}'') \in sh
\]

\[
\text{wf}(sh \ast \text{invEv}''(\overline{v}, o, m, i)) = \text{wf}(sh) \land \exists o', \overline{v}'. \text{newEv}'''(o', \overline{v}') \in sh \land
\]

\[
\exists o''', \overline{v}''. \exists o''', m'. \text{invREv}'''(\overline{v}'', o'', m', i) \in sh
\]

\[
\text{wf}(sh \ast \text{invREv}''(\overline{v}, m, i)) = \text{wf}(sh) \land \exists o. \text{invEv}'''(\overline{v}', o', m, i) \in sh \land
\]

\[
\exists o'''. \overline{v}''. \exists o''', m'. \text{invREv}'''(\overline{v}'', m', i) \in sh
\]

Fig. 8: Well-formedness for Actor language.

Global Trace Semantics
Definition 35 (Program Semantics for Actors). Given a finite program \( P \) with a lookup table \( \mathcal{G} \) and a main block \( \text{main} \), i.e., \( \Omega_{\text{init}}(\text{main}) = \{ \text{K(\text{main})} \} \). Let \( \sigma_{\varepsilon} \) denote the empty state, i.e., \( \text{dom}(\sigma_{\varepsilon}) = \emptyset \). Let \( sh_0, \Omega_0 \rightarrow sh_1, \Omega_1 \rightarrow \cdots \) be a maximal sequence obtained by the repeated application of the composition rules (Rules (45)–(48)), starting with \( \sigma_{\varepsilon} \).

\[
\langle \sigma_{\varepsilon} \rangle \upharpoonright \new E^{\text{dom}(\text{main}) \circ \text{main}}, \varepsilon, \Omega_{\text{init}}.
\]

If the sequence is finite, then it must have the form

\[
\langle \sigma_{\varepsilon} \rangle \upharpoonright \new E^{\text{dom}(\text{main}) \circ \text{main}}, \varepsilon, \Omega_{\text{init}} \rightarrow \cdots \rightarrow sh, \Omega^0,
\]

where \( \Omega^0(o) = \emptyset \) for all \( o \in \text{dom}(\Omega) \). If the sequence is infinite, let \( sh = \lim_{i \rightarrow \infty} sh_i \). In either case, \( sh \) is a trace of \( P \). The set of all such traces is denoted with \( \text{Tr}(P, \sigma_{\varepsilon}) \).

The new event at the start of a trace represents creation, by the system, of an initial object that runs the main method. The well-formedness of events ensures that subsequently created objects will not erroneously be the initial object, which is reserved for the code executed in the main method.

7.3 Active Objects

Active object languages \cite{22} have a mechanism like futures or promises that provides a reference to the value computed by an asynchronous method call. This makes it possible for a task to free its processor resource while waiting for a result to be finished (so-called cooperative multi-tasking). We modify the syntax from Section 7.2 and introduce futures, a \textit{return} statement, and \textit{get}-expressions to retrieve the value stored in a future; the resulting syntax is given in Figure 9. Note that the latter can block if this value is not yet available.

\[
P \in \text{Prog} ::= \text{CD sc}
\]
\[
\text{CD} \in \text{ClassDecl} ::= \text{class} \ C \ \{ \text{fd} \ \text{M} \}
\]
\[
M \in \text{MethDecl} ::= \text{method} \ C \ ( \ \text{M} \ ) \ \text{sc}
\]
\[
d \in \text{VarDecl} ::= \text{d} \ | \ x \ | \ e
\]
\[
\text{sc} \in \text{Scope} ::= \{ \ d \ s \ | \ \text{return} \ e \}
\]
\[
g \in \text{guard} ::= \text{e} \ ? \ | \ e
\]
\[
s \in \text{Stmt} ::= \text{skip} \ | \ x := \text{rhs} \ | \ \text{if} \ e \ \{ \ s \} \ | \ \text{while} \ e \ \{ \ s \} \ | \ \text{this} \ m(\text{T}) \ | \ \text{await} \ g \ | \ s \ | \ s
\]
\[
\text{rhs} \in \text{Rhs} ::= e \ | \ \text{new} \ C(\text{T}) \ | \ x m(\text{T}) \ | \ e \ \text{get}
\]

Fig. 9: Syntax of Active Objects with Futures.

We need to capture cooperative multi-tasking and the blocking of future access into the semantics. This cannot be done with \text{atomic}, as in the previous section, because the suspending statements might occur nested inside loops and recursive calls. It is more appropriate to switch to a semantics where a task \text{runs to completion} by default, unless it suspends or blocks. As a consequence we will specify a semantics with finer-grained, explicitly controlled interleaving between tasks. For this reason, we now consider both \text{while}-loops and synchronous self-calls \text{this} \ m(\text{T}) in the syntax.

Task suspension takes place in \text{await} \ g statements, where the guard \( g \) suspends the execution of a task; it works similarly to the guarded statements of Section 5.6. An \text{await} releases its object’s process, such that other tasks may be executed. The execution of the statements following the guard can resume when the guard evaluates to true. Even when the guard evaluates to true, the execution may be suspended. Guard expressions either have the form \( x? \), which synchronize with the future referenced by \( x \) receiving a value (the future thereby gets resolved), or they are Boolean expressions \( e \).

The second difference to the Actor language of Section 7.2 is that asynchronous method calls return values to their associated future.\cite{22} The \text{return} statement terminates the execution of an asynchronous method and returns its argument. The syntax enforces that the \text{return} statement is at the end of a method body. Asynchronous method calls now appear on the right hand side of an assignment, the variable on the left is a \text{future} associated with the call. The future’s value can be retrieved with \text{get}, whose argument expression must evaluate to a future. To avoid blocking, one can precede \( x \) \text{get} with \text{await} \ x? . Futures are first-class values and may be passed as method arguments to other objects.

\footnote{Note that we denote by \( \varepsilon \) an empty list of method arguments.}

\footnote{Obviously, synchronous calls can also be equipped with return values in a straightforward manner.}
Local Evaluation For similar reasons as for objects in Section 7.2, we need to provide the future towards whose value a local statement is contributing, as a parameter of the evaluation function. This future, sometimes called the destiny of the executing code [23], cannot possibly be known locally. Hence, the form of the semantic evaluation function becomes \( \text{val}_\sigma^{O,F}(s) \), where \( F \) is a symbolic variable of type future with values in \( \text{Fld} \); the evaluation function captures that \( s \) is running on object \( O \) and has destiny \( F \). To keep track of the destiny, we store it together with the continuations; in the configurations, continuations now take the form \( K^f(s) \).

The rule for assignment with an asynchronous call on the right-hand side first emits an invocation event \( \text{invEv}(\sigma,a,m,f) \), similar to Rule (43). The difference is that now the future \( F' \), that is the destiny of the call, must be recorded both in the left-hand-side variable on the left and in the invocation event. That future can also be used to identify the call, thus replacing the message identifier. Since the value of \( F' \) cannot be known locally, it is modeled as a fresh symbolic variable, similarly as in Rules (35)–(39).

\[
\text{val}_\sigma^{O,F}(x := e; m(\overline{e})) = \{ \emptyset \triangleright \text{invEv}_\sigma^{O,F}(\overline{e}) (\text{val}_\sigma^{O,F}(\overline{e}), m, F') \cap \sigma[x \mapsto F', F' \mapsto \ast] \cdot K(\emptyset) \}
\]

To ensure that only futures with an available value are retrieved, we introduce new events \( \text{compEv}_\sigma(f, v) \) and \( \text{compREv}_\sigma(f, v) \). These events denote the completion (the value of future \( f \) is available) and completion reaction (the value of \( f \) is retrieved) of an asynchronous method. The evaluation rule for returning the completed result simply inserts a completion event for the current future.

\[
\text{val}_\sigma^{O,F}(\text{return } e) = \{ \emptyset \triangleright \text{compEv}_\sigma(f, \text{val}_\sigma^{O,F}(e)) \cdot K(\emptyset) \}
\]

To retrieve the returned value stored in a future, Rule (44) inserts a completion reaction event and extends the current state with a symbolic variable \( V \) that holds the as yet unknown return value.

\[
\text{val}_\sigma^{O,F}(x := e \text{.get}) = \{ \emptyset \triangleright \text{compREv}_\sigma(V \sigma) (\text{val}_\sigma^{O,F}(e), V) \cap \sigma[x \mapsto V, V \mapsto \ast] \cdot K(\emptyset) \}
\]

The rule for evaluating a method body is similar to Rule (44), except that the future variable \( f \) of the freshly running process is unified with the variable \( f \) of the invocation reaction event. It also must contain the (as yet unknown) caller \( Y \). Well-formedness of the trace containing \( \text{invREv}(X,Y,m,f) \) will ensure that the future of the invocation reaction is matched with the same \( f \) for a matching invasion event (see the definition of \( \text{uf}(sh) \) below).

\[
\text{val}_\sigma^{O,F}(m(\overline{X}) \sigma) = \{ \emptyset \triangleright \text{invREv}_\sigma^{O,Y}(\overline{X}, Y, m, f) \cap \sigma[\overline{X} \mapsto X, X \mapsto \ast, Y \mapsto \ast] \cdot K(\sigma \mapsto X) \}
\]

For while-loops, we can use Rule (49). Rule (51) handles synchronous self-calls (no other synchronous calls are considered here) by inlining the method body. It obtains the method declaration of \( m \) with body \( sc \) using the auxiliary function \( \text{lookup}(e) \), and turns the formal parameters \( \overline{X} \) into local variable declarations bound to the argument values \( \overline{X} \). The entire statement sequence is wrapped into a scope for name disambiguation.

\[
\text{val}_\sigma^{O,F}(\text{this.m}(\overline{X})) = \text{val}_\sigma^{O,F}(\overline{X}; \overline{X} := \text{val}_\sigma^{O,F}(\overline{X}); sc), \quad \text{where} \quad \text{lookup}(m, G) = m(\overline{X}) \sigma
\]

Suspended tasks are introduced by \( \text{await} \) statements. We only need to specify how to progress after an \( \text{await} \)—the trace composition semantics will deal with actual task suspension by checking for the presence of an \( \text{await} \) guard. There are two syntactically distinct cases. The first corresponds to a guarded command in Rule (52), the second requires that the guarded future is resolved and thus introduces a completion reaction event. This event must match a previous completion event involving the same future, which will be ensured by well-formedness in the global rules.

\[
\text{val}_\sigma^{O,F}(\text{await } e) = \{ \{ \text{val}_\sigma(e) = \text{tt} \} \triangleright \sigma \cdot K(\emptyset) \}
\]

\[
\text{val}_\sigma^{O,F}(\text{await } e?) = \{ \emptyset \triangleright \text{compREv}_\sigma(V \sigma) (\text{val}_\sigma^{O,F}(e), V) \cdot K(\emptyset) \mid V \notin \text{dom}(\sigma) \}
\]

Trace Composition We extend the continuations in the configuration with a future identifier that corresponds to the future to be resolved by the considered task (thus, continuations take the form \( K^f(s) \)). With active objects, there is no data-race among concurrent tasks, because each data item belongs to one single active object and
there is at most a single active task for each active object. One way to realize this in the semantics is to assign a single process to each active object and make sure that among all the tasks of this process, only one is not waiting for its turn. In other words, for each object identifier $o$, all continuations, except possibly one, are of the form $K^f(\text{await } g; s)$.

We use the symbol $Q$ to denote a multiset of suspended or empty continuations of the form $K^f(\text{await } g; s)$ or $K^f(\mathit{id})$. The current global state of a program trace is represented by a mapping $\Sigma$ from object identifiers to multisets of continuations. For all object identifiers $o$, $\Sigma[o]$ is either empty or of the form $Q+\{K^f(s)\}$, which reflects that there is at most one active task. If $s$ is of the form $\text{await } g; s'$, then no task is currently executing on object $o$ and any task can be activated; otherwise, $s$ must be the only continuation that can be executed in object $o$. It is called the active task. The rewrite rule for empty trace simplification is extended to the new continuations: $Q + K^f(\mathit{id}) \leadsto Q$. The trace composition rule closely follows Rule (45):

$$
\Sigma[o] = Q+\{K^f(s)\}
$$

The main difference is that the global state has a different signature and the nature of $Q$ enforces the selection of the current task. Observe that this rule either evaluates the current active task or activates a new task in $o$ when there is no active task.

Rule (54) follows Rule (46) except that the evaluation function is now tagged with a concrete future identity $f$. The correctness of the concretisation is ensured by the well-formedness premise that requires an invocation event of the form $\text{invEv}(\mathcal{T}, o, m, f)$ to be present in $sh$. Note that we only run a new method if there is no active task ($\Sigma[o] = Q$). Here, the destiny of the created thread is the future that was created during the evaluation of the invocation event $\text{invEv}(\mathcal{T}, o, m, f)$. As no other task is active, the method can start running immediately.

$$
\Sigma[o] = Q
$$

$$
\sigma = \text{last}(sh) \quad pc \triangleright K(s') \in \text{val}_{\Sigma}^f(s) \quad \rho \text{ concretizes } \tau \quad \rho(pc) \text{ consistent} \quad \text{wf}(sh \leftrightarrow \rho(\tau)^o)
$$

$$
sh, \Sigma \leadsto sh \leftrightarrow \rho(\tau)^o, \Sigma[o \mapsto Q+\{K^f(s')\}]
$$

This last rule can be triggered when $Q$ is empty, i.e. when a newly created object handles its first invocation or when an object has no task currently running.

**Proposition 3.** The property that $\Sigma[o]$ contains at most one active task for any $o \in \text{Old}$ is an invariant preserved by applications of Rules (53) – (55).

**Proof.** When an object $o$ is created, $\Sigma[o]$ is empty. Every time one of the Rules (53) – (55) is applied to $o$, a continuation is added to $\Sigma[o]$. As long as $\Sigma[o]$ contains only suspended continuations, either rule can be applied to $o$. Consequently, a suspended task on $o$ can be activated or a new method invocation on $o$ can start to be executed. If there is one active task $K^f(s)$ in $\Sigma[o]$, only Rule (55) can be applied to $o$. In this case, execution on $o$ is forced by Rule (53) to continue with this specific $K(s)$, i.e., the active task on $o$.

The proposition guarantees that each object has at most one active task that at any time. This captures the semantics of sequential execution on an object between two suspension points.

**Well-Formedness** Compared to Section 7.2 well-formedness must reflect the life cycle of asynchronous method calls with completion and completion reaction events to ensure that return values are not delivered and retrieved too early:

\[
\ldots \text{newEv}^{o''}(a, v) \ldots \text{invEv}^o(\mathcal{T}, o, m, f) \ldots \text{invREv}^o(\mathcal{T}, o', m, f) \ldots \text{compEv}^o(f, v) \ldots \text{compREv}^{o''}(f, v) \ldots
\]

where $o'$ and $o''$ can be the same object, and $o''$ can be any object except $o$. Up to tagging, the first four events are unique in each trace, but not so the final completion reaction event. This is, because any object can retrieve the value stored in a future as long as it possesses the future’s identifier.

The fourth equation in Figure 10 is straightforward, because (i) a return can only be encountered after an invocation reaction event, which is guaranteed to be unique by the third equation, and (ii) Rule (53) makes sure that it is evaluated on the matching future and object.

The final equation ensures the value of a future can only be fetched after the future is resolved.

---

23 Running the method immediately allows us, for example, to encode a FIFO service policy by composing with the communication ordering rules of Section 6.2.
\[ wf(sh \mapsto newEv' (o, \sigma)) = wf(sh) \land \mathcal{B}o'', \mathcal{T}.newEv'' (o, \mathcal{T}) \in sh \]
\[ wf(sh \mapsto invEv' (\mathcal{V}, o, m, f)) = wf(sh) \land \exists o'', \mathcal{V}.newEv'' (o, \mathcal{V}) \in sh \land \]
\[ \mathcal{B}o'', \mathcal{T}', o''', m'. invEv'' (\mathcal{T}', o''', m', f) \in sh \]
\[ wf(sh \mapsto invREv' (\mathcal{V}, o, m, f)) = wf(sh) \land invEv' (o', m) \in sh \land \]
\[ \mathcal{B}o', \mathcal{T}', o'''', m'. invREv'' (\mathcal{T}', o'''', m', f) \in sh \]
\[ wf(sh \mapsto compEv' (f, v)) = wf(sh) \]
\[ wf(sh \mapsto compREv' (f, v)) = wf(sh) \land \exists o', compEv' (f, v) \in sh \]

Fig. 10: Well-Formedness for Actors with Futures.

Global Trace Semantics

Definition 36 (Program Semantics for Active Objects). Given a program \( P \) with a method table \( \mathcal{G} \) and a main block \( \text{main} \), i.e., \( \Sigma_{\text{init}}(\text{main}) = \{K_{\text{init}}(\text{main})\} \). Let \( \sigma_\epsilon \) denote the empty state, i.e. \( \text{dom}(\sigma_\epsilon) = \emptyset \). Let \( sh_0, \Sigma_0 \rightarrow sh_1, \Sigma_1 \rightarrow \cdots \) be a maximal sequence obtained by the repeated application of the composition rules (Rules [53]–[61]), starting with

\[ \langle \sigma_\epsilon \rangle \mapsto newEv^{\text{main}}(o_{\text{main}}, \epsilon), \Sigma_{\text{init}}. \]

If the sequence is finite, then it must have the form

\[ \langle \sigma_\epsilon \rangle \mapsto newEv^{\text{main}}(o_{\text{main}}, \epsilon), \Sigma_{\text{init}} \rightarrow \cdots \rightarrow sh, \Sigma^\beta, \]

where \( \Sigma^\beta(o) = \emptyset \) for all \( o \in \text{dom}(\Sigma) \). If the sequence is infinite, let \( sh = \lim_{i \rightarrow \infty} sh_i \). In either case, \( sh \) is a trace of \( P \). The set of all such traces is denoted with \( \text{Tr}(P, \sigma_\epsilon) \).

The new event at the start of a trace represents the creation, by the system, of an initial object that runs the main method. The well-formedness of events ensures that subsequently created objects will not erroneously be the initial object, which is reserved for code executed in the main method.

Example 19. Consider the following program \( P \):

\[
\begin{array}{l}
\text{class C} \{ \\
\quad m(n) \{ \\
\quad\quad n := n + 1; \\
\quad\quad \text{return} \ n; \\
\quad \} \\
\text{7} \ \{ \ // \text{main block} \\
\quad a; x; f; y; \\
\quad a := 1; \\
\quad x := \text{new} \ C(); \\
\quad f := x.m(a); \\
\quad \text{await} \ f'(); \\
\quad y := f.get(); \\
\} \\
\end{array}
\]

Let the global lookup table \( \mathcal{G} \) for this program be \( \{ (\text{C}, \epsilon, m(n)\{n := n + 1; \text{return} \ n; \}) \} \). In the following, we use \( s_i \) to indicate the sequence of statements of a method body starting from line \( i \).

We first show the abstract local traces. The evaluation of the main method is as follows, where \( s_{\text{main}} \) represents the body in main, and \( \mathcal{T} \) corresponds to \( s_{\text{main}}[a \leftarrow a', x \leftarrow x', f \leftarrow f', y \leftarrow y'] \).

\[
\begin{align*}
\text{val}^{\mathcal{O}, F}_{\sigma}(\{a; x; f; y; s_{\text{main}}\}) &= \{0 \mapsto (\sigma) \mapsto \sigma[a' \mapsto 0, x' \mapsto 0, f' \mapsto 0, y' \mapsto 0] \cdot \mathcal{K}\{s_0\} \\
\text{val}^{\mathcal{O}, F}_{\sigma}(\{a := 1\}) &= \{0 \mapsto (\sigma) \mapsto \sigma[a' \mapsto 1] \cdot \mathcal{K}(\emptyset)\} \\
\text{val}^{\mathcal{O}, F}_{\sigma}(\text{new} \ C()) &= \{0 \mapsto \text{newEv}^X(\mathcal{X}, \epsilon) \mapsto \sigma[x' \mapsto X, X \mapsto \ast] \cdot \mathcal{K}(\emptyset) \quad |\quad X \notin \text{dom}(\sigma), \text{class}(X) = \mathcal{C} \} \\
\text{val}^{\mathcal{O}, F}_{\sigma}(f' := \text{newEv}^X(\mathcal{X}, \epsilon)) &= \{0 \mapsto \text{newEv}^X(\mathcal{X}, \epsilon) \mapsto \sigma[f' \mapsto F', F' \mapsto \ast] \cdot \mathcal{K}(\emptyset) \\
\text{val}^{\mathcal{O}, F}_{\sigma}(\text{f' := x.m(a')}) &= \{0 \mapsto \text{invEv}^F(\mathcal{O}, \mathcal{F}, \mathcal{M}, \mathcal{F}, m') \mapsto \sigma[f' \mapsto F', F' \mapsto \ast] \cdot \mathcal{K}(\emptyset) \\
\text{val}^{\mathcal{O}, F}_{\sigma}(\text{f' := x.m(a')}) &= \{0 \mapsto \text{compEv}^F(\mathcal{O}, \mathcal{F}, \mathcal{M}, \mathcal{F}, m') \mapsto \sigma[f' \mapsto F', F' \mapsto \ast] \cdot \mathcal{K}(\emptyset) \\
\text{val}^{\mathcal{O}, F}_{\sigma}(\text{f' := x.m(a')}) &= \{0 \mapsto \text{compEv}^F(\mathcal{O}, \mathcal{F}, \mathcal{M}, \mathcal{F}, m') \mapsto \sigma[f' \mapsto F', F' \mapsto \ast] \cdot \mathcal{K}(\emptyset) \\
\text{val}^{\mathcal{O}, F}_{\sigma}(\text{y := f.get()}) &= \{0 \mapsto \text{compEv}^F(\mathcal{O}, \mathcal{F}, \mathcal{M}, \mathcal{F}, m') \mapsto \sigma[y' \mapsto V, V \mapsto \ast] \cdot \mathcal{K}(\emptyset) \\
\text{val}^{\mathcal{O}, F}_{\sigma}(\text{y := f.get()}) &= \{0 \mapsto \text{compEv}^F(\mathcal{O}, \mathcal{F}, \mathcal{M}, \mathcal{F}, m') \mapsto \sigma[y' \mapsto V, V \mapsto \ast] \cdot \mathcal{K}(\emptyset) \\
\end{align*}
\]
The evaluation of the body of method \( m \) is shown below, where \( sc \) represents \( \{ n := n + 1; \text{return} n; \} \) and \( \{ 1 \} \) the content of the block \( sc[n \leftarrow n'] \).

\[
\begin{align*}
\text{val}_{sc}^O(n, sc) &= \{ \emptyset \triangleright \text{invRE}_\sigma^{\langle N, X, F' \rangle}(N, X, m, F') \\
& \quad \land \sigma[n' \mapsto N, N \mapsto *, X \mapsto *, F' \mapsto *] \cdot K(sc[n \leftarrow n']) | n', N, X, F' \not\in \text{dom}(\sigma) \}
\end{align*}
\]

\[
\begin{align*}
\text{val}_{sc}^O(\{ 1 \}) &= \text{val}_{sc}^O(\{ 1 \}) \\
\text{val}_{sc}^O(n' \mapsto n + 1) &= \{ \emptyset \triangleright \langle \sigma \rangle \land \sigma[n' \mapsto \text{val}_{sc}^O(n' + 1)] \cdot K(\emptyset) \} \\
\text{val}_{sc}^O(\text{return} n') &= \{ \emptyset \triangleright \text{compEv}_\sigma(F, \text{val}_{sc}^O(n')) \cdot K(\emptyset) \}
\end{align*}
\]

We now continue with the computation of a global concrete trace. Let \( Ip \) be the initial state of \( P \). We consider the state where the statements in lines \([53,54]\) have already been executed. At this point, the concrete trace is \( sh = (Ip) \land \{ a' \mapsto 0, x' \mapsto 0, f' \mapsto 0, y' \mapsto 0 \} \land \sigma \land \sigma \land \sigma \land \sigma \) with \( \sigma = \{ a' \mapsto 1, x' \mapsto 0, f' \mapsto 0, y' \mapsto 0 \} \). We must continue with \([11]\) by applying Rule \([59]\) at \([59]\):}

\[
\begin{align*}
\Sigma[\sigma_{main}] &= \{ K^{f_{\text{main}}}(\{ 1 \}) \} \quad \sigma' = \text{last}(sh') \\
\rho &= [X \mapsto o_m] \quad \emptyset \triangleright \text{wf}(sh'') \\
\text{val}_{\sigma_{\text{main}}}^{f_{\text{main}}}(sh', \Sigma[\sigma_{\text{main}}] \mapsto \{ K^{f_{\text{main}}}(\text{wait } f''?) : \{ 13 \} \})
\end{align*}
\]

where \( sh'' \) is the concrete trace

\[
\begin{align*}
sh'' &= \text{rho}(\text{invRE}_\sigma^{\langle F' \rangle}(1, o_m, m, F')) \land \sigma'[f' \mapsto F', F'' \mapsto *] \cdot K(\text{wait } f''?) ; \{ 13 \}
\end{align*}
\]

with \( \sigma'' = \sigma'[f' \mapsto f_m] = \{ a' \mapsto 1, x' \mapsto o_m, f' \mapsto f_m, y' \mapsto 0 \} \).

At this point, one could choose to continue with the \text{wait} statement in \text{main} with Rule \([53]\) or to start executing method \( m \) on object \( o_m \) with Rule \([54]\). However, Rule \([53]\) is not applicable, because it does not result in a well-formed trace before method \( m \) returns. Therefore, we proceed with the second option:

\[
\begin{align*}
\Sigma[\sigma_m] &= \emptyset \quad \text{lookup}(m, G) = m(n, sc) \quad \sigma'' = \text{last}(sh'') \\
\rho &= [F' \mapsto f_m] \quad \emptyset \triangleright \text{wf}(sh''') \\
\text{val}_{\sigma_{\text{main}}}^{f_m}(sh''' \cdot \sigma_{\text{main}}[m \mapsto \{ K^{f_m}(\{ 13 \}) \}])
\end{align*}
\]

where the mapping \( \Sigma \) is updated to \([12]\) and \( \{ 14 \} \) and \( \{ 15 \} \), and \( sh_m \) is the concrete trace

\[
\begin{align*}
sh''' &= \text{rho}(\text{invRE}_\sigma^{\langle N, X', F'' \rangle}(N, X', m, F'')) \land \sigma''[n' \mapsto N, N \mapsto *, X' \mapsto *, F'' \mapsto *] \cdot K(\emptyset) \\
\rho &= [N \mapsto 1, X' \mapsto o_m] \quad \emptyset \triangleright \text{wf}(sh_m) \\
\Sigma[\sigma] &= \text{lookup}(m, G) = m(n, sc) \quad \sigma'' = \text{last}(sh''') \\
\rho &= [F' \mapsto f_m] \quad \emptyset \triangleright \text{wf}(sh''') \\
\text{val}_{\sigma_{\text{main}}}^{f_m}(sh''' \cdot \sigma_{\text{main}}[m \mapsto \{ K^{f_m}(\{ 13 \}) \}])
\end{align*}
\]

with \( \sigma'' = \sigma''[n' \mapsto 1] \).

\[\text{We simplify the states in the concrete trace by removing the symbolic variables once they are instantiated.}\]
We have to continue with \( \{\text{[3]}\} \) from the method \( m \). Executing \( n' := n' + 1 \) in \( \text{[3]} \) updates \( \sigma_m \) to \( \sigma'_m = \sigma_m[n' \mapsto \text{val}^\text{main}_{\sigma_m}(n' + 1)] = \{x' \mapsto 1, x' \mapsto m, f' \mapsto \text{f}, y' \mapsto 0, n' \mapsto 2\} \), which extends the concrete trace to \( \text{sh}'_m \) as follows:

\[
\langle I_P \rangle \cap \ldots \cap \sigma_m \cap \sigma'_m.
\]

We proceed with the \textit{return} statement in method \( m \) by applying Rule \([53]\) once again:

\[
\Sigma[\sigma_m] = \{K_f^\text{main} (\text{return } n')\} \quad \sigma'_m = \text{last}(\text{sh}'_m)
\]

\[
\emptyset \triangleright \text{compEv}^\sigma_{\sigma_m} (f_m, 2) \cdot K(\emptyset) \in \text{val}^\text{main}_{\sigma_m}(\text{return } n') \quad \rho = [\text{[1]}] \quad \emptyset \text{ consistent } \omega(\text{sh}'_m)
\]

\( \text{sh}'_m, \Sigma \rightarrow \text{sh}''_m, \Sigma[\sigma_m] \rightarrow \emptyset \)

where \( \Sigma[\sigma_m] \rightarrow \emptyset \) is the result of simplifying \( \Sigma[\sigma_m] \rightarrow \emptyset + K_f^\text{main}(\emptyset) \). The resulting concrete trace \( \text{sh}''_m \) is:

\[
\text{sh}''_m \triangleright \rho(\text{compEv}^\sigma_{\sigma_m} (f_m, 2))^{\sigma_m}
\]

\[
= \langle I_P \rangle \cap \ldots \cap \sigma_m \cap \text{compEv}^\sigma_{\sigma_m} (f_m, 2) \cap \sigma'_m \cap \sigma'_m.
\]

The mapping \( \Sigma \) is now updated to \( [\sigma_{\text{main}} \rightarrow \{K_f^\text{main}(\text{await } f'?: [\text{[1]}], \sigma_m \rightarrow \emptyset\}] \). Executing the \textit{await} statement in \( \text{main} \) at this point produces a well-formed trace by Rule \([55]\):

\[
\Sigma[\sigma_{\text{main}}] = \{K_f^\text{main}(\text{await } f'?: [\text{[1]}])\} \quad \sigma'_m = \text{last}(\text{sh}''_m)
\]

\[
\emptyset \triangleright \text{compEv}^\sigma_{\sigma_{\text{main}}} (f_{\text{main}}, V) \cap \sigma'_m[V \mapsto *] \cdot K(\text{[1]}) \in \text{val}^{\text{main}}_{\sigma_{\text{main}}}(\text{await } f'?: [\text{[1]}])
\]

\[
\rho = [V \mapsto 2] \quad \emptyset \text{ consistent } \omega(\text{sh}''_m)
\]

\( \text{sh}''_m, \Sigma \rightarrow \text{sh}''_m, \Sigma[\sigma_{\text{main}}] \rightarrow \{K_f^\text{main}(\text{[1]}\}$\]

with the concrete trace \( \text{sh}'''_m \):

\[
\text{sh}'''_m \triangleright \rho(\text{compEv}^\sigma_{\sigma_{\text{main}}} (f_{\text{main}}, V) \cap \sigma'_m[V \mapsto *])^{\sigma_{\text{main}}}
\]

\[
= \langle I_P \rangle \cap \ldots \cap \sigma_m \cap \text{compEv}^\sigma_{\sigma_{\text{main}}} (f_{\text{main}}, 2) \cap \sigma'_m \cap \sigma'_m.
\]

The final state \( \sigma'_m \) is actually a simplification of \( \sigma'_m[V \mapsto 2] \) by removing the concretised symbolic variable \( V \) and thus identical to \( \sigma'_m \).

Finally, we execute the \textit{get} statement, again by Rule \([56]\):

\[
\Sigma[\sigma_{\text{main}}] = \{K_f^\text{main}(\text{[1]}\}$\]

\[
\emptyset \triangleright \text{compEv}^\sigma_{\sigma_{\text{main}}} (\text{val}^{\text{main}}_{\sigma_{\text{main}}}(f), V') \cap \sigma'_m[y' \mapsto V', V' \mapsto *] \cdot K(\text{[1]}) \in \text{val}^{\text{main}}_{\sigma_{\text{main}}}(\text{[1]})
\]

\[
\rho = [V' \mapsto 2] \quad \emptyset \text{ consistent } \omega(\text{sh}''_m)
\]

\( \text{sh}''_m, \Sigma \rightarrow \text{sh}_P, \Sigma[\sigma_{\text{main}}] \rightarrow \emptyset \)

which results the mapping \( \Sigma = [\sigma_{\text{main}} \rightarrow \emptyset, \sigma_m \rightarrow \emptyset] \) and produces the concrete trace \( \text{sh}_P \):

\[
\text{sh}'''_m \triangleright \rho(\text{compEv}^\sigma_{\sigma_{\text{main}}} (\text{val}^{\text{main}}_{\sigma_{\text{main}}}(f), V') \cap \sigma'_m[y' \mapsto V', V' \mapsto *])^{\sigma_{\text{main}}}
\]

\[
= \langle I_P \rangle \cap [a' \mapsto 0, x' \mapsto 0, f' \mapsto 0, y' \mapsto 0] \cap \sigma \cap \text{newEv}^{\text{main}}(o_{\text{main}}, \emptyset) \cap \sigma \cap \sigma' \cap \sigma' \cap \text{invEv}^{\text{main}}(1, o_{\text{main}}, m, f_m) \cap \sigma' \cap \sigma_m \cap \sigma'_m \cap \sigma'_m \cap \sigma'_m \cap \text{compEv}^\sigma_{\sigma_{\text{main}}} (f_m, 2) \cap \sigma'_m \cap \text{compEv}^\sigma_{\sigma_{\text{main}}} (f_m, 2) \cap \sigma'_m \cap \sigma'_m \cap \sigma_P
\]

with \( \sigma_P = [a' \mapsto 1, x' \mapsto m, f' \mapsto \text{f}, y' \mapsto 2, n' \mapsto 2] \).

**ABS** ABS is an actor-based executable modeling language \([19, 34, 2] \) that falls in the class of Active Object languages \([22]\). ABS is closely related to the language in Figure \([9]\). Before we make this relation precise, we mention the main features of ABS that have not been discussed in this paper:

**Functional Expressions** ABS lets the user declare algebraic datatypes and provides a pure, functional language with pattern matching over these. An evaluation semantics for such a language is standard \([57]\). It is easily incorporated into states and their evaluation.

**Interfaces** ABS supports multiple implementations of interfaces, but no inheritance or dynamic dispatch. It is sufficient to equip the lookup table \( \mathcal{G} \) with suitable selectors.
Modules, Traits ABS has a simple module system. Modules do not have an operational semantics, but manage the name space. One can remove them by replacing relative with absolute names. ABS supports code reuse via traits: sets of method declarations that can be added to a class via a uses clause. Like modules, traits can be assumed to have been resolved.

Error Handling ABS can throw and catch exceptions. The semantics of the corresponding statements is a combination of the case distinction rule and the local jump rule. The design of the corresponding local evaluation rules is left as an exercise.

Otherwise, ABS is identical to the Active Object language discussed in the present section. Specifically, ABS tasks are atomic by default. Their execution is only suspended explicitly, either at the end of a method, or with a suspend statement (equivalent to “await true”), or by await g.

8 Related Work

We position our work within denotational semantics. The discussion focuses on three different strands of work on trace semantics: Semantics based on execution traces, on communication traces, and on hybrid traces combining execution states and communication events. To first motivate the use of traces semantics, we start by drawing some lines from state-transformer semantics. We then consider related work on execution traces and communication traces. We finally discuss related work on hybrid traces, combining these directions.

State-transformer semantics. State-transformer semantics explain a program statement as a transition from one program state to another. This style of semantics elegantly hides intermediate states in the transition, thereby providing an abstraction from the inner, intermediate states visited in the actual execution of statements. State-transformer semantics is fully abstract for sequential while-programs, resulting in a compositional semantics with respect to, for example, partial correctness behavior. However, for parallel shared-variable languages the final outcome of a program may depend on the scheduling of the different atomic sections, leading to non-deterministic behavior. For a parallel statement, the state transformer that results from the parallel composition of component statements cannot be determined from the transformer for these statements alone. Hence, state-transformer semantics for parallel languages are not compositional; it is necessary to capture the intermediate states at which interleaving may occur. Moses observes that by capturing these intermediate states as so-called resumptions, the resulting denotational semantics corresponds much more closely to operational semantics.

Early work on verification of concurrent systems extended state-transformer semantics with additional side-conditions, and is as such non-compositional; for example, interference freedom tests were used for shared variable concurrency and cooperation tests for synchronous message passing. Compositional approaches were introduced for shared variables in the form of rely-guarantee and for synchronous message passing in the form of assumption-commitment. Extending these principles for compositional verification, object invariants can be used to achieve modularity (for example).

Execution traces The use of execution traces to describe program behavior can be motivated by the need for additional structure in the semantics of statements, such that parallel statements can be described compositionally from the semantics of their components. Brookes developed a trace semantics for a shared-variable parallel language based on transition traces. In his work, a command is described by a sequence of state transformers reflecting the different atomic blocks in the execution of the command, but abstracting from the inner states of these blocks. Transition traces are thus more abstract than resumptions that are discussed above. The semantics of parallel commands then corresponds to the union of these segments, obtained by stitching together the state transitions corresponding to the different atomic sections in different ways. Brookes shows that this semantics, which can be realised at different levels of granularity, is fully abstract. In fact, we considered this solution in our work, but decided against it because it constructs infinitely large mathematical objects in order to include all possible states in which the next atomic block can start. Instead, we opted for continuation markers, to be resolved in the composition, as well as symbolic traces that are concretised on demand during the composition phase. This ensures that all semantic elements are finite, which makes the LAGC semantics easy and effective to compute.

Communication traces Communication traces first appeared in the object-oriented setting and then for CSP. Soundararajan developed an axiomatic proof system for CSP using histories and projections, which was compositional and removed the need for cooperation tests. Zwiers developed the first sound and
complete proof system using communication traces \cite{28}. Jeffrey and Rathke introduced a semantics for object-oriented programs based on communication traces, and showed full abstraction for testing equivalence \cite{17,18}. Reasoning about asynchronous method calls and cooperative scheduling using histories was first done for Creol \cite{31} and later adapted to Dynamic Logic \cite{5}. Din introduced a proof system based on four communication events, significantly simplifying the proof rules \cite{26}, and extended the approach to futures \cite{25,29}. This four-event proof system, which forms the basis for KeY-ABS \cite{25}, was the starting point for the communication events used in our paper. This way, communication events can always be local to one semantic object, and their ordering is captured by well-formedness predicates. Compared to this line of work, we introduce continuation markers and locally symbolic traces. This allows us to constructively derive global traces, in contrast to, for example, Din’s work which, building on Soundararajan’s work, simply eliminates global traces which do not project correctly to the local trace sets of the components.

Hybrid traces. Brookes’ action traces \cite{17} bear some similarity to our work. He aims at denotational semantics using collecting semantics, explicitly represents divergence, synchronises communication using events, and captures parallel execution of two components by means of a so-called mutex fairmerge which ensures that both components get the chance to be executed. Action traces were used to develop a semantics for concurrent separation logic \cite{15}, where scheduling is based on access to shared resources with associated invariants and data races are exposed. Brookes’ work elegantly develops a trace semantics for low-level programming mechanisms with lock resources. However, it does not cover the dynamic spawning of processes, procedure calls, method invocations, and similar topics covered in our work, which led to the locally abstract, globally concrete formulation of hybrid trace semantics. In previous work \cite{24} we used scheduling events and well-formedness properties over scheduling events to capture all legal interleavings among concurrent objects at a granularity similar to that of action traces. In contrast, parallel execution in the present paper is based on a more fine-grained interleaving of processes, exploiting continuations, by means of different composition rules (for example, \cite{63} and \cite{71}) to capture global and local interleaving of processes. The approach of Brookes \cite{17,27} is easily expressible within our framework. We obtain the equivalent of the fairmerge operator by collecting all traces that can be constructed by the composition rules from a given concrete initial state.

In trace semantics, the composition of traces from parallel executions can be formalised in different ways; e.g., as continuation semantics, erasure semantics or collecting semantics. We have opted for the first approach and captured the interleaved execution by means of local continuations, such that the global trace is obtained by gradually unfolding traces that correspond to local execution by means of continuations. Kamburjan has explored erasure semantics in a hybrid trace semantics developed as a foundation for behavioral program logic \cite{52,51}. This work uses an explicit representation of the heap which is exploited for composition by introducing a fresh symbolic heap as a local placeholder for execution in other objects at the scheduling points. The introduction of fresh symbolic states for merging local behaviors can equivalently be replaced by a set collecting all possible concrete states after the scheduling point, such that the composition of local behaviors can be done by selecting the appropriate, compatible concrete traces rather than by instantiating a symbolic trace. This approach has been studied in the context of hybrid trace semantics in \cite{53}.

Recent work \cite{6} on similar communication structures for ASP/ProActive uses parameterised labelled transition systems with queues to model interaction with futures in a fine-grained, operational manner. In contrast, our work with traces allows futures to be abstracted into communication events and well-formedness conditions. We are unaware of previous work on programming language semantics that captures different communication patterns as well-formedness constraints over trace semantics; these constraints are in fact orthogonal to the building blocks of the trace semantics and allow to study language behavior ranging over architectures that support different forms of communication within a single semantic framework.

More recently, \cite{68,68} defined a data structure called interaction trees that enable a denotational and somehow functional definition of the semantics for imperative programs where interaction trees encode the interaction with the environment. An interaction tree constitutes a form of trace that expresses the effects of the program but abstract away from states. The authors provide co-inductive principles for reasoning on diverging programs, which is more precise than our current handling of infinite traces. Their semantics can be considered as more compositional than ours, because no concretisation is needed, but the approach is only valid for sequential programs.

The pure trace-based proof system of ABS \cite{25,29} requires strong hiding of local state: the state of other objects can only be accessed through method calls, so shared state is internal and controlled by cooperative scheduling. Consequently, specifications can be purely local. More expressive specifications require significantly more complex proof systems, for example modifies clauses in Boogie \cite{66}, fractional permissions \cite{40} in Chalice \cite{52}, or dynamic frames in KeY \cite{59}. To specify fully abstract interface behavior these systems need to simulate
histories in an ad hoc manner, see [46, Figure 1]. A combination of permission-based separation logic and histories has recently been proposed for modular reasoning about multi-threaded concurrency [69]. The motivation for our work stems from our aim to devise compositional proof systems to verify protocol-like behavior for object-oriented languages [27] by combining communication histories for ABS with the trace modality formulas of Nakata et al. [60].

9 Future Work and Conclusion

9.1 Future Work

The original motivation for the present work was to create a modular semantics that aligns well with the kind of program logics used in deductive verification [35]. In Sections 4 and 5 we reached this goal by providing a program logic and calculus for the shared variable language and by giving a compact soundness proof (Thm. 1) for the sequential fragment. This result can and should be extended to a state-of-art calculus for the language in Section 7.3 [53].

An obvious direction for future work is to fully mechanize the LAGC semantics in a proof assistant [61]. In fact, all definitions and theorems from Sections 2, 3, and 5 have been mechanized and proved in Isabelle/HOL. The mechanization is executable in the sense that all traces in the examples of the mentioned sections can be generated automatically from the HOL theories. We plan to extend the Isabelle/HOL mechanization to cover also Sections 6, 7.2, and 7.3.

In Sections 5–7 we showed that a wide variety of parallel programming concepts can be formalised in LAGC style with relative ease. It would be interesting to explore how far this can be carried. On the one hand, one could try to formalise the semantics of a major programming language, such as Java or C. On the other hand, one could try to apply the LAGC framework to weakly consistent memory models [3] or to the target the language of concurrent separation logic [15]. A further possible extension concerns programs with non-terminating, atomic segments, see Section 5.2. A mechanized, executable LAGC semantics opens the possibility of early prototyping new semantics of concurrent and distributed languages with relative ease.

We rely heavily on well-formedness of traces, but we did not discuss how to define properties on possibly infinite sets of infinite traces with events, for example, notions related to fairness. This is a complementary problem to trace generation, and not the focus of the present paper.

Our approach makes composition of local rules easy, and extension of the language straightforward. Global trace composition on the contrary relies on well-formedness criteria for the whole trace; even if this criteria is defined modularly, it is not compositional in the sense that a trace can become invalid by extension of the criteria or parallel composition. This is often unavoidable because the semantics of many concurrent models like CCS and $\pi$-calculus are by nature very much sensitive to the execution context. However, depending on the language and the form of concurrency, different compromises could be found, defining a greater part of the concurrent semantics in a symbolic and compositional way. For example our semantics of futures is similar to message passing but one could probably specify new composition tools that better take into account the single-assignment property ensured by futures.

9.2 Conclusion

The semantics of concurrent programming languages is inherently a technically demanding subject. In the best case, a formal semantics can illuminate the design space created by the choice of different concurrency concepts, it shows the consequences of these choices, and it makes different version comparable. This is only possible in a semantic framework that enforces uniform and modular definitions, and it is what we strove to achieve with LAGC: the central design decision is to strictly separate local, sequential computations and their parallel composition. Also, we decided to render local evaluations abstract. In this way, one and the same schematic semantic evaluation rule can be re-used for any initial state, executing processor, and destiny of the result. While abstract local rules are not a theoretical necessity, they drastically simplify the complexity of definitions.

A central technical problem to address in a locally-globally divided setup is to ensure that enough context information is available when composing concurrent behavior. Instead of computing all possible states, in which an atomic segment can continue, we pass the remaining code to be executed as a continuation. Again, this constitutes a considerable technical simplification compared to the former option. For example, in Section 7.3 we characterised the behavior of active objects concisely with a suitable definition of a continuation pool.

See [https://gitlab.com/Niklas_Heidler/mechanization-of-lagr-semantics-in-isabelle] and [38].
But mere continuation is not sufficient: one needs to orchestrate different local evaluations within a global trace, for example, to ensure a method is called before it is being executed. This is achieved by suitable events emitted during local evaluation. Orchestration of local computations by events leads to a further separation of concerns: many concurrency models can be characterised in a declarative manner by well-formedness of events inside traces, as shown in Section B.2.

We believe the achieved separation of concerns, locally abstract evaluation—trace composition with a continuation pool—orchestration of computations by well-formedness, provides a flexible and usable semantic framework to formalise and compare concurrent languages in. It is close modern deductive verification calculi and could even be fully mechanised.

Acknowledgment

We would like to thank the following people for carefully reading drafts of this paper and for spotting several omissions, errors, typos, and inaccuracies: Lukas Grätz, Dilian Gurov, Niklas Heidler, Eduard Kamburjan, and Marco Scaletta.
